Foreword

VOLUM66 of the Transactions of The American Society of Mechanical Engine contains the individual papers published during 1944 under the sponsors of the Society's professional divisions and technical committees, incln the contributions of the Applied Mechanics Division, issued originally in uarterly known as *Journal of Applied Mechanics*, and the 1944 Society Rec and Index. The technical papers and reports that make up this volume resent the Society's annual contribution to the permanent record of manical-engineering achievement. Most of these papers and reports were sented at meetings of the Society and its professional divisions and local secns and were published in monthly issues, eight being distributed as the Trantions of The American Society of Mechanical Engineers and four as the *rnal of Applied Mechanics*. Indexes to other A.S.M.E. papers and publicats will be found on page RI-51 at the end of this volume.

In view of e fact that the material of which this volume is composed was originally iss periodically as the Transactions, *Journal of Applied Mechanics*, and Society ecords, three sets of page numbers will be found. Numbers without lett ymbols are those of the eight issues of Transactions, those with letter symbA preceding the number refer to the pages of the *Journal of Applied Mnics*, which follow, and those with letter symbol RI to the Society Recs and Index section, which concludes the volume.

All sectiof the Transactions are bound together at the end of the year for the conv ence of libraries and of engineers who wish all of the papers in permanent fn. Copies of the bound Transactions will be found in depositories locate selected engineering, university, and public libraries throughout the wor A complete list of these depositories will be found on pages RI-49 and -50 of the Society Records and Index. Copies of the Transactions hav so been set aside for sale.

The Soci Records of the A.S.M.E. for 1944, which form a part of these Transactio are the permanent records of the Society's activities for the year, includ lists of committees. The Index provides a means of locating special A.S.E. publications and articles in *Mechanical Engineering*, as well as in the Tran tions.

THE COMMITTEE ON PUBLICATIONS

Requirements for Relief of Overpressure in Vessels Exposed to Fire

By J. J. DUGGAN,[1] C. H. GILMOUR,[1] and P. F. FISHER[1]

Pressure-vessel codes and regulations prescribe pressure-relief equipment but do not completely specify the necessary relief capacity to insure safety. Investigations show that the most effective cause of pressure increase is fire exposure as encountered in accidental conflagrations, and tests of the effects of such fire exposure on pressure vessels have been made and analyzed. Part 1 of the paper details these tests and analyzes the results. Parts 2 and 3 develop the necessary formulas to determine the sizes and capacities of the relief connections and apparatus and also present detailed statements of the applications of these formulas to pressure vessels and atmospheric tanks.

PART 1 OBSERVED RATE OF HEAT ABSORPTION

Introduction

FROM the standpoint of protection from excessive internal pressure, probably the severest hazard to which a vessel may be subjected is that which accompanies exposure to external conflagration. (Internal reaction will be discussed in Part 2.)

Some 12 to 14 years ago, the American Petroleum Institute Committee on Fire Prevention, after study and deliberation, proposed the basis of 100 Btu per min per sq ft of surface wetted by the contents as a practical basis for determining the necessary relief area to limit the rise of pressure. In connection therewith a theoretical analysis of "The Rates of Vaporization in Gasoline in Storage Tanks Exposed to Fire,"[2] and a chart from which to determine the capacity and size of relief were made. This chart was drawn so that heat-input rates varying from 6000 Btu to 24,000 Btu per sq ft of wetted surface per hr might be selected. So far as is known, there was no practical basis for the choice of a heat rate, nor was any suggested.

The National Fire Protection Association and the National Board of Fire Underwriters, as well as other regulatory bodies, were given the benefit of these studies. They performed a valuable service in this matter of emergency relief and related considerations by providing the best generally known criterion for the "Safe Handling and Storage of Flammable Liquids."[3] The relief standards proposed were based upon 6000 Btu per hr per sq ft of wetted surface and are still generally recognized.

Some interest appeared later among the associations and concerns promulgating and using this information to inaugurate a variable heat-input rate. It is believed the suggestion which received widest acceptance was that which proposed a heat rate varying from 24,000 Btu per hr per sq ft for small tanks having 10 sq ft of surface to 3000 Btu per hr per sq ft for large vessels having 10,000 sq ft of surface. On this basis, a 6000-Btu rate held for vessels having a wetted surface of 1000 sq ft. So far as is known, no official action was taken on this variable rate, nor was it published for general use.

It was the unfortunate experience of the authors to learn that, while the 6000-Btu rate on tank surfaces of the order of 1000 sq ft was satisfactory for all ordinary circumstances, it was totally inadequate for severe exposures of even less than 15 min duration. Some of these cases are a matter of private record, and it may be stated that the materials contained were more stable than gasoline upon which existing standards are based. From information reviewed, it is believed that other organizations have encountered similar experiences.

Accordingly, known available literature on the subject was analyzed and a series of tests was conducted which follows:

Summary

It is concluded that pressure-relief areas should be designed on a basis of 20,000 Btu per hr per sq ft of wetted surface exposed to fire.

Exception is proposed to this heat-input rate for atmospheric-working-pressure tanks, as outlined in Part 3 of this paper.

So far as can be learned, there is no substantial theory or evidence to support the limiting of heat-input rates to any particular height. There are some indications to the contrary; that is, high gas temperatures apparently exist at relatively great heights above the fuel during large fires.

Analysis of Fetterly's Formula and Test

In order to specify safety valves for the protection of containers charged with liquefied gas, a formula was derived and a test conducted by John F. Fetterly, inspector, Bureau of Explosives, Association of American Railroads. His report[4] furnishes data of considerable interest on heat-input rates for tanks exposed to fire.

It will be seen that it is possible for the contents of a 300-gal tank exposed to fire to absorb heat at about 20,000 to 23,000 Btu per sq ft of wetted surface per hr during vaporization.

Probably the factor in the formula which might arouse criticism is that represented by C, namely, the over-all heat-transfer coefficient. The coefficient used was obtained from an empirical formula which was based on tests made before the film theory of heat transfer was recognized. However, having been based on actual test data, it is not surprising that the numerical value of C is of the order of magnitude that would be predicted by present-day theory.

For example, the heat-transfer coefficient from a flame to a surface would be calculated today approximately as follows

$$U = h_c + h_r = \text{Fetterly's } C \text{ or heat-transfer coefficient} \quad \ldots [1]$$

$$h_c = 0.27\,(T_f - T_s)^{1/4} \quad \ldots [2][5]$$

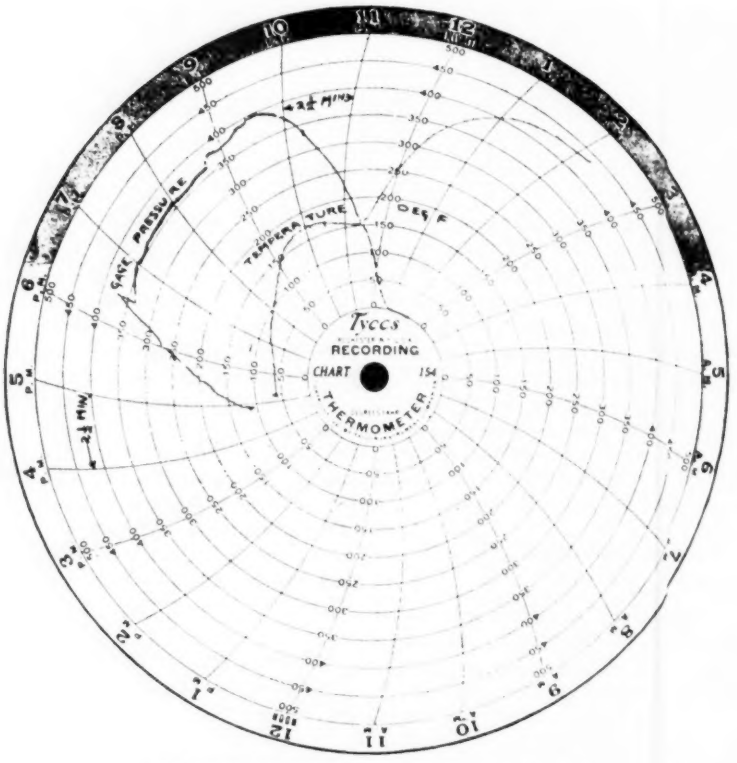

FIG. 1 FETTERLY'S TANK FIRE-EXPOSURE TEST[4]

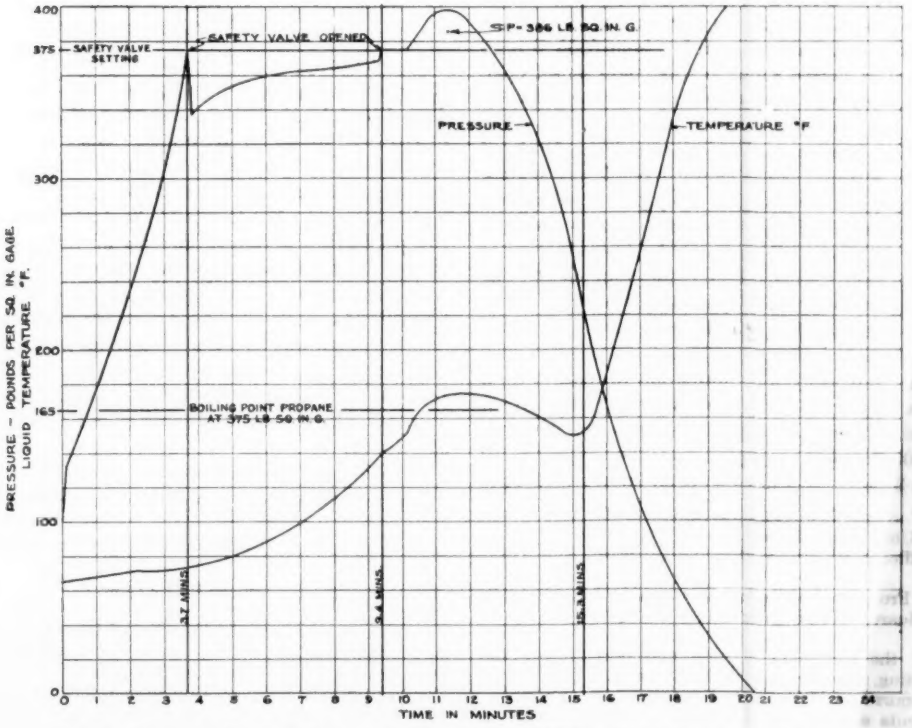

FIG. 2 OBSERVED DATA IN FETTERLY'S FIRE TEST OF 300-GAL TANK CONTAINING PROPANE
(Replotted from recording chart, Fig. 1.)

$$h_r = \frac{0.173\left[\left(\frac{T_f}{100}\right)^4 - \left(\frac{T_s}{100}\right)^4\right]}{(T_f - T_s)} \quad \ldots\ldots\ldots [3][6]$$

(Assuming the hot gas and tank surface are black, i.e., have a black-body coefficient of 1, the shape factor is unity, and that the heat resistance of the retaining wall and boiling liquid is negligible compared with the resistance of the film in contact with the flame.) Then if the flame is 1200 F and tank surface is 165 which are the temperatures used by Fetterly, the value of U would be

$$U = 0.27\,(1660 - 625)^{1/4} + \frac{0.173[(16.6)^4 - (6.25)^4]}{(1660 - 625)}$$

$$= 0.27 \times 5.67 + \frac{0.173\,(75{,}940 - 1540)}{1035}$$

$$= 1.53 + 12.44 = 13.97 \text{ Btu per hr per sq ft per deg F}$$

This is more than 95 per cent of the value obtained by Fetterly, specifically 14.68 Btu. It should be noted that this is equivalent to [13.97 (1200 — 165)] 14,500 Btu per hr per sq ft of wetted surface for a flame temperature of 1200 F, and a 23,000-Btu rate for a T_f of the order of 1400 F, as calculated from the test data to be given. It will be seen later that flame temperatures of this magnitude are conservative for industrial fires, particularly those involving flammable liquids.

Of particular interest and value are the test data obtained by Fetterly which consist of continuous pressure and temperature measurements taken while a wood fire burned around a tank containing 1000 lb of propane. From this record, it is possible to calculate the heat input to the tank and contents during the various phases of the test. The charts of pressure and temperature versus time are reproduced in Figs. 1 and 2 of this paper; the former is the actual instrument record and the latter is a replot of the same data to clarify the analysis. In order to give a better picture of the nature of the fire surrounding the tank, a diagram of the test setup, as interpreted from the description contained in Fetterly's paper, is shown in Fig. 3.

The safety valve was set to open at 375 psig. Note that the relief valve opened and closed again long before the liquid approached the boiling point (about 165 F), which is evidence that the vapor was superheated to a temperature sufficient to cause the pressure to rise to 375 psi. By reference to Fig. 3, it is obvious that the vapor space was subjected to intense fire for the first few minutes of the test, during which time the vapor was heated from 65 F to an estimated temperature of 1000 F, at the time the safety valve first opened after 3.7 min of exposure. This temperature was estimated from the best available physical characteristics[7] for propane. In this same period the liquid was heated from only 65 to 74 F.

The second phase of the test consists of the period in which part of the liquid was heated to the boiling point and the safety valve opened for the second time. This is the interval observed from 3.7 to 9.4 min in Fig. 2. During this time the fire level probably lowered, the intensity of the flame on the unwetted surface decreased, and the vapor did not expand as rapidly as before, as observed from the pressure curve.

The final phase of the test consists of the period of the vaporization and discharge of the contents. As shown in Fig. 2, this appears to have occurred in about 5.9 min. At the end of this period, the pressure had fallen rapidly to 245 psi (probably the safety valve stuck open), and the liquid temperature began to rise sharply as it would when the thermocouple was exposed to the hot vapor and tank walls. On the basis of 5.9 min, the heat absorbed by the contents may be calculated as follows:

Heating Liquid to Boiling

$$1000 \times 0.68\,(165 - 140) \times \frac{60}{3.2} = 318{,}800 \text{ Btu per hr}$$

Vaporizing Liquid

$$1000 \times 101 \times \frac{60}{5.9} = \frac{1{,}027{,}000 \text{ Btu per hr}}{1{,}345{,}800 \text{ Btu per hr}}$$

Heat Intensity

$$\frac{1{,}345{,}800}{57.82} = 23{,}300 \text{ Btu per hr per sq ft of wetted surface}$$

Vaporization Rate

$$1000 \times \frac{60}{5.9} = 10{,}170 \text{ lb per hr}$$

Safety-Valve Capacity

$$W = 306\,aP\sqrt{\frac{M}{T}} = 306 \times 0.312 \times 386\sqrt{\frac{44}{625}}$$

$$= 9800 \text{ lb per hr} \quad \ldots\ldots\ldots\ldots [4][5]$$

The vaporization rate is then 3.8 per cent greater than the calculated valve capacity, but some of the contents may have been discharged as droplets of liquid. However, if the vaporization rate had been as low as the safety-valve capacity, the heat intensity would still have remained as high as 22,600 Btu per hr per sq ft of wetted surface.

If it is assumed that the steel temperature is about 100 deg F higher than that of the boiling liquid, the effective flame temperature necessary to transmit the foregoing heat input may be calculated as follows:

(1) $U\Delta T = Q/A\theta = U(T_f - T_s) = 23{,}300$ Btu per hr per sq ft ..... [5]

(2) $$U = 0.27(T_f - T_s)^{1/4} + \frac{0.173\left[\left(\frac{T_f}{100}\right)^4 - \left(\frac{T_s}{100}\right)^4\right]}{(T_f - T_s)}$$ ..... [1]

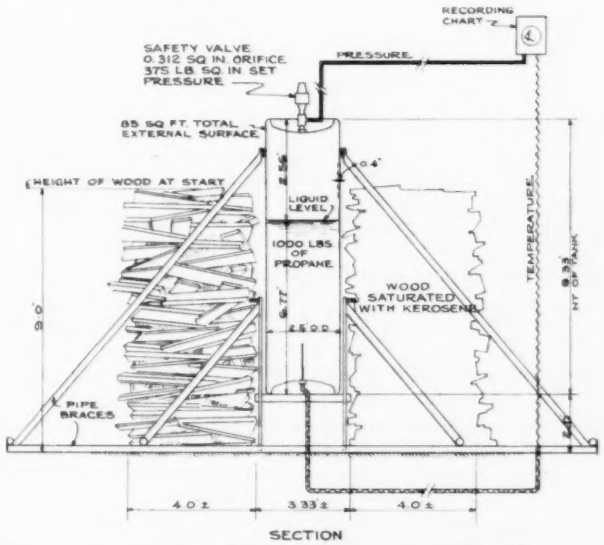

FIG. 3 DIAGRAMMATIC REPRESENTATION OF THE FIRE-EXPOSURE TEST OF A 300-GAL TANK CONTAINING PROPANE
(As described in ref. 4.)

FIG. 4 FIRE CONDITIONS 9 MIN AFTER IGNITION
(Appears to be height of fire, but note limited surface exposure.)

(3) $$U(T_f - T_s) = 0.27\,(T_f - T_s)^{5/4} + 0.173\left[\left(\frac{T_f}{100}\right)^4 - \left(\frac{T_s}{100}\right)^4\right]$$

$$= 23{,}300 \text{ Btu per hr}$$

(4) $T_s = 165 + 100 = 265$ deg F $= 725$ deg R

(5) $0.27(1888 - 725)^{5/4} + 0.173[(18.88)^4 - (7.25)^4]$

$$= 23{,}300 \text{ Btu per hr}$$

$1834 + 21{,}503 = 23{,}337$ compared to 23,300 Btu

$T_f = 1888$ deg R, or 1428 deg F, approximately

This is a reasonable mean effective temperature for a kerosene-soaked open wood fire. The National Bureau of Standards in co-operation with the National Fire Protection Association observed temperatures of 2000 F within 20 min from burning wood within a large brick building.[9]

NOMENCLATURE USED IN FETTERLY TEST ANALYSIS

The nomenclature used in analysis of Fetterly's test is as follows:

C = heat-transfer coefficient, Btu per hr per sq ft per deg F; Fetterly's
U = heat-transfer coefficient, Btu per hr per sq ft per deg F; over-all
h_c = heat-transfer coefficient, Btu per hr per sq ft per deg F; convection
h_r = heat-transfer coefficient, Btu per hr per sq ft per deg F; radiation
T_f = effective flame temperature, deg F absolute
T_s = temperature of tank surface, deg F absolute
ΔT = temperature difference, deg F
Q = total heat transferred, Btu
A = surface heated, sq ft
θ = time, hr
W = vapor rate of safety valve, lb per hr
a = orifice area of safety valve, sq in.
P = absolute pressure at inlet of safety valve, psi
M = molecular weight of vapor
T = vapor temperature, deg F absolute

ANALYSIS OF UNDERWRITERS' LABORATORIES, INC., TEST

In January, 1938, there appeared the results of some tests to show the effect of a film of water running over a plate exposed to fire.[10] The results of the tests were reported in terms of temperature or per cent of total heat input. The data are comprehensive enough to be used to calculate the heat absorbed from the flame.

The test apparatus consisted of a vertical plate 8 ft high by 3 ft wide by 1/8 in. thick suspended from one of its 3-ft edges. A fire was produced by burning gasoline in a pan 3 ft sq, placed directly in front of the plate. Tests were conducted both with and without a water film flowing down the plate.

After equilibrium had been established during the run, in which there was a protective water film, the following data were observed:

Water rate, 45 gpm; water temperature off, 97.5 F; water temperature on, 63 F; water temperature rise, 34.5 F.

From these data, the heat-absorption rate is calculated as follows:

$$45 \times 8.337 \times 60 \times 1 \times 34.5 = 776{,}000 \text{ Btu per hr}$$

[9] "Handbook of Fire Protection," by Crosby, Fiske, Forster, National Fire Protection Association, Boston, Mass., 1941, ninth edition, p. 384.

[10] "Opacity of Water to Radiant Heat Energy," Underwriters' Laboratories, Inc., Bulletin of Research No. 3, Chicago, Ill., Jan., 1938.

FIG. 5 CONDITIONS INTERPRETED TO BE ABOUT 25 MIN AFTER IGNITION
(Note no fire visible in pan under tanks.)

The intensity of heat absorption is

$$\frac{776{,}000}{24} = 32{,}300 \text{ Btu per hr per sq ft}$$

The average temperature of the water was 80 F, when flowed over the plate during the fire. The effective gas temperature required to transmit this quantity of heat would be approximately 1580 F, as calculated by the same procedure as given for the analysis of the Fetterly tests. A maximum flame temperature, a point temperature, of 3000 F was read with an optical pyrometer.

The results of this test show that the intensity of heat absorbed from a fire under these conditions is of the order of magnitude of 30,000 Btu per hr per sq ft.

Fire Tests on Truck Tanks

During 1930, the Aluminum Company of America, under supervision of committees from the American Petroleum Institute and the National Fire Protection Association, conducted fire-exposure tests[11] on two 150-gal tank-truck compartments made of aluminum (refer to Figs. 4 and 5). The data were taken to establish the suitability of the metal for truck-tank construction and are not sufficiently broad to record directly information essential to the calculation of heat-input rates. As will be explained, sufficient data were interpreted to estimate maximum and minimum heat-input rates for tank B in the report.

The time-temperature curves of thermocouples 9, 10, 11, and 12 were transposed from the original data[11] to Fig. 6 of this paper. This indicates by the abrupt temperature rises that the gasoline between three fourths and one fourth of the tank height vaporized in 10 min. By using the dimensions in the report, this was calculated to have been 90 gal. It appeared from the illustrations in the report that probably an area equivalent to not more than the lower half of the tank less one head was exposed to the flame during the period. This is about 15 sq ft of area. The gasoline weighed 6.3 lb per gal at normal conditions. Its latent heat of vaporization was about 130 Btu per lb. Then the heat absorbed would be calculated as follows:

$$\frac{90 \times 6.3 \times 130}{15} \times \frac{60}{10} = 29{,}500 \text{ Btu per hr per sq ft}$$

The data indicate that the exposure fire lasted in all about 25 min, during which time the tank metal was heated, the gasoline raised to the boiling point, and 129 gal were vaporized. On this over-all basis, the intensity of the fire to the tank may be calculated, as follows:

To Heat Metal

$$113 \text{ lb} \times 0.23 \times 325 \text{ deg avg } dt = 8{,}450 \text{ Btu}$$

To Heat Liquid to Boiling Point

$$147 \text{ gal} \times 6.3 \text{ lb} \times 0.57 \times 207 \text{ deg avg } dt = 109{,}200 \text{ Btu}$$

Latent Heat of Vaporization

$$129 \text{ gal} \times 6.3 \text{ lb} \times 130 = 105{,}700 \text{ Btu}$$

$$223{,}350 \text{ Btu}$$

Intensity

$$\frac{223{,}350}{31.5 \text{ sq ft total exposed}} \times \frac{60}{25} = 17{,}000 \text{ Btu per hr per sq ft}$$

The time-pressure curves show that rapid ebullition started at about 4 min after ignition. The vaporization period for 129 gal was then about 21 min, and a heat-input rate to the contents may be approximated:

$$\frac{105{,}700}{15} \times \frac{60}{21} = 20{,}100 \text{ Btu per hr per sq ft.}$$

It is concluded that the actual maximum heat-input rate lies between 20,000 and 29,000 Btu per hr per sq ft of wetted surface exposed.

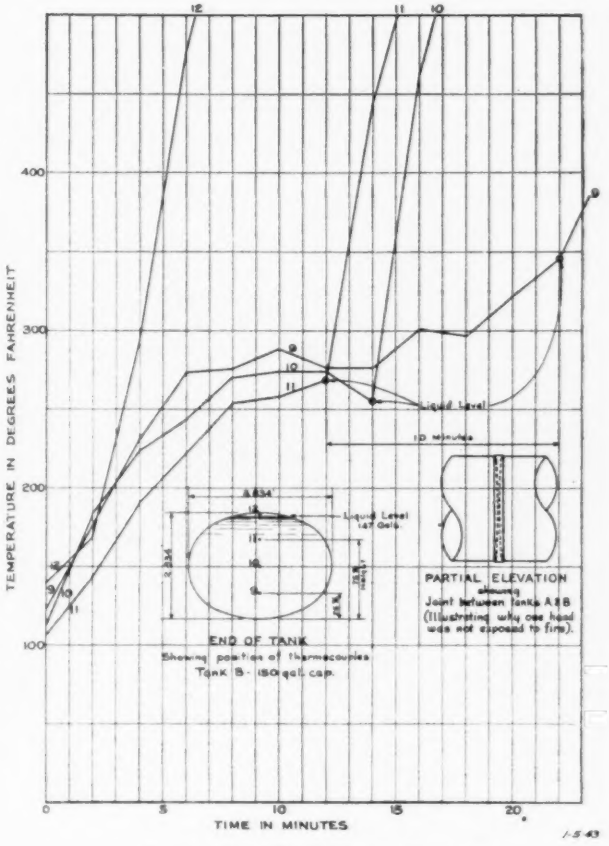

Fig. 6 Time-Temperature Curves
(Transposed from Fig. 4 of ref. 11.)

Tank Fire-Exposure Tests by the Authors

Introduction. Since existing information on the subject seemed inadequate, a series of exposure tests was conducted by the authors' company, in which a 3000-gal nominal-capacity tank containing 2300 gal of water was surrounded by an intense fire. These were begun in the fall of the year 1938 and were concluded in April, 1940. Herein are described and analyzed the last four tests, since the results obtained during these are considered the more accurate and comprehensive.

The tests were conducted (1) to establish a safe minimum heat-input rate for the basis of requirements for emergency relief, (2) to determine the necessary rate of application of external cooling-water film both to maintain a specified temperature within the contents and to approximate the amount required to preserve such vessels when involved in a conflagration. The latter consideration is the subject of a separate discussion, the present purpose being to determine a heat-input rate.

Summary. When a tank is surrounded by an intense fire having an effective temperature of about 1400 F, heat is absorbed from the flame at a rate of the order of 20,000 Btu per hr per sq ft of wetted surface exposed.

[11] Report on "Impact, Hydrostatic, and Fire Tests—Aluminum Alloy Compartments for Tank Trucks," Aluminum Company of America, New Kensington, Pa., 1930.

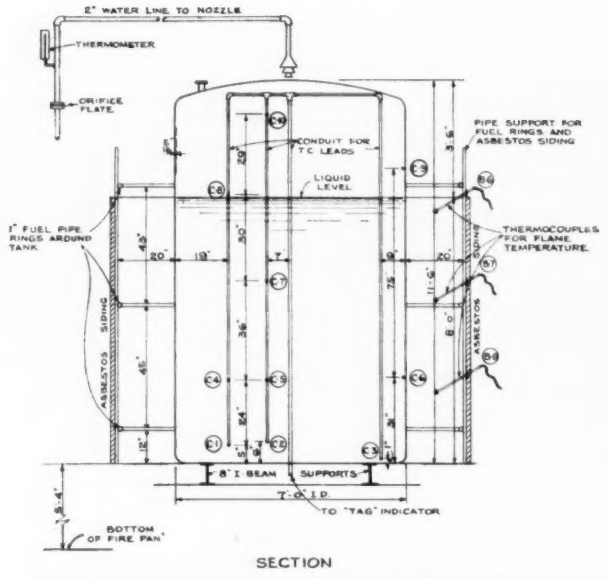

FIG. 7 EQUIPMENT ASSEMBLY TANK FIRE-EXPOSURE TESTS
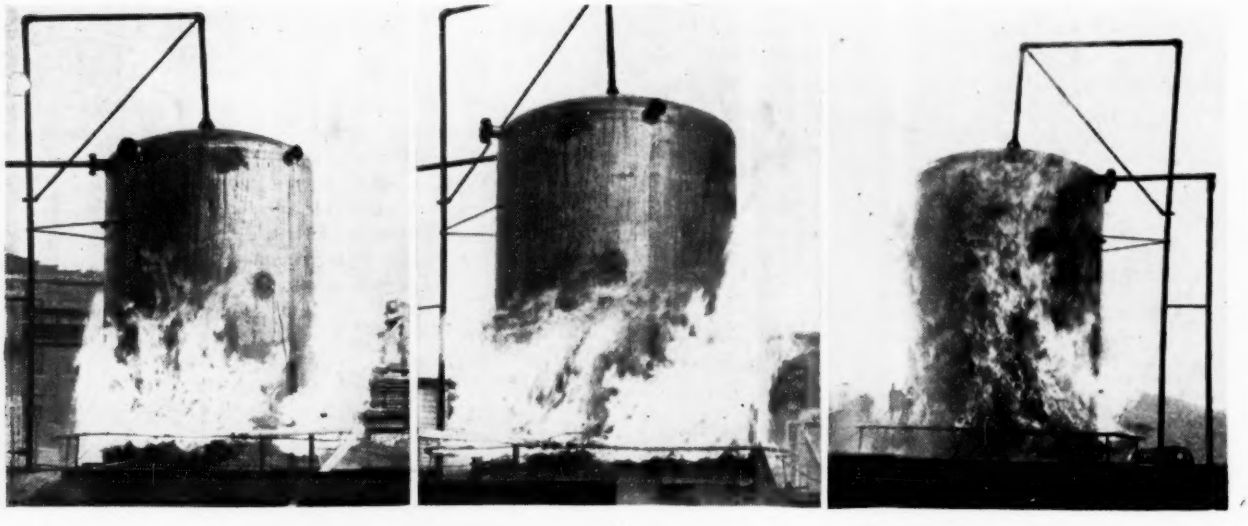
(Carbide & Carbon Chemicals Corporation, South Charleston, W. Va.)

Test Setup. The general assembly of the equipment used is shown in Fig. 7. The tank used for the test was 7 ft in diam × 11 ft 6 in. high. It was found necessary to surround the equipment with a corrugated asbestos cylinder 10 ft, 4 in. in diam, in order to prevent wind from blowing the flame away from the tank, as may be observed in Figs. 8 and 9. For convenience and safety, the tank was set on steel beams at 5 ft 4 in. above the bottom of an existing fire pan.

The temperatures were measured with thermocouples placed inside the tank, on the tank wall, and in the flame. A direct-reading "Celectray" potentiometer was used for converting the electromotive-force readings to deg C. Mercury-in-glass thermometers were used to measure the cooling water and atmospheric temperatures.

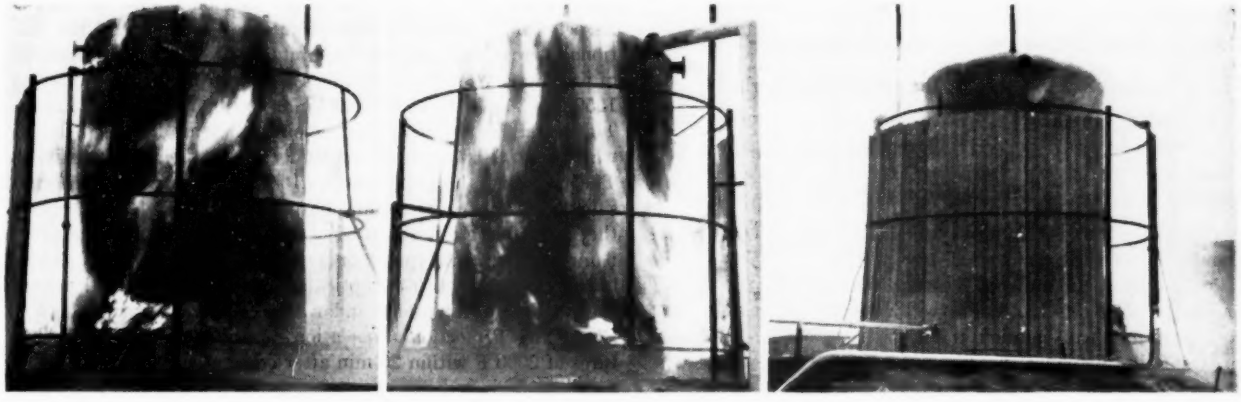
The cooling water was measured with an orifice and was released on top of the tank through a funnel-type nozzle. It flowed over the head and wall in a uniform film and was collected in a trough. The cooling water was not only a part of the experiment but preserved the vessel as intended.



The fire was made by burning hydrocarbons in atmospheric air. The fuel was released through three 1-in. standard-pipe perforated rings, concentric with the tank. The fuel rings were about 4 ft apart vertically, as shown in Fig. 9, and from inspection produced a flame which surrounded the tank thoroughly. The liquid fuel was measured by observed difference in level, as indicated by calibrated tank gages.

Test Procedure. At the start of the tests, the tank contained 2300 gal of water. After making zero readings of the temperatures, the cooling water was started and the fuel was ignited. The fuel rate was kept relatively constant throughout a test run. The temperatures of the flame, cooling water, atmosphere, and contents (water) were recorded at approximately 15-min intervals. The cooling-water rate was adjusted to three values, 143 gpm, 71 gpm, and 37 gpm. No cooling water was used during run No. 4 and partial boiling occurred. During this last test, the fuel rate was reduced to less than one third that of the previous runs, but the flame temperature at the points read was maintained.

Data Obtained. When the temperature of the contained water remained constant, a condition of equilibrium existed, and the data shown in Table 1 correspond to that phase of the first three runs. During test No. 4 in which no cooling water was used, the experiment was stopped before stabilized conditions were reached (contents averaged 73.5 C), in order to avoid possible rupture of the vessel.



Discussion of Data. Surrounding the equipment with a cylinder to control windage no doubt increased radiation to the tank, but it is believed conditions are equally as severe where a vessel is surrounded by flame of considerable depth. As a counteractant to this effect, there occurred a strong updraft between the cylinder and tank. This was partly due to the 5-ft clearance under the tank as described.

The flame temperatures read are not believed to be maximum since the unshielded thermocouples could "see" the cooling-water film. The lower flame temperatures shown in runs Nos. 2 and 3 were apparently due to wind and rain. This resulted in lowered heat-input rates during these runs.

TABLE 1 OBSERVED AND CALCULATED DATA PERTAINING TO A 3000-GAL STEEL TANK CONTAINING 2300 GAL OF WATER AND EXPOSED TO A FIRE

	Run No. 1	Run No. 2	Run No. 3	Run No. 4
Total cylindrical surface exposed to fire, sq ft	242	242	242	242
Cylindrical surface in contact with contained liquid, and exposed to fire, sq ft	176	176	176	132[a]
Rate of cooling water on external surface of tank, gpm	143	71	37	0
Temperatures, average, deg C:				
Cooling water off	61.2	61.3	58.0	...
Cooling water on	12.5	12.2	11.5	...
Cooling water rise	48.7	49.1	46.5	...
Cooling water average	37.0	37.0	35.0	...
Flame temperature	820	690	714	721
Water inside tank	58	84	92	9 to 73.5 per hr
Surface of tank, external	58	84	92	12 to 100 per hr
Surface of tank, internal	58	84	92	10 to 95 per hr
Surface of tank not in contact with contained water	36	58	66	10 to 190 per hr
Surface of tank, log mean average	46	70	78	10 to 140 per hr
Fuel vapor rate, cfh	40,857	40,857	40,857	12,200
Total available heat in fuel, Btu per hr	106,000,000	106,000,000	106,000,000	29,900,000
Heat absorbed by tank, contents, and cooling water, Btu per hr	6,270,000	4,186,000	4,522,000	2,311,100
Heat absorbed by radiation, Btu per hr	5,760,000	3,737,000	4,050,000	2,100,000
Heat absorbed by convection, Btu per hr	510,000	449,000	472,000	211,100
Sensible heat absorbed by cooling water, Btu per hr	6,270,000	3,137,000	1,550,000	0
Latent heat absorbed by partial evaporation of cooling water, Btu per hr	0	1,049,000	2,972,000	0
Heat absorbed by tank contents, Btu per hr	0	0	0	2,225,000
Rate of heat absorption (heat density), Btu per hr per sq ft	25,900	17,300	18,700	16,850 by contents

[a] See section "Discussion of Data."

During run No. 4 in which no cooling water was used and the fuel rate was reduced to less than one third by using only the lower fuel-pipe ring, it was estimated that 2 ft of the wetted height of the tank was not exposed to flame. Conditions were similar to those shown in Fig. 8 (*a* and *b*). This reduced the wetted surface exposed to 132 sq ft.

The experiment covered three conditions of a tank exposed to fire: namely,

1 Contents maintained at a certain maximum temperature as in run No. 1. The vent rate was kept low and the absorbed heat appeared as sensible heat in the cooling water film.

2 Contents heated to higher maximum temperatures as in runs Nos. 2 and 3. The absorbed heat appeared as both sensible heat and heat of vaporization in the cooling-water.

3 Contents allowed to heat up as under actual conditions where a tank is unprotected and exposed to fire. The vent rate became high and the absorbed heat appeared as sensible heat in the contained water.

Observed Heat Absorbed Compared With Theoretical Calculations. The data indicate that the flame transmits heat to the tank by radiation and that the heat thus transmitted is again transferred by convection to the water film flowing over the tank surface. As a result, no heat is transmitted to the contents after equilibrium conditions are established. The film of water flowing over the surface of the tank also absorbed heat directly from the flame by convection, and under conditions of low water flow, as in runs Nos. 2 and 3, some water is vaporized from the flowing film. Calculations for this apparent mechanism of heat transfer compare well with the observed heat absorbed in runs Nos. 1, 2, and 3 and are submitted as further evidence to support the heat-input rates tabulated for these runs. The sensible heat absorbed during run No. 4 is direct evidence and, of course, not affected by this theory since no cooling water was used.

Calculated values for run No. 1 follow:

The sensible heat absorbed by the water film is

$$143 \times 8.337 \times 60 \times 1.0 \times 1.8 \times 48.7 = 6{,}270{,}000 \text{ Btu per hr}$$

or 25,900 Btu per hr per sq ft

Theoretically, the heat transmitted to the tank surface by radiation using the data in Table 1 is

h_r = 18.5 Btu per hr per sq ft per deg F by Equation [3]

$$18.5 \times 242 \times (1508 - 114.8) = 6{,}240{,}000 \text{ Btu per hr}$$

The heat absorbed by the water film by convection using the data in Table 1 is

h_c = 1.65 Btu per hr per sq ft per deg F by Equation [2]

$1.65 \times 242 \times (1508 - 98.6) = 563{,}000$ Btu per hr

Then by the proposed theory, the total heat absorbed by the water film is

$$6{,}240{,}000 + 563{,}000 = 6{,}803{,}000 \text{ Btu per hr}$$

or 28,100 Btu per hr per sq ft

This theoretical, total heat absorption is only 8.5 per cent greater than the observed heat absorbed.

By the theory, the radiated heat absorbed by the tank surface is again transferred to the cooling-water film by convection. For this type of heat transmission, the transfer coefficient is obtained from the following equation

$$h_w = \frac{1}{2} \cdot \frac{f^{2/3}}{(CZ/h)^{2/3}} C(2g\rho^2\Gamma)^{1/3} \quad \ldots\ldots [6][12]$$

Using this and the observed data in Table 1, the heat absorbed from the tank surface by the water film is

h_w = 1490 Btu per hr per sq ft per deg F, by Equation [6]

$1490 \times 242 \times (114.8 - 98.6) = 5{,}840{,}000$ Btu per hr

This is only 6.41 per cent less than the calculated heat absorbed by the tank surface by radiation as given (6,240,000) and apparently establishes the heat-transfer theory.

Further, according to theory $\left(\frac{18.5}{(18.5 + 1.65)} \times 100\right)$, 91.8 per cent of the heat absorbed by the cooling water was taken by convection from that radiated to the tank surface, so

$$6{,}270{,}000 \text{ (observed)} \times 0.918 = 5{,}760{,}000 \text{ Btu per hr}$$

This compares well with the 5,840,000 Btu per hr calculated with the theoretical heat-transfer coefficient (1490).

Calculations for run No. 4 are as follows:

The sensible heat absorbed by the contents water is

$$2300 \times 8.337 \times 1.0 \times 1.8\ (64.5) = 2{,}225{,}000 \text{ Btu per hr}$$

or 16,850 Btu per hr per sq ft

The observed heat absorbed by the tank is

$$242 \times \frac{0.3125}{12} \times 487 \times 0.12 \times 1.8\ (130) = 86{,}100 \text{ Btu per hr}$$

Total heat absorbed ..... 2,311,100 Btu per hr

This observed heat absorbed is only 8.45 per cent less than the theoretical heat input when calculated as for run No. 1. The calculations indicate the heat absorbed by radiation to be 90.8 per cent of the total heat absorbed by the tank.

Flame Temperatures and Effective Height

Since the heat-input rate to a vessel exposed to fire is sensitive to the mean effective flame temperature, as previously noted under the discussion of Fetterly's work, it is well to emphasize the fact that high temperatures are common during fires. It has been shown that effective flame temperatures of about 1400 F produce heat-input rates of the order of 20,000 Btu per hr per sq ft of wetted surface exposed.

The standard time-temperature curve,[13] used by the American Society for Testing Materials, the National Fire Protection Association, the Underwriters' Laboratories, Inc., and the National Bureau of Standards for a "standard scale of measurement of fire severity" rises to 1000 F in 5 min, to 1300 F in 10 min, to 1550 F in 30 min, to 1700 F in 1 hr, and so on up to 2300 F, in 8 hr. These are effective temperatures since they are furnace heats to which materials are subjected to determine their fire resistivity. The authors of this paper observed 1600 F temperatures with unshielded thermocouples while burning liquefied hydrocarbons in the open. The Underwriters' Laboratories, Inc., read 3000 F flame temperatures (point or maximum) from an open pan of burning gasoline with an optical pyrometer. As stated before, the National Bureau of Standards in co-operation with the National Fire Protection Association observed wood-fire temperatures of 2000 F within 20 min after ignition within a large brick building.

The authors are unable to learn of a substantial theory or to find convincing evidence to support the limiting of heat inputs into vessels exposed, to any particular height above the fuel. Insurance underwriters' recommendations of fireproofing supporting columns within 20 ft of a source of fire, as well as the practice by reliable organizations to limit heat inputs to 20 ft elevation, have been noted, but these do not seem adequate. Aluminum (1125 F to 1490 F melting point), glass (1400 F to 1600 F melting point), and brass (1575 F to 1800 F melting point) have been observed melted more than 20 ft above grade after flammable-liquid-spillage fires in open areas. These fires were of less than 1 hr duration. Examination of the analysis of fires by the National Fire Protection Association and the Factory Mutual Fire Insurance Companies, particularly those involving storage-tank farms and elevated tanks, discloses that high heats do prevail at comparatively great heights above the fuel during severe fires.

The foregoing evidence and experience support the following suggestion:

Where vessels are in confined areas, buildings, or enclosures, and an intense fire could occur, no reduction from the maximum height of the surface to be wetted by the contents should be used when designing emergency pressure-relief or other fire protection. Where such equipment is in open areas, properly spaced, diked, and otherwise installed in accordance with the insurance inspection organization having jurisdiction, it is considered not economical to design for a heat-input height of less than 40 ft, and unsafe under average conditions to use less than 30 ft. Further, no reduction of heat input is proposed (except for atmospheric tanks as outlined in Part 3) to allow for the possibility that vessels may not be completely surrounded with flame during a general fire.

Conclusion

A rate of heat absorption for vessels exposed to fire as a basis of requirements for relief of overpressure is concluded as outlined under Summary from the foregoing experiments, theory, and experience.

The employment of this basis follows in Parts 2 and 3 of this paper.

The authors are cognizant that the observed absorption rate (20,000 Btu per sq ft per hr) appears high when compared to overall heat-absorption rates of boilers, tube stills, etc. It is reasonable, however, when compared to those rates[14] for waterwall sec-

tions and tubes adjoining combustion chambers which may absorb heat at rates from 50,000 to 150,000 Btu per sq ft per hr, based upon the projected area.

PART 2 REQUIREMENTS FOR RELIEF OF PRESSURE VESSELS[15]

Introduction

One of the fundamental considerations in all codes and regulations applying to boilers and unfired pressure vessels has been that of preventing overpressure and its attendant hazards. In all boiler codes and regulations, it has been almost universal practice to base the size and capacity requirements for safety valves on the potential heat input, which is computed from the total area of the heat-absorbing surfaces of a boiler. In codes and regulations applying to unfired pressure vessels, however, while pressure-relief devices are required and an overpressure limit is specified, there is no measurable basis upon which to compute the capacity of such relief devices. In Paragraph U-2 of the A.S.M.E. Unfired Pressure Vessel Code,[16] the question of relieving capacity is referred to by specifying that the relief devices shall be of such capacity as to prevent a rise of more than 10 per cent above the maximum allowable working pressure, but the user of a pressure vessel receives no directions from that code as to how to proceed to compute that capacity.

Actual operating experiences in industrial plants tend to give the general impression that an appreciable number of "code pressure vessels," if investigated, would be found to be under-equipped with pressure-relief capacity. It is often contended that pressure vessels equipped with automatic controls are inherently more safe than those not so equipped; yet it is a matter of record that when such automatic controls fail or become inoperative (as will happen occasionally) an accident often follows. The very natural relaxation of vigilance, which comes from depending upon automatic controls, causes neglect of the pressure-relief devices; and if they will operate, they are likely to be found inadequate in capacity. When pressure vessels do fail in service, it is always found that some one of the important safety considerations has been overlooked or neglected, and in many of such cases, it is found that the pressure-relief devices are inadequate in capacity.

Our experience during the past 8 years, in inspecting thousands of pressure vessels and testing thousands of relief valves and safety devices, has indicated a very definite need for more information on the subject of pressure relief, and the authors have undertaken an investigation to obtain additional data. The results to date appear to warrant presentation of a statement in order to learn whether the data will be useful to the A.S.M.E. Code Committee and other code-making bodies. The authors have in the past found the Unfired Pressure Vessel Code a most valuable aid in their work and, in appreciation thereof, desire to offer their co-operation in every way possible. If the data obtained appear likely to prove helpful to the code committees, they will be placed at the disposal of such committees, and if necessary, additional information will be gathered.

In any comprehensive study of this broad question of protection against overpressure, it is advantageous to consider the sources from which pressure is induced in vessels. In a large percentage of cases, the source of the pressure is mechanical pumping or compression with pressure regulation possible at the source, as is exemplified in air compressing and refrigerating systems; in these, overpressure is likely only on the rare occasions when control apparatus fails. In the large number of cases where pressure is transmitted from the source through systems of piping, as in chemical and petroleum processes, there is no such simplified control possible; and the pressure may be increased from overfilling, overheating, chemical action, or improper operation. Of these several causes, probably the most serious is overheating. In chemical and petroleum plants, where the condition of volatile contents in vessels is inherent and in cases where pressure vessels with relatively nonvolatile contents have been subjected to exposure fires, disastrous explosions have occurred. This class of equipment (chemical and petroleum) is probably representative of those most difficult to control from a safety viewpoint.

It is the observed tendency of codes and regulations to call for safety protection to meet the worst possible hazard which may be encountered and which, in pressure-vessel operation, is probably the overheating that may result from exterior fire exposure. In the past, it has been customary (with few exceptions) to treat such disasters as acts of the elements which are beyond human control, but our investigations tend to show that this conclusion is not warranted. During the past 4 years, the authors have been devoting study to this phase of relief of overpressure and are now of the belief that even such extreme conditions as fire exposure can be foreseen and provided for. Our studies have covered the effects of exterior heating by small fires and conflagrations, the heat-absorbing capacity of pressure vessels with differing contents, and the capacity necessary in the form of pressure-relief devices; and it is now our desire to present the results for general consideration.

From the observation that pressure vessels surrounded by fire, as in conflagrations, represent what is probably the most hazardous condition to which they may be subjected, the primary objective in the investigation mentioned has been to determine the resulting rise in pressure and the extent of relief capacities necessary to limit pressure rises to safe values. It is believed that, if we thus provide adequately for the worst possible condition, more complete safety can be assured, and that some judicial body, such as the A.S.M.E. Code Committee, will be able to determine what measures are necessary for intermediate cases. It will thus be evident that the primary condition to be studied was that of a pressure vessel filled or partly filled with a volatile liquid and completely surrounded by flame. With this object in view, the foregoing tests (summarized in Part 1) were carried out.

A heat-input rate having been concluded in Part 1, it now becomes necessary to correlate the several variables of container dimensions, working pressures, and properties of contents into useful expressions whereby the necessary relief capacity can be calculated in terms of relief area. This will be done in this section for vessels to operate at pressures above 15 psig.

Summary

Developments herein are based upon the premise that the liquid contents of vessels involved in fire will absorb heat at the rate of 20,000 Btu per hr per sq ft of wetted surface exposed, as developed in Part 1 of this paper.

It was concluded that two formulas, which are derived in the appendix, if properly applied to any vessel to operate at pressures above 15 psig, will specify the relief capacity in terms of area of opening required to limit the pressure rise within 10 per cent above the maximum allowable working pressure. These are as follows:

The diameter of a relief connection (a short tube) necessary to relieve a pressure vessel adequately, when the volatile-liquid contents are vaporized by the heat of the external fire, is determined by the following formula

$$d = \sqrt{\frac{97.3\,S_w}{(P + 14.7)}} \left(\frac{P + 448}{3333.3}\right) \quad \text{[7]}$$

[15] Above 15 psig.

[16] "A.S.M.E. Code for Unfired Pressure Vessels," New York, N. Y., 1940 edition, p. 2.

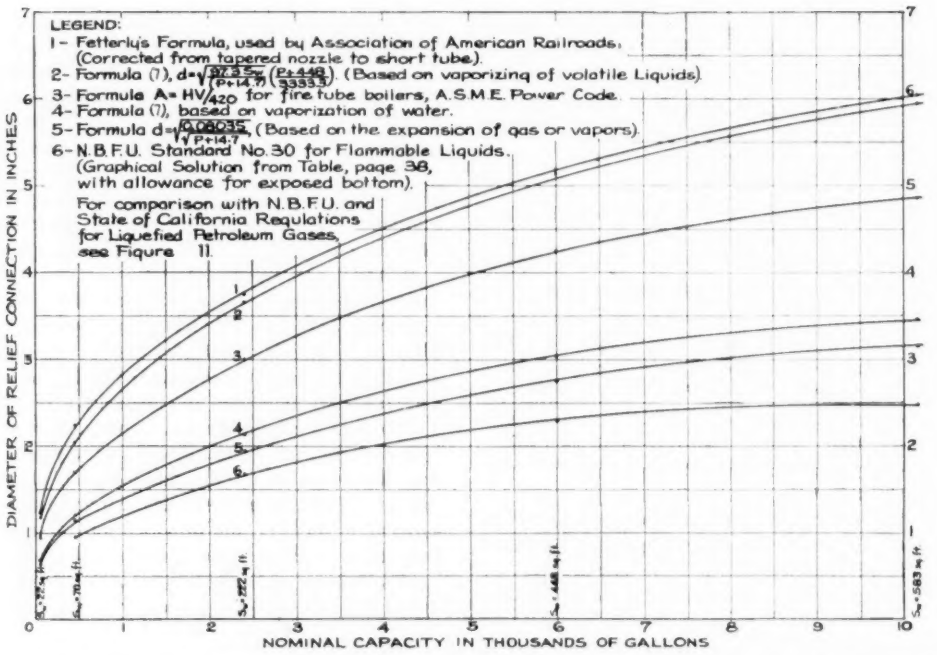

FIG. 10 COMPARISON OF REQUIRED DIAMETER OF CONNECTION TO RELIEVE PRESSURE VESSELS OF 15 PSIG WORKING PRESSURE WHEN EXPOSED TO FIRE

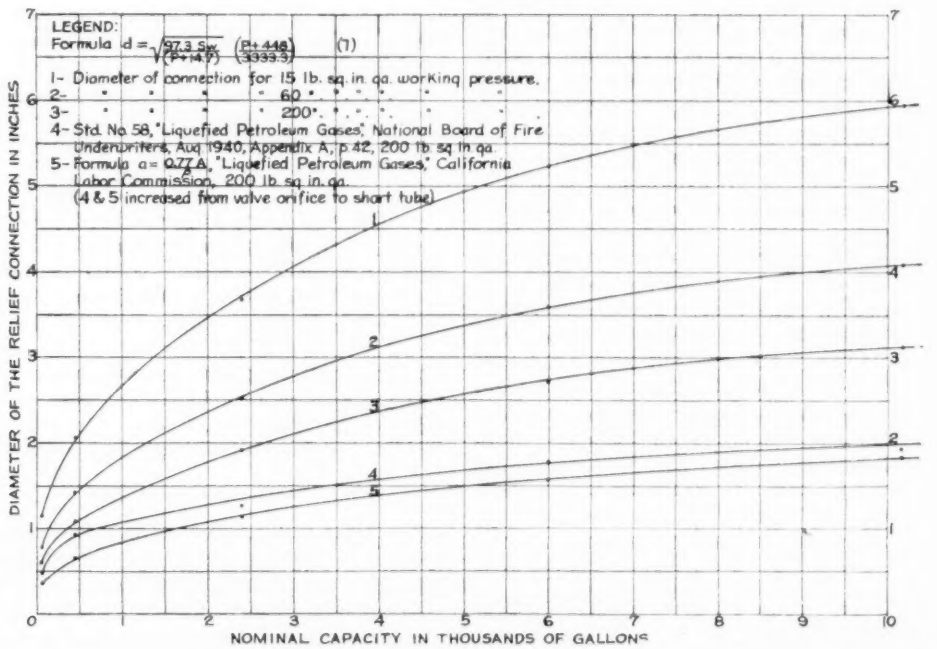

FIG. 11 COMPARISON OF REQUIRED DIAMETER OF RELIEF CONNECTION AT DIFFERENT WORKING PRESSURES FOR VESSELS EXPOSED TO FIRE

The diameter of a relief connection (a short tube) necessary to relieve a pressure vessel adequately when a gas or vapor (the only contents) is expanded by the heat of external fire is determined by the following formula

$$d = \sqrt{\frac{0.0803\,S}{\sqrt{(P + 14.7)}}} \qquad [8]$$

in which d is in inches, S_w under Equation [7] is wetted surface exposed in square feet, S under Equation [8] is total surface exposed in square feet, and P in either case is maximum allowable working pressure in pounds per square inch gage plus 10 per cent or the safety-device opening pressure, whichever is the lowest. The P in the second term of Equation [7] is not to exceed the numerical value of the critical pressure in pounds per square inch gage of the contents regardless of the working pressure.

In order that the results of these formulas may be compared with other known proposals or standards, Fig. 10 has been in-

cluded. In this it may be noted that the specifications for tank cars of the Association of American Railroads[17] (Fetterly's formula analyzed in Part 1) give relief areas (average over the range) about 10 per cent in excess of Equation [7]; that Equation [7] for volatile liquids gives relief areas about 50 per cent (in larger sizes) greater than those specified by the A.S.M.E. Code[18] for steam; and Equation [7] when modified by the properties of water, gives relief areas about 50 per cent less than the regulations for steam boilers. Although comparison of pressure vessels with boilers is hardly justified (wetted surface exposed to fire compared with boiler heating surface), it does show that the developed formulas give results in the logical direction. (About 6 times as much heat is required to vaporize water as to vaporize an equivalent weight of the volatile liquid considered.)

For comparison of Equation [7] with the National Board of Fire Underwriters' Regulations[19] and the Safety Orders by the Industrial Accident Commission of the State of California[20] for liquefied petroleum gases, see Fig. 11.

Analysis and Method

The reasoning in arriving at Equations [7] and [8] is as follows.

When a vessel is enveloped with flame, heat is absorbed by the contents and temperature within rises. If the contents be liquid, vapors are formed and boiling eventually occurs. The relief capacity must then be at least equal to the vaporization rate, or internal pressure will continue to rise and rupture may follow. If the weight rate of the relief connection is equated to the weight rate vaporized, Equation [9] results which is the origin of Equation [7]

$$d = \sqrt{\frac{IS_w}{205.5P}} \left(\frac{T}{Mr^2}\right)^{1/4} \quad \ldots\ldots\ldots\ldots [9]$$

in which I is the heat-input rate in Btu per hour per square foot, S_w is surface as in Equation [7], P is absolute pressure; and the last term is the contents factor F, in which T is the boiling point at the pressure P in deg F absolute, r is the latent heat of vaporization in Btu per pound at temperature T, and M is the molecular weight. The simplification of this factor is outlined under the heading *Contents Factor*, to be discussed later.

If a vessel contains gas or vapor and is exposed to fire, rapid expansion of the contents takes place (refer to the pressure curve, Fig. 2, Part 1). The relief capacity must then be at least equal to the rate of volume increase, or uncontrolled pressure rise results. If the weight rate of the relief connection is equated to the weight rate of expansion, the following equation results, which is the origin of Equation [8]

$$d = 0.02615 \frac{S^{1/2}}{P^{1/4}} \cdot \frac{(T_w - T)^{5/8}}{T^{0.325}} \quad \ldots\ldots\ldots [10]$$

in which S is surface as in Equation [8], P is absolute pressure, and the last term is the gas-expansion variable, in which T_w is the temperature to which the tank shell is heated, and T is the initial gas or vapor temperature both in deg F absolute. This term is reduced to a constant by inserting temperature limits, as described under *Gas Expansion Variable*, to be discussed. The rate of volume increase of a gas is always less (other conditions being equal) than the vaporization rate of liquids as will be seen.

For derivations of Equations [9] and [10] refer to the Appendix.

The relief capacity is proposed in terms of area of the relief connection (or connections) because the designer is primarily interested in selecting an adequate fitting of standard size for the vessel to be constructed, and because of the great variation in the capacity of commercial relief apparatus. This connection is ordinarily an inserted short tube with a square inner edge, somewhat rough from the standpoint of fluid flow. The relief device may afterwards be selected of a capacity (based on approved flow test) to pass the vapor rate of flow computed from relief area, as will be explained later. Although the vapors and gases to be contained and discharged have been assumed as perfect gases, the formulas give results in the direction of safety when there is deviation from the gas law.[21]

Weight Rate of a Short Tube. The formula[8] $W = 306\ aP \times \sqrt{M/T}$, which is generally known, is used in this development. It is universally employed and of proved accuracy. This expression is incorporated in the "API-ASME Code for Unfired Pressure Vessels," as the calculated capacity of relief devices of nozzle design. It was derived from the adiabatic flow of an ideal gas through an orifice, modified for flow above the critical-pressure ratio, and holds for this class of equipment having working pressures above 15 psig.

As written, the formula incorporates an orifice coefficient of 0.97 for a tapered nozzle. Generally, 0.83 is used for a short tube, such as the relief connection described (at pressures of this magnitude). Thus the constant has been multiplied by 0.83/0.97 so that the formula reads

$$W = 262\ aP \sqrt{\frac{M}{T}} \quad \ldots\ldots\ldots\ldots [11]$$

for the vapor weight rate of a short tube in pounds per hour. Refer to the Appendix for nomenclature.

The Contents Factor F, $\left(\frac{T}{Mr^2}\right)^{1/4}$. To use Equation [9], $d = \sqrt{\frac{IS_w}{205.5P}} \left(\frac{T}{Mr^2}\right)^{1/4}$, it is necessary to find values of temperature and latent heat of vaporization for the compounds contained, compatible with the set pressure of the device, P. For many liquids (at various pressures) common to industry, these are not available; and if they were, their use in individual cases would result in numerous vent sizes adequate only for materials of like properties at the same condition. In an effort to facilitate the use of the expression, several studies were undertaken.

Finally, it appeared possible that, if the properties of the known hazardous liquids were graphed, a value of the factor F might be chosen which would be satisfactory for the many compounds to be contained. Accordingly, Fig. 12 was prepared. This is a plot of the numerical value of the contents factor versus the vapor pressure of 36 compounds so far as latent-heat data are available. In so far as possible, a cross section was shown of the many types of liquids and gases commonly found in industry. If the graph were enlarged, additional curves at low pressures could be made intelligible in the more congested area for materials such as hexane, ethylene oxide, styrene, ordinary motor gasoline, isobutylene, vinyl chloride, and "Tetralin." Although of limited number, those shown are sufficient for the development of the discussion.

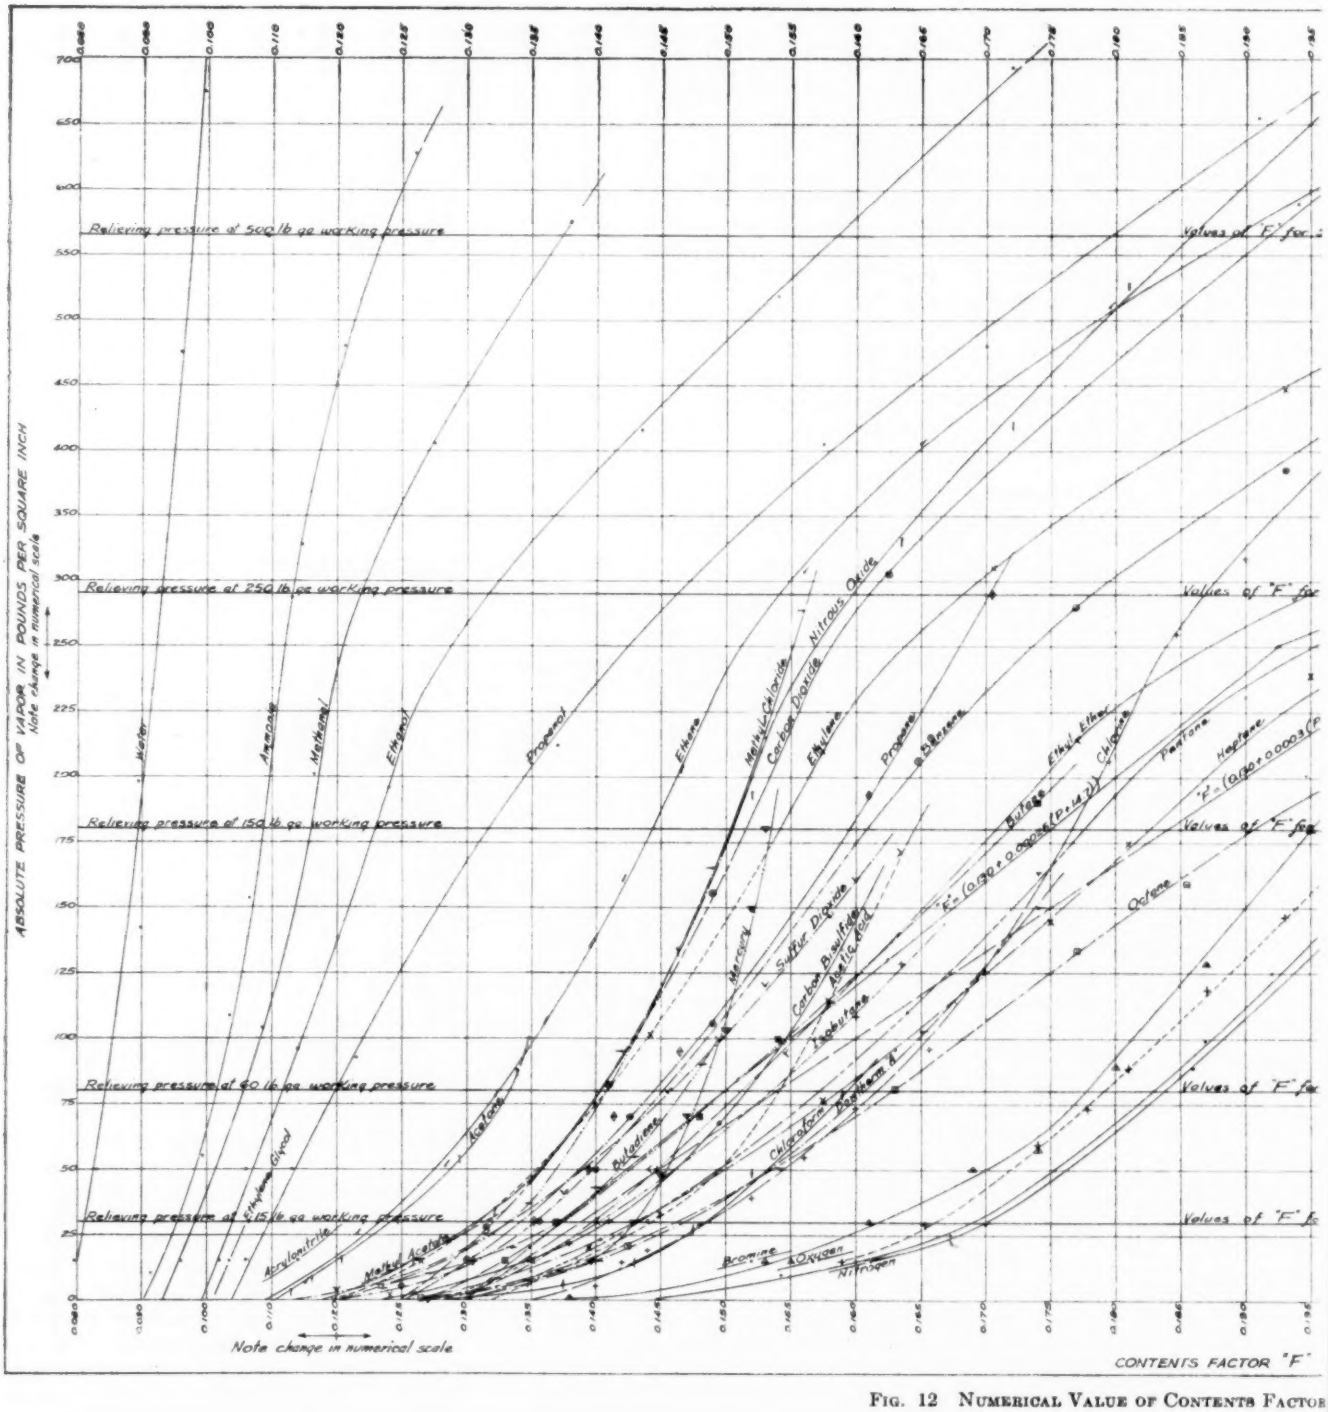

FIG. 12 NUMERICAL VALUE OF CONTENTS FACTOR F VARIO

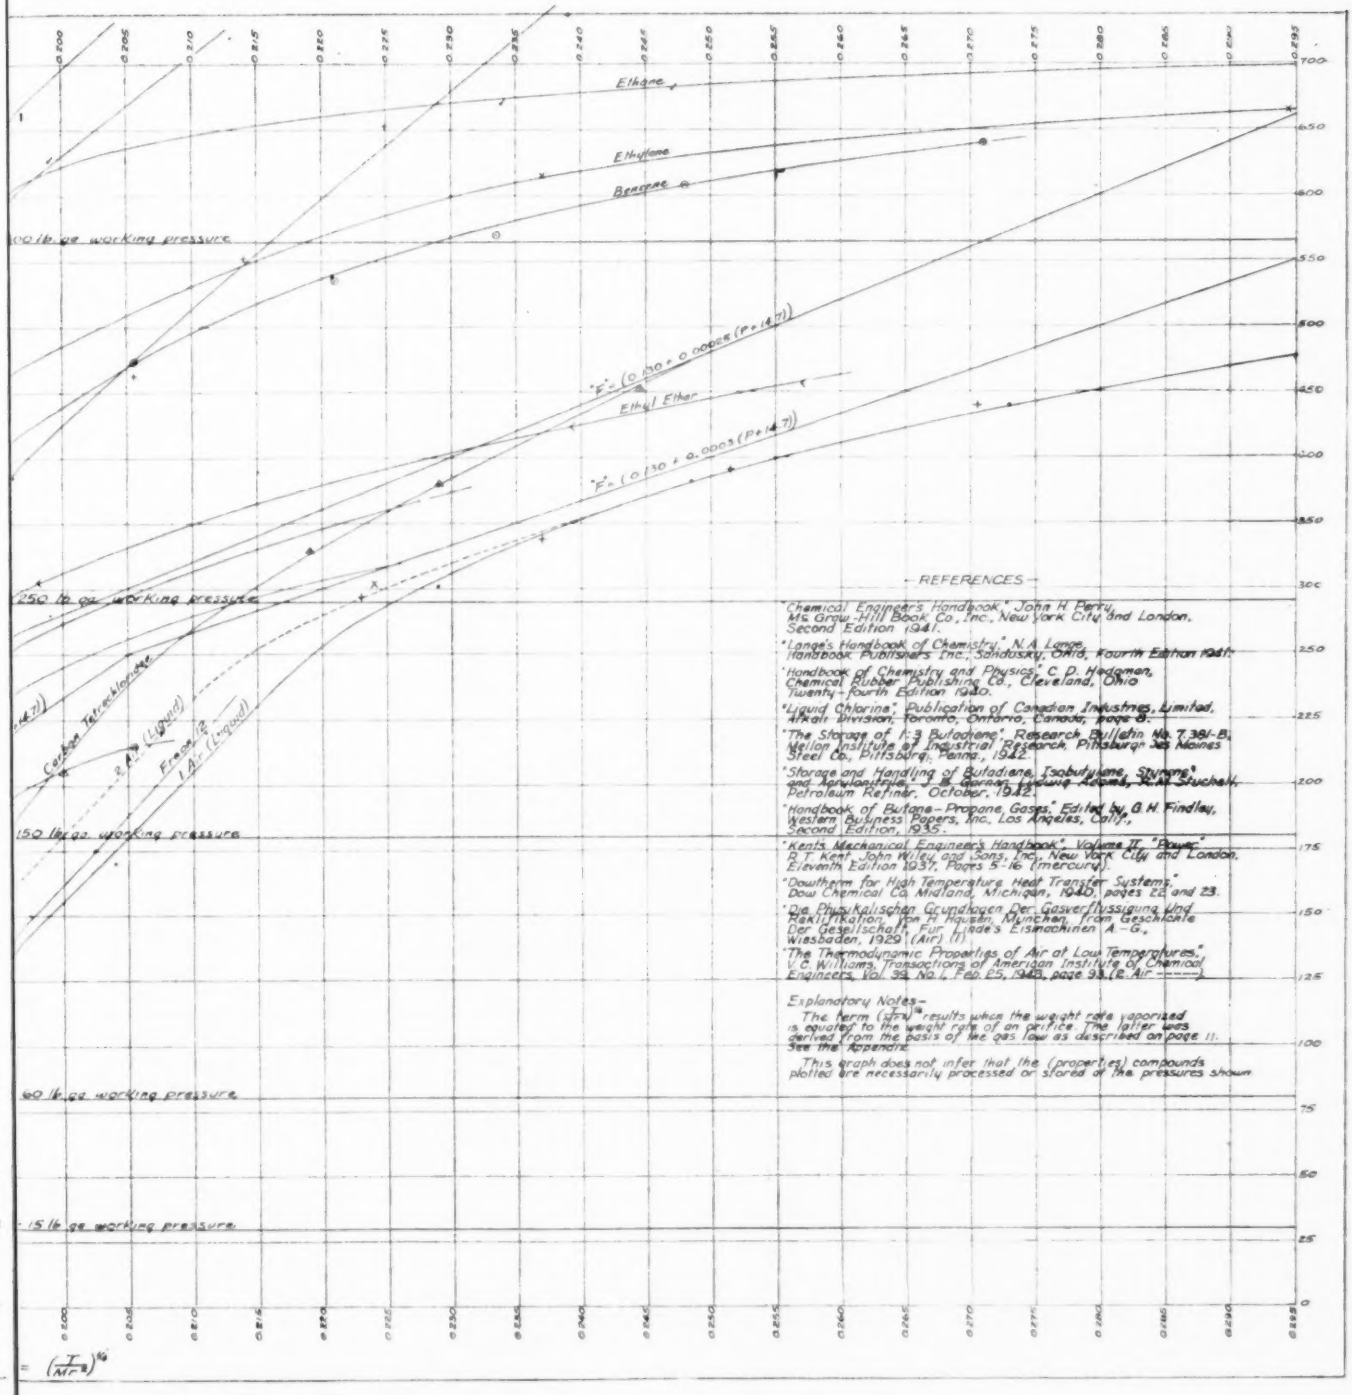

Latent-heat data may be calculated with satisfactory accuracy for other liquids of particular interest by any of several methods found in recent literature. Those provided by H. P. Meissner[22] and Donald F. Othmer[23] are recommended.

Further, the value of F for any compound at 15 psia may be quickly estimated by Trouton's rule, under which conditions F is equal to $(M/T\ 484)^{1/4}$, in which M is the molecular weight and T is the normal boiling point in deg F absolute. It would then be expected from the similarities in the curves in Fig. 12 that the loci of values for the compound considered would approximately parallel those of the compound shown on the graph which is most like that considered in chemical structure and properties.

Where two or more compounds are contained in a vessel, the value of the contents factor should be based on that which will produce the greatest vaporization rate when the volatility and weight per cent of the several components are considered.

[23] "Correlating Vapor Pressure and Latent Heat Data," by D. F. Othmer, *Industrial and Engineering Chemistry*, vol. 34, 1942, p. 1072.

Various Liquids at Absolute Pressures

To illustrate the relative effect of type of contents and magnitude of pressure on the required relief area, Table 2 is given. The diameters were calculated for a large pressure vessel by Equation [9], using values of the contents factor from the graph. The multiplicity of the sizes resulting, the increase of relief diameter with ratio of M/T of the compounds, and the decrease of relief diameter with pressure in the ordinary ranges are then readily apparent. (The decrease in relief diameters above 200 psi working pressure is slight.)

To simplify the use of these data, it has been suggested that similar tables for various sizes of vessels be made, or that the properties of a liquid such as benzene be employed as a standard for values of the contents factor. However, these do not promote what appears to be the more practical manner of assuring adequate relief area for the contingency of fire exposure. The authors suggest that an arbitrary value of F be used which would specify minimum relief-connection size for vessels of any given capacity within certain ranges of pressure. This will also provide an adequate relief connection (within the limits shown in Table 2) for that class of equipment which undergoes changes in service

[a] Dimensions of pressure vessel, 10 ft 6 in., diam; 18 ft 10 in., height.
[b] Approximate.
NOTE: This table does not infer that the compounds shown are necessarily processed or stored at the pressures listed. Calculations are based on the set pressure of the relief device being 10 per cent in excess of the working pressure.

and which would be desirable from the standpoint of maintenance and operation.

Values of F which might be used to specify the relief-connection size are represented by the designated straight lines in Fig. 12. Reference to Table 2 will show that practical values of d are obtained when F equals $0.130 + 0.00025\ (P + 14.7)$ or $0.130 + 0.0003\ (P + 14.7)$, and when relief devices are applied as suggested in the section, Summary for Use. For purposes of facilitating this development, it is the latter value of F which has been employed in simplifying Equation [9] to Equation [7], since it not only appears adequate, as will be explained, but is not exceeded (except by liquid air),[24] within the limits of available data at higher pressures by the individual contents-factor curves. Very probably, the relief area for pressure vessels larger than 10,000 gal nominal capacity should be computed by Equation [9] for the individual contents when the necessary latent heat - vaporpressure data are obtainable.

It is to be noted that the suggested value [0.130 + $0.0003\ (P + 14.7)$] of F gives diameters consistent with the large majority of the compounds, but less than for some of those tabulated which have high ratios of M/T. Calculations show that this inadequacy holds only at pressures below 100 psig when the next larger pipe size is used as the relief connection. Inasmuch as pressure vessels usually incorporate a strength safety factor of 5, the relief diameters are based upon a pressure increase limited to 10 per cent of the working pressure, and the vessels are assumed to be 90 per cent full of volatile material when exposed to fire, no doubt the straight-line value of F would prove adequate at any pressure. Such a value would also afford the benefits of standardization. It is understood, however, that such standardization will not be wholly agreeable to all concerned, and further improvement in regard to simplifying the contents factor appears warranted. Nevertheless, the suggested value of F in no degree nullifies the value of Equation [9] in calculating the required relief diameter directly for any contents.

Further, it should be noted that the individual curves of the contents factor flatten as the critical pressures of the compounds are approached. It is in this region that the latent heat of vaporization of the liquid approaches zero; and consequently, the individual value of F increases more rapidly so that the relief diameter increases slowly after having decreased rapidly with pressure below 200 lb working pressure. Such increase is in conformance with the trend of accelerated vaporization. However, the value of F should not be increased beyond the point of critical temperature and pressure in those exceptional cases where processes operate at pressures such that the relieving pressure exceeds the critical pressure of the material being processed. Critical pressures and temperatures of representative compounds are listed in Table 2. (Processes which operate altogether above the critical pressure and temperature are in gas service and Equation [10] applies.)

The Gas Expansion Variable, $\dfrac{(T_w - T)^{5/8}}{T^{0.325}}$.

The rate of volume increase just discussed is dependent upon

[24] This is as might be expected; since in the evaluation of the contents factor for gases, $(T/MC_p)^{1/2}$, the numerical value of the factor for air was found to be larger than that for any other gas whose properties were available in the reference literature (refer to the Appendix).

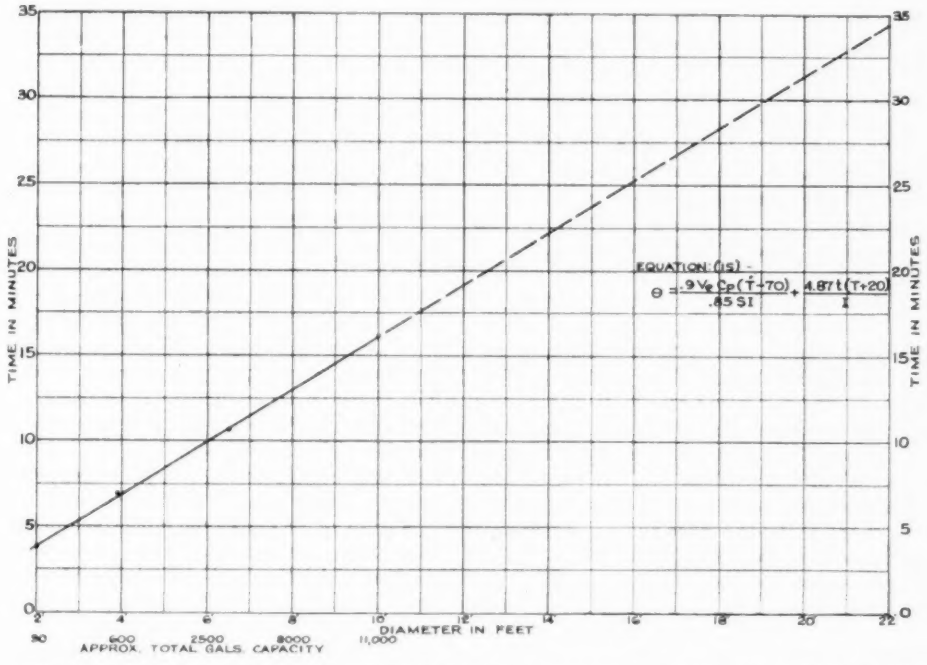

FIG. 13 ESTIMATED TIME FOR VOLATILE LIQUID CONTENTS OF PRESSURE VESSELS TO REACH 158 F WHEN ABSORBING HEAT AT 20,000 BTU PER SQ FT PER HR

(Contents of properties of F equals 0.142, T = 158 F; M = 74; r = 143 Btu; C_p = 0.447; ρ = 54.7 lb, at 15 psig.)

the rate of temperature rise in the contents (gas or vapor). This reduces mathematically (see derivation in Appendix) to the term shown. The probable maximum temperature difference is considered to be 1100 F; that is, $(T_w - T)$ = (1560 — 460) F abs, initial vapor temperature being zero F, and tank-wall temperature rising to 1100 F. Conceivably, this temperature difference may be greater, but distortion and possible failure of steel plate above 1100 F may be expected, even though the internal pressure is limited to a 10 per cent rise. When these temperature limits, typifying severest conditions, are inserted, the variable reduces to the constant 10.85.

The variable was derived using the properties of air in order to obtain maximum values and so provide adequate relief for any gas or vapor. Refer to the Appendix for comparison of values obtained with properties of other gases.

Flow Capacity in Terms of Area

If the relief area (not the next larger pipe size) as just determined, the molecular weight of the contents, and the absolute vapor temperature at the relieving pressure are inserted in weight rate Equation [11] of a short tube (a relief connection), the necessary capacity of the relief device may be computed. The apparatus may then be selected of a capacity (based on approved flow test) to pass the calculated rate which is as follows:

$$W = 262\ aP\ \sqrt{\frac{M}{T}}\ \text{lb per hr of vapor} \quad \ldots\ldots [11]$$

$$Q = \frac{1682\ aP}{\sqrt{MT}}\ \text{cfm at 68 F of free vapor} \quad \ldots\ldots [12]$$

$$Q = \frac{353.0\ aP}{\sqrt{T}}\ \text{cfm of free air at 68 F} \quad \ldots\ldots [13]$$

$$W = 42.7\ aP\ \text{lb per hr of saturated steam} \quad \ldots [14]$$

In all these cases, a is in square inches, P is the opening pressure of the relief device in pounds per square inch absolute, M is the molecular weight of the contents, and T is the contents vapor temperature in deg F absolute at the pressure P.

For conditions of fire exposure, T is approximately the temperature of the liquid contents when P is the vapor pressure, which may be obtained from temperature-vaporpressure data. For vessels in gas or vapor service only, T is approximately the temperature necessary to raise the pressure in the vessel from the absolute working pressure and temperature to the absolute set pressure of the relief device, as computed by the gas law, $T/P = T'/P'$.

The source of Equations [11], [12], [13], and [14] will be found in the Appendix.

It is in this determination of the capacity of the relief device (or devices) that allowance is made for the individual contents and immediate service, it being proposed, as already inferred, that the relief connection be the same size on all vessels of given capacity and range of working pressure. When equipment is so provided with adequate relief area for volatile compounds in the form of relief connections, the relief devices may be replaced to provide for any change in contents or more severe working conditions from the standpoint of relief requirements.

The procedure in determining the size of connections, capacity of devices, and selection of relief apparatus will be outlined in the Summary for Use.

The Time Element

If a vessel exposed to fire is large and the contents are of such properties that there would be a long delay before boiling and maximum efflux would occur, it would be desirable to select the relief device to provide for the vaporization rate which would take place within a certain safe period. The time required for the liquid contents of a steel vessel to reach a given average temperature during fire exposure may be approximated by use of the following formula

$$\theta = \frac{V\rho C_p(T - 70)}{S_w I} + \frac{4.87t(T + 20)}{I} \quad \ldots\ldots [15]$$

in which θ is the time in hours, V is volume of liquid contents in cubic feet, ρ is the density of the liquid in pounds per cubic foot, C_p is the specific heat of the liquid, T is the boiling point at the opening pressure of the relief device or temperature reached in a period θ in deg F, S_w is the wetted surface exposed to fire in square feet, I is the heat-input rate (20,000 Btu per hr per sq ft), and t is the thickness of the tank shell (steel) in inches. Derivation of this expression will be found in the Appendix.

The time required for volatile contents to reach the boiling point during fire exposure is very short. To illustrate, Fig. 13 has been included. It was assumed that the vessels were 90 per cent full with 85 per cent of the total surface wetted and exposed—a quite normal condition. Properties of the contents were taken as those having an F value of 0.142, and as otherwise noted in the caption of Fig. 13. Under these conditions, a short time element and a maximum venting rate may be expected. It will be seen that the time element is very largely a function of the diameter of the vessel. The calculations indicate that most (those under 20 ft diam) pressure vessels with volatile contents at 15 psi will boil when exposed to intense fire in less than $^1/_2$ hr.

When vessels are in gas or vapor service and become exposed to fire, the maximum venting rate will be reached within such a short period as to permit no reduction of the relief capacity as calculated by Equation [8]. Fig. 2, Part 1, shows this very clearly.

Effect of "Outage"

The term "outage" is used in the literature pertaining to containers to indicate the proportion of a tank which contains vapor rather than liquid. Thus, a tank which is only 40 per cent filled would have an "outage" of 60 per cent. Although this term does not appear in the developed formula, it has been considered. If the wetted height of the tank shell is used rather than the nominally full wetted height, the effect of "outage" is provided for. It is true that as the "outage" increases, the unwetted wall temperature will rise; but heat will be lost by conduction and radiation to the colder portions of the tank, and the hot wall temperature (steel) will probably not rise above the "critical" point of about 1100 F. When the "outage" is large, the wetted height is small, and the rate of vaporization is low; and although the vapor temperature will be higher than the temperature corresponding to the boiling point, it can be shown that the highest venting rate will occur when a tank is full of liquid.

The time required for a completely empty steel tank to reach 1100 F in a fire of intensity I would be approximately

$$\theta = \frac{5144\ t}{0.8\ I} \text{ or } 0.320\ t \text{ for 20,000 Btu input rate} \ldots . [16]$$

in which θ is time in hours for the tank wall to reach 1100 F, t is thickness of tank in inches, and I is intensity of fire in Btu per hr per sq ft. Thus in a fire of the intensity of 20,000 Btu per hr per sq ft, a tank made of $^1/_4$-in. steel would reach 1100 F in about 5 min.

$$\theta = 0.320 \times 0.25 = 0.080 \text{ hr} = 4.8 \text{ minutes}$$

This agrees very closely with time-temperature observations made by the Underwriters' Laboratories, Inc., in their tests previously referred to.[10] The source of this formula will be found in the Appendix.

Effect of Ranges of Pressure on Relief Areas

As mentioned previously, the internal diameters of the required relief connections vary rapidly with changes in working pressure up to about 200 psig. To show this clearly, Equation [7]

$$d = \sqrt{\frac{97.3\ S_w}{(P + 14.7)}} \left(\frac{P + 448.0}{3333.3}\right)$$

for vessels in volatile-liquid service has been graphed at 15, 60, and 200 psig working pressure, Fig. 11. Above 200 psi, a very gradual change in the required relief diameter continues, but the pipe size will not be affected for vessels of 10,000 gal nominal capacity or less until pressures above 700 psig are reached.

It is seen from Fig. 11 that it would be practical and economical to use different size relief connections for different ranges of working pressure on vessels of the same capacities. Further examination of the graph will disclose that the curves at the pressures indicated conform largely (more so than at other pressures when trial calculations are made) to pipe sizes. To take advantage of this effect, relief-connection formulas for ranges of working pressure will be provided in the Summary for Use.

In order to complete the comparison described under the Summary, of Part 2, the relief sizes of the National Board of Fire Underwriters and the State of California for liquefied petroleum gases at 200-psig working pressure have been added to Fig. 11. The difference between these and Equation [7] is principally due to the higher heat-absorption rate, although a somewhat larger contents factor is used in Equation [7].

A study of the shapes and proportions of vessels will disclose, as mentioned previously, that when calculating relief areas for connections, it is always adequate to use 85 per cent of the total exterior surface as the wetted area, provided the normal filling is not more than 90 per cent of the total volume. This has been employed in providing formulas for sizes of connections.

Emergency and Normal Relief

It is to be recognized that the requirement for relief of overpressure due to fire exposure represents an abnormal condition, and that this requirement, in most cases, is greatly in excess of that required to provide for operation fluctuations or disturbances. This latter requirement is considered by the authors to be "normal" relief and the former "emergency" relief. More specifically, normal relief is that required by process overheating, overfilling, improper operation, failure of control apparatus, the human element, plugging or mechanical failure within the system, etc. Emergency or abnormal relief is considered that due to fire exposure or uncontrolled, internal, chemical reaction.

The two present separate problems. Required normal relief can be determined from analysis of physical conditions within the system and calculation of the possible maximum "through-put." Relief required, due to fire exposure, may be provided for as outlined in this paper. As stated, the two requirements are widely separated in most cases, and it is practical to provide separate devices for the purposes as will be proposed.

Internal reaction is an emergency requirement not easily determined. The multiplicity and range of chemical reactions or rapid decompositions defy classification of rates of volume increase. Where likelihood of such expansion exists, special analysis and provisions are necessary to safeguard the individual installation.

On the other hand, there are special installations and processes in which the normal relief is the larger requirement. Some of these may be (depending upon analysis) vessels covered with substantial, fire-resistive insulation, those partly so insulated, vessels protected with reliable cooling systems, vessels processing nonhazardous plastics and semi-solids, etc. In some such cases, it will be apparent after analysis that no supplemental relief capacity need be provided for fire exposure as long as the immediate service is not made more severe from the standpoint of fire contingency; but these allowances in relief-device capacity should not effect a reduction in the area of the relief connection for fire exposure as previously specified. When vessels are partly protected with nonflammable insulation, the formulas may be correctly applied to the exposed surface in determining the necessary capacity of the relief device.

Relief due to fire exposure is assumed to be the release of vapor only. Liquid expansion due to the increased temperature is relatively negligible.

Proposed Summary for Use

1 Minimum sizes of relief connections for vessels not exceeding 10,000 gal nominal capacity (585 sq ft of wetted surface exposed): All pressure vessels should be provided with an emergency relief area (or areas) in the form of nozzles or connections. This area should be that computed by the following formulas or that required to limit the rise in working pressure to 10 per cent (as based on maximum possible "through-put" due to operation fluctuations or disturbances as defined), whichever of the two is the larger:

For vessels to have a working pressure from 15 to 60 psig, use

$$a = 0.0405\,S \text{ or } d = \sqrt{0.0515\,S} \quad \ldots\ldots\ldots [1]'$$

For vessels to have a working pressure from 60 to 200 psig, use

$$a = 0.0192\,S \text{ or } d = \sqrt{0.0244\,S} \quad \ldots\ldots\ldots [2]'$$

For vessels to have a working pressure from 200 to 700 psig use

$$a = 0.01112\,S \text{ or } d = \sqrt{0.01415\,S} \quad \ldots\ldots\ldots [3]'$$

In Equations [1]', [2]', and [3]', a is the relief area (or total areas) in square inches, S is the total external surface of the vessel in square feet, and d is the internal diameter of the circular relief opening in inches.

For vessels to have a working pressure above 700 psig, use

$$d = \sqrt{\frac{97.3\,S_w}{(P + 14.7)}} \left(\frac{P + 448}{3333.3}\right) \quad \ldots\ldots\ldots [4]'$$

in which d is as just given, P is the set pressure of the relief device (normally 1.1 the working pressure) in pounds per square inch gage, and S_w is the surface in square feet wetted by the contents and exposed to fire, P in the second term is limited to the critical pressure of the compound in process.

For vessels larger than 10,000 gal nominal capacity (585 sq ft of wetted surface exposed), use

$$d = \sqrt{\frac{97.3\,S_w}{(P + 14.7)}} \left(\frac{T}{Mr^2}\right)^{1/4} \quad \ldots\ldots\ldots [5]'$$

in which the symbols are as in the preceding paragraph except those in the last term which is the contents factor. It should be evaluated directly from Fig. 12, or calculated as recommended under the heading *Contents Factor*. In all cases, the nearest suitable pipe size (or sizes) of adequate area should be used.

2 Relief capacity in terms of area required at any pressure; liquid service: All pressure vessels in liquid service, or if used in systems which contain liquids, should have a relief flow capacity equivalent to the internal cross-sectional area (not the nearest pipe size) of a short tube, as calculated by the following formula, or that area required for "normal" relief, as described in paragraph 1, whichever is the larger

$$d = \sqrt{\frac{97.3\,S_w}{(P + 14.7)}} \left(\frac{T}{Mr^2}\right)^{1/4} \text{ and } a = 0.7854\,d^2 \quad \ldots\ldots [6]'$$

In Equation [6]', a is the relief area (or total of areas) in square inches, S_w is the wetted (wetted by the liquid contents when nominally full) surface exposed in square feet, d is the inside diameter of the free circular opening in inches, and P is the maximum allowable working pressure plus 10 per cent in pounds per square inch gage. The term $\left(\frac{T}{Mr^2}\right)^{1/4}$ is the contents factor and is evaluated as described in the preceding paragraph under Equation [5]'. (This is the emergency relief capacity required for vaporization of liquids due to fire exposure.)

Exceptions: In those exceptional cases where a, as determined by Equation [6]', exceeds the area of the relief connection, as set forth in paragraph 1, the relief connection will have to be increased or allowance permitted as suggested near the end of the section *The Contents Factors F*, $\left(\frac{T}{Mr^2}\right)^{1/4}$. If the relief capacity in terms of area approaches that of the relief connection, multiple relief devices will be required and should be applied as described in paragraph 5.

3 Relief capacity in terms of area required at any pressure; gas or vapor service only: All pressure vessels in gas or vapor service and in gas systems where no liquid can accumulate should have a relief flow capacity equivalent to the internal cross-sectional area of a short tube, as determined by the following formula, or that area required for "normal" relief, as described in paragraph 1, whichever is the larger

$$a = \frac{0.0631\,S}{\sqrt{(P + 14.7)}} \quad \text{or} \quad d = \sqrt{\frac{0.0803\,S}{\sqrt{(P + 14.7)}}} \quad \ldots\ldots [7]'$$

In Equations [7]', a is the relief area in square inches, S is the external exposed surface in square feet, d is the inside diameter of the relief connection in inches, and P is the maximum allowable working pressure plus 10 per cent in lb per sq in. gage. This is the emergency relief capacity required for gas or vapor expansion due to fire exposure.

4 Relief capacity of the required areas in terms of fluid flow: To select a relief device (or devices) of adequate capacity (based on approved flow test), use the area a, as determined in paragraph 2 or 3, in any one of the following formulas as the case may require:

$$W = 262.0\,aP\,\sqrt{M/T} \text{ lb of contents vapor per hr} \quad \ldots\ldots\ldots [8]'$$

$$Q = \frac{1682\,aP}{\sqrt{MT}} \text{ cfm of vapor at 68 F and atmospheric pressure} [9]'$$

$$Q = \frac{353.0\,aP}{\sqrt{T}} \text{ cfm of air at 68 F and atmospheric pressure} [10]'$$

$$W = 42.7aP \text{ lb per hr of saturated steam} \quad \ldots\ldots\ldots [11]'$$

In Equations [8]', [9]', [10]', and [11]', a is in square inches, and P is the opening pressure of the relief device in pounds per square inch absolute; M is the molecular weight of the contents, and T is the contents vapor temperature in deg F absolute at the pressure P. For conditions of fire exposure, T is approximately equal to the temperature of the liquid contents when P is the vapor pressure, which temperature may be obtained from temperature-vapor pressure data. For vessels in gas or vapor service only, T is approximately the temperature necessary to raise the pressure in the vessel from the absolute working pressure and temperature to the absolute set pressure of the relief device, as computed by the gas law, $T/P = T'/P'$.

5 Normal and emergency relief devices: It is preferable that separate spring- or weight-loaded safety devices be used for the "normal" relief requirement as described under that heading. The additional devices necessary to provide for fire exposure or internal reaction may supplement those required for operation fluctuations or disturbances. These may be in the form of rupture disks, safety heads, pilot-operated valves, or other apparatus and should be installed as specified in the recognized codes. If

rupturing devices are used, they should be calibrated to release at a pressure 50 to 100 per cent above the working pressure but not to exceed the test pressure of the vessel. In the exceptional cases where the "normal" and "emergency" relief are so nearly equivalent as to make the installation of multiple devices not economical, the one device should be of the capacity of the larger of the two requirements and set to relieve 10 per cent above the working pressure.

In those cases where the relief for operation fluctuations may be the larger requirement because of substantial fire-resistive insulation, nonhazardous contents or surroundings, etc., Equations [6]′ and [7]′ may be applied on the basis of the part of the surface not covered, or the part possible to be exposed when arriving at the relief capacity.

6 Back pressure: The pressure on the downstream side of the relief device should be limited to a maximum of from 10 to 25 per cent of the set pressure which must be adjusted to counteract the back pressure. If this limit is exceeded the capacity of the relief device may be reduced and redesign become necessary.[21]

7 Lower limit of size: For reasons of mechanical strength, it is recommended that no relief connection or safety device for manufacturing or service equipment be smaller than $^1/_2$ in. pipe size, regardless of the size of vessel to be protected.

8 Time element: To estimate the time for volatile liquids in a vessel exposed to fire to reach a given average temperature, apply the following formula

$$\theta = \frac{V\rho C_p(T - 70)}{S_w\, 20{,}000} + \frac{4.87\, t(T + 20)}{20{,}000} \quad \ldots\ldots [12]'$$

In Equation [12]′, θ is the time in hours, V is the volume of the liquid in cubic feet, ρ is the density of the liquid in pounds per cubic foot, C_p is the specific heat of the liquid, T is the boiling point at the opening pressure of the relief device, or temperature reached in a period θ in deg F, S_w is the wetted surface exposed in square feet and t is the thickness of the steel shell in inches.

If θ is $^1/_2$ hr or more (approximate time element for 20-ft-diam vessels containing volatile liquids at just above 15-psig working pressure) and there is assurance that effective cooling or fire-extinguishing equipment will come into operation during the half-hour period, the emergency-relief capacity may be reduced to the vaporization rate produced by the temperature rise within the half hour. For vessels exposed to fire in gas service, the maximum venting rate will occur within such a short time as to permit no modification of the calculated emergency relief.

Conclusion

The conclusions as outlined under Summary and detailed under Summary for Use are based upon the foregoing theory which is mathematically expressed in the Appendix.

The formulas proposed give relief capacities much greater than are at present employed and which are not adequate for the abnormal condition of fire exposure.

For example of use of the formulas refer to the Appendix.

Proposals herein hold only for pressures above 15 psig. For vessels operating at pressures not exceeding 0.50 psig, Part 3 will give details. Part 4 will appear at a later date covering vessels operating from 0.50 through 15 psig.

In addition to the lack of complete specifications in the recognized codes for the pressure-relief requirements of vessels, and the general statement that present relief areas as proposed by regulatory bodies were found to be inadequate for fire exposure, it has been suggested that further information be given to justify this study which shows a method of computing relief capacities for the contingency of fire exposure.

In its present form, the paper is based upon the mathematical development of the observations of vessels exposed to seven man-made fires by four separate organizations, as described in Part 1 of this paper. Since its preparation, two other similar tests by another company have been received, which support the tests herein analyzed.

Also in evidence are the reports of four equipment failures from accidental fire. These were vessels constructed in accordance with the A.S.M.E. Unfired Code and provided with relief areas compatible with a heat-absorption rate when exposed to fire of 7000 Btu per sq ft of wetted surface per hr. Three contained stable compounds, and the contents of the fourth probably underwent partial dissociation above the boiling point. All of the several contents had low-vapor pressures, boiling at much higher temperatures than water. No exact data on the fire intensity were obtained, but trial calculations by the developed formulas, using what data were available, gave results favorable to the test observations.

Further, the authors have reports of 31 failures of equipment (not due to fire exposure) other than those which may be obtained from several recording associations. Of these, 20 were due to excessive external pressure and 10 from excessive internal pressure. The overpressures occurred from miscellaneous causes for which the "normal" relief capacity should have been adequate, and it is not doubted that many of the failures would have been prevented had relief capacity for fire exposure also been incorporated in the installations.

Since it is not possible to specify a "normal" relief requirement for pressure vessels except by individual analysis of physical conditions within the process, and since it is possible to determine and provide relief capacity for fire exposure in a practical and relatively inexpensive manner, it is felt that this paper may provide a beginning for discussion, compilation of experience, and study which might eventually lead to more specific and safe specifications for minimum pressure-relief requirements.

Appendix to Part 2

Derivation of General Equations [9] or [3]*, and [10] or [15]″

Vapor weight rate of a short tube (above 15 psig)

$$W = 306\, aP\sqrt{\frac{M}{T}}$$

API-ASME Code: Weight rate of tapered nozzle

$$W = 306 \times \frac{0.83}{0.97}\, aP\sqrt{\frac{M}{T}}$$

$$W = 262\, aP\sqrt{\frac{M}{T}}$$

or

$$W = 262 \times 0.7854\, d^2P\sqrt{\frac{M}{T}}$$

$$W = 205.5\, d^2P\sqrt{\frac{M}{T}} \quad \ldots\ldots [1]''$$

in which

(Coefficient of flow of a short tube = 0.83)

W = rate, lb per hr
a = orifice area, sq in.
P = inlet pressure, psia
M = molecular weight of vapor
T = vapor temperature, deg F abs
d = orifice diameter, in.

Weight rate vaporized

$$\frac{Q}{S_w} = \frac{Wr}{S_w} = I$$

$$W = \frac{IS_w}{r} \quad \text{[2]''}$$

in which

Q = total heat input, Btu per hr
S_w = wetted surface heated, sq ft
r = latent heat of vaporization, Btu per lb
I = unit heat input, Btu per hr per sq ft
W = liquid vaporized, lb per hr

Required diameter of a short tube to pass the weight rate vaporized: Equate [1]'' and [2]''

$$\frac{IS_w}{r} = 205.5\, d^2 P \sqrt{\frac{M}{T}}$$

$$d^2 = \frac{IS_w}{r}\left(\frac{T}{M}\right)^{1/2}\left(\frac{1}{205.5\,P}\right)$$

$$d = \sqrt{\frac{IS_w}{205.5(P + 14.7)}}\left(\frac{T}{Mr^2}\right)^{1/4} \quad \text{[3]'' or [9]}$$

To apply Equation [3]''

d = diameter of relief connection, in.
I = 20,000 Btu per hr per sq ft
S_w = wetted surface heated, sq ft
P = set pressure of device, 1.1 working pressure, psig
T = boiling point at P, deg F abs
M = molecular weight of contents
r = latent heat of vaporization at T

Weight rate of expansion of gas or vapor due to heat transferred to a tank:

$$wC_p \frac{dT}{d\theta} = \frac{Q}{\theta} \quad \text{[4]''}$$

$$hS\,\Delta T = \frac{Q}{\theta} \quad \text{[5]''}$$

$$w = V\rho = V\frac{MP}{RT} \quad \text{[6]''}$$

From Equations [4]'' and [6]''

$$V\rho C_p \frac{dT}{d\theta} = \frac{Q}{\theta} \quad \text{[7]''}$$

$h = F\Delta T^{1/4}$ (ref. 5, Equation [16], p. 240)

From Equation [5]''

$$F\overline{\Delta T}^{1/4} S\,\Delta T = \frac{Q}{\theta} \quad \text{[8]''}$$

Equate [7]'' to [8]''

$$V\rho C_p \frac{dT}{d\theta} = FS\Delta T^{5/4}$$

$$\frac{dT}{d\theta} = \frac{FS\overline{\Delta T}^{5/4}}{V\rho C_p} \quad \text{[9]''}$$

From Equation [6]''

$$dw = \frac{-VMP}{R}\cdot\frac{dT}{T^2} \quad \text{[10]''}$$

$$-dw = \frac{w}{\theta}\,d\theta \quad \text{[11]''}$$

Equate [10]'' to [11]''

$$\frac{VMP}{R}\cdot\frac{dT}{T^2} = \frac{w}{\theta}\,d\theta \quad \text{[12]''}$$

$$\frac{dT}{d\theta} = \frac{w}{\theta}\cdot\frac{RT^2}{VMP} \quad \text{[13]''}$$

Equate [9]'' to [13]''

$$\frac{FS\overline{\Delta T}^{5/4}}{V\rho C_p} = \frac{w}{\theta}\,\frac{RT^2}{VMP} \quad \text{[14]''}$$

in which

w = weight of contained gas or vapor, lb
C_p = specific heat of gas or vapor
dT = change in temperature
$d\theta$ = change in time
Q = total heat transferred, Btu
θ = time, unit hr
h = heat-transfer coefficient, Btu per hr per sq ft per deg F
S = tank surface heated, sq ft
ΔT = difference between tank wall and contained gas, deg F
V = volume of contents gas or vapor, cu ft
ρ = density of contents gas, lb per cu ft
M = molecular weight of gas or vapor
P = pressure, psia
R = gas constant, 10.72
T = temperature of gas or vapor, deg F abs
F = function of physical properties of a gas
dw = change in weight
$W = \frac{w}{\theta}$ = venting rate, lb per hr

Required diameter of a short tube to pass the weight rate of gas expanded due to heat transferred to a tank (the same nomenclature is used as in the preceding group):

Insert Equation [1]'' in [14]''

$$205.5\, d^2 P\sqrt{\frac{M}{T}}\cdot\frac{RT^2}{VMP} = \frac{FS\overline{\Delta T}^{5/4}}{V\rho C_p}$$

$$d^2 = \frac{FS\overline{\Delta T}^{5/4} VMP}{V\rho C_p RT^2\, 205.5\, P}\left(\frac{T}{M}\right)^{1/2}$$

$$d^2 = \left(\frac{F}{C_p M^{1/2}}\right)\frac{S}{205.5}\cdot\frac{M\overline{\Delta T}^{5/4}}{RT^{3/2}\rho}$$

in which $\left(\rho = \frac{MP}{RT}\right)$

$$d = \left(\frac{F}{C_p M^{1/2}}\right)^{1/2}\cdot\frac{S^{1/2}}{14.33\,P^{1/2}}\cdot\frac{\Delta T^{5/8}}{T^{1/4}}$$

$$d = \left(0.375\,\frac{P^{1/4}}{T^{0.0753}}\right)\cdot\frac{S^{1/2}}{14.33\,P^{1/2}}\cdot\frac{\Delta T^{5/8}}{T^{1/4}}$$

Refer to following paragraph for $0.375\,\frac{P^{1/4}}{T^{0.0753}}$

$$d = 0.02615\,\frac{S^{1/2}}{P^{1/4}}\cdot\frac{\Delta T^{5/8}}{T^{0.325}} \quad \text{[15]'' or [10]}$$

To apply Equation [15]''

d = diameter of relief connection, in.
S = surface exposed, sq ft

P = set pressure of relief, 1.1 gage working pressure plus 14.7
$\Delta T = (T_w - T)$
T_w = temperature to which tank wall is heated, deg F abs
T = initial temperature of tank vapor, deg F abs

The term $\left(\frac{F}{C_pM^{1/2}}\right)^{1/2}$ in the foregoing, relating the properties of the contents fluid, was replaced by its maximum value $0.375\,\frac{P^{1/4}}{T^{0.0753}}$. This is justified in the following manner: The value of F, a function of the physical properties of a gas, varies with both temperature and pressure as will be seen. The value C_p, specific heat at constant pressure, varies with temperature. Inasmuch as pressure and temperature are working conditions to remain in the relief diameter Equation [15]', it is desirable to express the subject variable in terms of P and T. Now

$$F = D\left(\frac{\rho^2BC_pk^3}{Z}\right)^{1/4} \text{ (ref. 5, Equation [20], p. 242)}$$

$$\left(\frac{F}{C_pM^{1/2}}\right)^{1/2} = D\left(\frac{\rho^2BC_pk^3}{C_p{}^4M^2Z}\right)^{1/8}$$

$$= D\left[\rho^2Z^2\cdot\frac{B}{M^2}\cdot\left(\frac{k^3}{C_p{}^3Z^3}\right)\right]^{1/8}$$

in which

F = 0.27 for air at 68 F and atmospheric pressure
D = proportionality constant
k = thermal conductivity
C_p = specific heat
ρ = density
B = coefficient of thermal expansion
Z = viscosity
M = molecular weight
R = gas constant

Since B, M, and the ratio C_pZ/k (ref. 5, p. 417) are independent of P and T, we may write

$$\left(\frac{F}{C_pM^{1/2}}\right)^{1/2} = D'(\rho^2Z^2)^{1/8}$$

and ρ for a gas is MP/RT, then

$$\left(\frac{F}{C_pM^{1/2}}\right)^{1/2} = D'\left(\frac{M^2P^2}{R^2T^2}\cdot Z^2\right)^{1/8}$$

Again M and R are independent of P and T, so

$$\left(\frac{F}{C_pM^{1/2}}\right)^{1/2} = D''\left(\frac{P^2Z^2}{T^2}\right)^{1/8}$$

$$= D''\left(\frac{P^2T^{1.398}}{T^2}\right)^{1/8}$$

$$= D''\left(\frac{P^2}{T^{0.602}}\right)^{1/8}$$

$$\left(\frac{F}{C_pM^{1/2}}\right)^{1/2} = D''\left(\frac{P^{1/4}}{T^{0.0753}}\right)$$

Z^2 Varies with T for air as follows:

T	Z	Z^2
460 deg R	0.0162	0.0002625
528	0.018	0.000323
660	0.021	0.000440
860	0.025	0.000625
1060	0.029	0.000840
1260	0.032	0.001050
1460	0.036	0.001295
1560	0.038	0.001444

$$\left(\frac{1560}{460}\right)^n = (3.39)^n = \frac{1.444}{0.2625} = 5.50$$

$$n = 1.398$$

When P = 14.7 psia, and T = 528 deg R, C_p = 0.24 and F = 0.27 for air

$$\therefore D'' = \left(\frac{0.27}{0.24\times 29^{1/2}}\right)^{1/2}\times\frac{(528)^{0.0753}}{(14.7)^{1/4}}$$

$$D'' = 0.375$$

and

$$\left(\frac{F}{C_pM^{1/2}}\right)^{1/2} = 0.375\,\frac{P^{1/4}}{T^{0.0753}}$$

Now, it is also necessary to show that $\left(\frac{F}{C_pM^{1/2}}\right)^{1/2}$ gives higher values for air than for any other gases whose properties are available in the reference literature. To do this we use McAdams Equation [20],[25] again which is

$$F = D\left(\frac{\rho^2BC_pk^3}{Z}\right)^{1/4}$$

and in which the nomenclature is as before. Again, $\rho = MP/RT$ and $B = 1/492$. Then, at a constant pressure and temperature it would be expected that F would vary for different gases as follows:

$$F = D'\left(\frac{M^2C_pk^3}{Z}\right)^{1/4}$$

At 1 atm pressure and 20 C, F = 0.27 and $\left(\frac{M^2C_pk^3}{Z}\right)^{1/4}$ = 0.465 for air, so that the F value for any other gas, whose molecular weight, specific heat, thermal conductivity, and viscosity are known, may be determined from the relation

$$F_g = \frac{0.27}{0.465}\left(\frac{k^3C_pM^2}{Z}\right)_g^{1/4}$$

in which the subscript g applies to the gas other than air. On this basis, the F value for a number of representative gases has

[25] Ref. 5, p. 242.

TABLE 3 VALUE OF F FOR REPRESENTATIVE GASES

Gas	k[a]	C_p[a]	Z[a]	M[a]	$\frac{k^3C_pM^2}{Z}$	$\left(\frac{k^3C_pM^2}{Z}\right)^{1/4}$	F	$\frac{F}{C_pM^{1/2}}$
Air	0.0161	0.24	0.018	29	0.0468	0.465	0.270	0.209
Hydrogen	0.1075	3.50	0.009	2	1.9324	1.181	0.685	0.138
Acetone	0.0065	0.34	0.0077	58	0.0408	0.448	0.260	0.100
Acetylene	0.0124	0.43	0.010	26	0.0554	0.485	0.281	0.128
Benzene	0.0062	0.26	0.0075	78	0.0502	0.472	0.273	0.135
Ethyl alcohol	0.0089	0.40	0.0094	46	0.0634	0.501	0.290	0.107
Ethyl ether	0.0088	0.46	0.0077	74	0.222	0.687	0.398	0.100
Water	0.0110	0.48	0.0097	18	0.0213	0.382	0.221	0.108
Pentane	0.0083	0.34	0.0063	72	0.1599	0.632	0.366	0.127
Carbon dioxide	0.0109	0.21	0.0146	44	0.0360	0.436	0.252	0.181
"Freon 113"	0.0054	0.16	0.0103	187	0.0855	0.542	0.313	0.143

[a] Ref. 5, various pages.

been calculated as shown in Table 3, and it will be noted that the value of $\left(\frac{F}{C_p M^{1/2}}\right)^{1/2}$ for air is greater than for any of those values so obtained; and for many others, such as ammonia, nitrogen, and oxygen, whose properties were considered but not listed in the table.

Use of General Equations [9] or [3]', and [10] or [15]'

The following example is given of the use of Equation [3]' for a 10 ft 6 in. diam (D) × 18 ft 10 in. high over-all vertical tank with dished heads, nominally full of ethyl ether, operating at 15 psig, and surrounded with intense fire

$$d = \sqrt{\frac{IS_w}{205.5(P + 14.7)}} \left(\frac{T}{Mr^2}\right)^{1/4}$$

$$d = \sqrt{\frac{20{,}000 \times 583}{205.5 \times 31.2}} \times 0.140$$

$$d = 5.96 \text{ in.}$$

in which

$S_w = \pi D(0.266\ D + L)$
L = height of straight shell to filling level, ft
$S_w = \pi\ 10.5(0.266 \times 10.5 + 14.9)$
$S_w = 583$ sq ft
$P = (16.5 + 14.7) = 31.2$
$\left(\frac{T}{Mr^2}\right)^{1/4} = 0.140$ (see Fig. 12)

An example of the use of Equation [15]' for a 10 ft 6 in. diam (D) by 18 ft 10 in. high over-all air tank with dished heads, operating at 15 psig and surrounded by intense fire, is as follows

$$d = 0.02615 \frac{S^{1/2}}{P^{1/4}} \cdot \frac{(T_w - T)^{5/8}}{T^{0.325}}$$

$$d = \frac{0.02615 \times 26.45 \times 10.85}{2.363}$$

$$d = 3.17 \text{ in.}$$

in which

$S = \pi D(0.532\ D + L)$
L = length of straight shell between heads, ft
$S = \pi\ 10.5(0.532 \times 10.5 + 15.67)$
$S = 700$ sq ft, $S^{1/2} = 26.45$
$T = (0 + 460) = 460$ F abs
$T_w = (460 + 1100) = 1560$ F abs
$(T_w - T)^{5/8} = (1100)^{5/8} = 79.5$

$$T^{0.325} = (460)^{0.325} = 7.33$$

$$(T_w - T)^{5/8}/T^{0.325} = 10.85$$

$$P = (16.5 + 14.7) = 31.2$$

$$P^{1/4} = 2.363$$

Simplification of General Expressions to Equations [7] or [16]', and [8] or [17]'

The diameter of a connection necessary to relieve a pressure vessel in liquid service when involved with conflagration is as follows:

$$d = \sqrt{\frac{IS_w}{205.5\ P}} \left(\frac{T}{Mr^2}\right)^{1/4} \quad \text{[3]'}$$

$$d = \sqrt{\frac{20{,}000\ S_w}{205.5\ (P + 14.7)}} \times [0.130 + 0.0003\ (P + 14.7)]$$

$$d = \sqrt{\frac{97.3\ S_w}{(P + 14.7)}} \left(\frac{P + 448.0}{3333.3}\right) \quad \text{[16]'}$$

in which

I = 20,000 Btu per hr per sq ft
$\left(\frac{T}{Mr^2}\right)^{1/4}$ = contents factor, Fig. 12
S_w = wetted surface exposed, sq ft
P = 1.1 working pressure, psig

The diameter of a connection necessary to relieve a pressure vessel in gas or vapor (only) service when involved with conflagration is as follows

$$d = 0.02615 \frac{S^{1/2}}{P^{1/4}} \cdot \frac{(T_w - T)^{5/8}}{T^{0.325}} \quad \text{[15]'}$$

$$d = 0.02615 \left(\frac{S^{1/2}}{P^{1/4}}\right) \times 10.85$$

$$d = \sqrt{\frac{0.0803\ S}{\sqrt{(P + 14.7)}}} \quad \text{[17]'}$$

in which

S = surface exposed, sq ft
$\frac{(T_w - T)^{5/8}}{T^{0.325}}$ = *gas expansion variable*, as described under that heading, and as reduced to maximum constant (10.85) in preceding example
P = 1.1 working pressure, psig

Use of Equations [7] or [16]', and [8] or [17]'

An example of the use of Equation [16]' for a 10 ft 6 in. diam by 18 ft 10 in. high over-all vertical tank with dished heads, nominally full of volatile liquid, operating at 15 psig, and surrounded by intense fire is as follows

$$d = \sqrt{\frac{97.3\ S_w}{(P + 14.7)}} \left(\frac{P + 448.0}{3333.3}\right) = \sqrt{\frac{97.3 \times 583}{(16.5 + 14.7)}} \left(\frac{464.5}{3333.3}\right)$$

$d = 5.94$ in.

The following example gives the use of Equation [17]' for a 10 ft 6 in. diameter by 18 ft 10 in. high over-all tank with dished heads in gas (only) service, operating at 15 psig, and surrounded by intense fire

$$d = \sqrt{\frac{0.0803\ S}{\sqrt{(P + 14.7)}}} = \sqrt{\frac{0.0803 \times 700}{\sqrt{(16.5 + 14.7)}}}$$

$d = 3.17$ in.

Simplification of Weight Rate to Vapor Flow Capacity in Terms of Area

Weight rate of flow

$$W = 262\ aP \sqrt{\frac{M}{T}} \text{ lb per hr} \quad \text{[1]'}$$

Flow capacity in terms of cubic feet of vapor per minute

$$Q \text{ cu ft} = \frac{W \text{ lb}}{\rho \text{ lb per cu ft}}$$

$$Q = \frac{262}{60}\ aP \left(\frac{M}{T}\right)^{1/2} \frac{10.72(528)}{M(14.7)}$$

$$Q = \frac{1682\ aP}{\sqrt{MT}} \text{ cfm of free contents vapor at 68 F} \quad \text{[18]'}$$

where

$$\rho = \frac{MP}{RT} = \frac{M(0 + 14.7)}{R(68 + 460)} = \frac{M(14.7)}{10.72(528)}$$

at 68 F and atmospheric pressure

Flow capacity in terms of cubic feet of air per minute:

$$W = \frac{0.533\,CAP}{\sqrt{T}} \text{ lb per sec of air}^{26}$$

$$Q \text{ cu ft} = \frac{W \text{ lb}}{\rho \text{ lb per cu ft}}$$

$$Q = \frac{0.533 \times 0.83 \times aP \times 60}{0.0752\sqrt{T}}$$

$$Q = \frac{353.0\,aP}{\sqrt{T}} \text{ cfm free air at 68 F} \ldots\ldots [19]''$$

where

C = orifice coefficient, 0.83

$$\rho = \frac{MP}{RT} = \frac{29(14.7)}{10.72(528)}$$

$\rho = 0.0752$ at 68 F and atmospheric pressure

Flow capacity in terms of pounds of saturated steam per hour:
Napier's formula

$$W = \frac{aP}{70} \text{ lb per sec}$$

$$W = \frac{aP}{70} \times 3600 \times 0.83$$

(0.83 coefficient of flow for a short tube)

$$W = 42.7\,aP \text{ lb per hr of saturated steam} \ldots\ldots [20]''$$

Derivation and Use of Time Element Formulas

The estimated time required for the liquid contents of a vessel to reach a given temperature is derived as follows:

IS_w = total heat input, in Btu per hr

$\frac{V\rho C_p \Delta T}{\theta}$ = heat absorbed by liquid contents, Btu per unit time

$S \cdot \frac{t\rho C_p \Delta T}{12\,\theta}$ = heat absorbed by tank, Btu per unit time

$$IS_w = \frac{V\rho C_p(T - 70)}{\theta}^{*} + S \cdot \frac{t}{12} \cdot \frac{487 \times 0.12(T + 20)}{\theta}^{*}$$

$$(S_w \leq 0.85\,S)$$

$$\theta = \frac{V\rho C_p(T - 70)}{IS_w} + \frac{4.87\,t(T + 20)}{I} \ldots\ldots [21]''$$

In which

I = unit heat input rate, 20,000 Btu per hr per sq ft
S_w = wetted surface exposed to fire, sq ft
V = volume of liquid contents, cu ft
ρ = density, lb per cu ft (487 for steel)
C_p = specific heat (0.12 for steel)
ΔT = temperature difference, deg F
θ = time, hr
S = tank surface heated, sq ft
t = thickness of tank shell, in.
T = temperature of contents, deg F

The following example is given of the estimated time, Equation [21]'', required for the contents to reach the boiling point in a 10 ft 6 in. diam by 18 ft 10 in. high over-all tank with dished heads, nominally full of ethyl ether, operating at 15 psig, and surrounded by intense fire (the same nomenclature is used as for the preceding group):

$$\theta = \frac{V\rho C_p(T - 70)}{IS_w} + \frac{4.87\,t(T + 20)}{I}$$

$$\theta = \frac{(10{,}200 \text{ gal}/7.48) \times 44.5 \times 0.552\,(134.6 - 70)}{20{,}000 \times 583} + \frac{4.87 \times 0.375\,(134.6 + 20)}{20{,}000}$$

$\theta = 0.186 + 0.0141 = 0.2001$ hr or 12.0 min

Estimated time required for an empty steel tank to reach the "critical" temperature of 1100 F (the same nomenclature is used as before)

$$IS = S \cdot \frac{t}{12} \cdot \frac{487 \times 0.12(T - 50)}{\theta}$$

$$I = \frac{4.87\,t(1100 - 50)}{\theta}$$

$$\theta = \frac{5114\,t}{0.8I} = 0.320\,t \ldots\ldots [22]''$$

During the period of heating to 1100 F, the input I will be found only about 80 per cent effective due largely to reradiation losses.

Origin of Formulas for Ranges of Pressure

From 15 to 60 psig working pressure

$$d = \sqrt{\frac{97.3\,S_w}{(P + 14.7)}}\left(\frac{P + 448.0}{3333.3}\right) \ldots\ldots [16]''$$

in which

$$d = \sqrt{\frac{a}{0.7854}}$$

$$S_w \leq 0.85\,S$$

$$d = \sqrt{\frac{97.3 \times 0.85\,S}{(16.5 + 14.7)}}\left(\frac{16.5 + 448.0}{3333.3}\right)$$

$$d = \sqrt{0.0515\,S}\,; \quad \frac{a}{0.7854} = 0.0515\,S$$

$$a = 0.0405\,S \ldots\ldots [23]''$$

From 60 to 200 psig working pressure:

$$d = \sqrt{\frac{97.3 \times 0.85\,S}{(66 + 14.7)}}\left(\frac{66 + 448.0}{3333.3}\right)$$

[26] "Chemical Engineer's Handbook," by J. H. Perry, McGraw-Hill Book Company, Inc., New York, N. Y., 1934, Equation [21a], p. 710.

* Liquid contents are considered to have an average temperature of 70 F, and tank steel an average of 60 F, before exposure. The tank shell after heating is considered to be an average of 100 F hotter than the liquid contents, although this will vary somewhat with the compound contained.

$$d = \sqrt{0.0244S}; \qquad \frac{a}{0.7854} = 0.0244S$$

$$a = 0.0192\ S \ldots\ldots [24]''$$

From 200 to 700 psig working pressure

$$d = \sqrt{\frac{97.3 \times 0.85S}{220 + 14.7}\left(\frac{220 + 448.0}{3333.3}\right)}$$

$$d = \sqrt{0.01415\ S}; \qquad \frac{a}{0.7854} = 0.01415\ S$$

$$a = 0.0112\ S \ldots\ldots [25]''$$

EXAMPLE OF USE OF FINAL FORMULAS FOR RELIEF REQUIREMENTS

Relief requirements for a 10 ft 6 in. diam (D) by 18 ft 10 in. high over-all tank with dished heads, in gas service, operating at 150 psig are determined as follows (equation numbers refer to Summary for Use):

Relief-connection size

$$a = 0.0192\ S \text{ or } d = \sqrt{0.0244\ S} \ldots\ldots [2]'$$

$$a = 0.0192 \times 700 \text{ or } d = \sqrt{0.0244 \times 700}$$

$$a = 13.44 \text{ sq in. or } d = 4.13 \text{ in. (use 4 in. ASA150)}$$

where

S = tank surface, sq ft
$S = \pi D(0.532\ D + L)$
L = length straight shell, ft
$S = \pi\ 10.5(0.532 \times 10.5 + 15.67)$
$S = 700$ sq ft

Relief capacity in terms of area:

$$a = \frac{0.0631\ S}{\sqrt{(P + 14.7)}} \text{ or } d = \sqrt{\frac{0.0803\ S}{\sqrt{(P + 14.7)}}} \ldots\ldots [5]'$$

$$a = \frac{0.0631 \times 700}{\sqrt{(165 + 14.7)}} \text{ or } d = \sqrt{\frac{0.0803 \times 700}{\sqrt{(165 + 14.7)}}}$$

$$a = 3.30 \text{ sq in. or } d = 2.047 \text{ in.}$$

Relief capacity of the device in terms of fluid flow

$$Q = \frac{353.0a\ P}{\sqrt{T}} \ldots\ldots [10]'$$

$$Q = \frac{353 \times 3.30\ (165 + 14.7)}{\sqrt{666}}$$

$Q = 8100$ cfm of air at 68 F, and atmospheric pressure

in which the temperature required to open valve, air having initial temperature of 150 F, is

$$T/P = T'/P'$$

$$T = \frac{179.7 \times (150 + 460)}{164.7}$$

$$T = 666 \text{ F abs}$$

[Provided the relief capacity required for operation fluctuations and disturbances (capacity of the compressor at 165 lb discharge) is not greater. Three and four-inch valves of this capacity are commercially available.]

PART 3 REQUIREMENTS FOR RELIEF OF ATMOSPHERIC VESSELS[27]

INTRODUCTION

A considerable number of references in the literature specifying the relief requirements of atmospheric storage tanks have been available for many years. Various methods have been developed to establish the normal venting requirements, and at least three nationally known, reliable organizations have agreed upon and proposed venting capacities necessary to limit internal pressure safely in event of exposure to fire. The fire records of the National Fire Protection Association and similar bodies clearly indicate the need and value of emergency vent areas for this contingency and emphasize the inadequacy of normal relief apparatus when a vessel is involved with intense fire. The inadequacy of the latter will be very apparent in this presentation.

In this section a recent investigation of the normal requirement made by the authors will be set forth and compared with previous methods. By the procedure used in Part 2 for pressure vessels, the emergency requirement will be developed, compared, and discussed. Thereafter, a summary for the suggested employment of this information will be given.

SUMMARY

To summarize briefly the principal results of Part 3, Fig. 14 has been included, which shows the relation and suggested combination of normal and emergency vent sizes as determined for vertical cylindrical atmospheric storage tanks.

Study of Fig. 14, practical experience with present-day venting apparatus, and consideration for economy led to the venting requirements given in Table 7, which are considered adequate for both normal (1 in. water external, 3 in. water internal, pressure) venting and vaporization (at 0.5 psi at 50 gal, proportionally reduced to 3 in. water pressure at 70,000 gal) of contents due to fire exposure. The formulas from which the foregoing were calculated appear under the descriptive headings for which they apply. Other formulas which provide relief specifications for all vessels in liquid or gas service at working pressures not to exceed 0.50 psig are also given.

The suggested application of the information herein will be found under the heading, Proposed Summary for Use.

THERMAL BREATHING OR NORMAL VENTING OF UNINSULATED, ABOVE GROUND, ATMOSPHERIC STORAGE TANKS WHEN EXPOSED TO EXTREME ATMOSPHERIC CHANGES

Introduction During the years 1939 and 1940, for a period of 14 months, a continuous record of breathing characteristics was kept on a 440,000-gal (nominal capacity) gasoline storage tank at South Charleston, West Va., (38 deg north latitude, 600 ft elevation). Rates of venting, specific gravities of the vapors, vapor pressures, liquid levels, liquid temperatures, vapor temperatures, and atmospheric temperatures were measured and recorded. The data obtained furnished information for vapor-conservation analysis (the subject of a separate discussion) and the determination of normal breathing requirements.

Summary. Maximum thermal breathing was found to be that due to contraction during a hailstorm. A temperature drop of 41 deg F (average) in 20 min was observed within the tank vapor. The inhaling rate resulted in vent-size requirements larger than those determined by a number of well-known methods, except those sizes proposed by the National Board of Fire Underwriters[28] (up to 800,000 gal capacity).

[27] Conditions: 1 in. water external, 0.50 psi internal, pressure.

[28] "Containers for Storing and Handling Flammable Liquids," National Board of Fire Underwriters, Pamphlet No. 30, New York, N. Y., 1941, p. 37.

It was concluded that the maximum rate of thermal breathing of an atmospheric (1 in. water external, 3 in. water internal, pressure) storage tank is

$$Q = (S/0.290) + \text{emptying rate} \quad [16]$$

where Q and emptying rate are in cubic feet of air per hour at 68 F and atmospheric pressure, and S is the area of the tank roof and shell in square feet.

The diameter of the relief connection required for this venting rate is

$$d = \sqrt{Q/921} \quad [17]$$

where d is in inches and Q is in cubic feet of air per hour at the conditions given. Derivation of these formulas will be found in the Appendix of this section.

In order that the vent sizes determined by Equations [16]

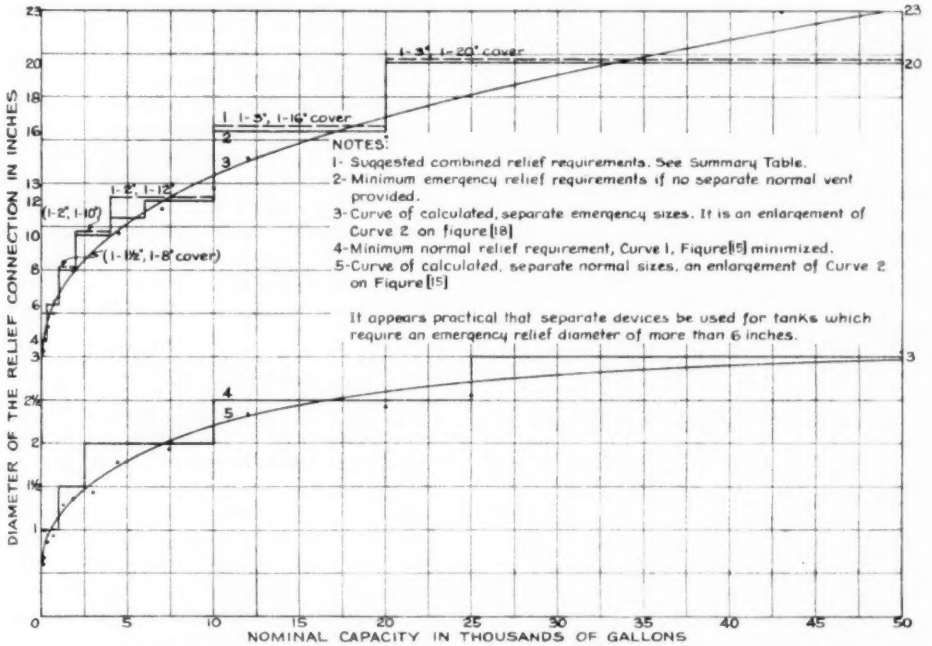

FIG. 14 COMPARISON OF NORMAL AND EMERGENCY RELIEF AREAS FOR ATMOSPHERIC TANKS TO FACILITATE SELECTION OF PRACTICAL AND ECONOMICAL COMBINATIONS OF THE TWO

(1 in. water external, 3 in. water internal, pressure.)

and [17] may be compared with those specified by other methods, Fig. 15 is given.

Equipment Arrangement. The tank on which a continuous record was kept was 50 ft diam × 30 ft 3 in. high (cylindrical shell), with an umbrella-type roof, and was painted with aluminum paint. The vessel was in active storage of finished gasoline.

An existing 8-in. standard pipe header about 600 ft long was used as a vent line. Two recording orifice meters were installed near the end of the line to measure both high and low flows in either direction. Also in connection therewith, a continuous-recording gravitometer was used to provide data for the vapor-density correction. A three-pen recording thermometer furnished atmospheric, tank vapor, and liquid-contents temperatures.

At the same time, other data were collected pertinent to related studies. Periods when the contained vapors were flammable were recorded by a combustible-gas instrument and recording potentiometer. While the effects of external water spray on vapor losses were being observed, a third orifice meter was used to measure the cooling-water rate. Frequent periodic analyses of the discharge vapors were made to determine the percentage of product contained at the indicated specific gravities.

Procedure. The experiment was given continuous attention and maintenance by operation and investigation personnel while the tank was being operated normally. A daily log was kept on all observations including weather, liquid level, vapor pressure, and pertinent comment. The data were transposed to a graph, a sample of which is included as Fig. 16. On this will be noted both ordinary and extreme breathing action during three representative periods.

Vapor and liquid temperatures and flammability of vapors were observed at various levels to obtain mean temperatures and to get indication of the location, frequency, and extent of combustible zones. Flash-arrester and emergency vacuum and pressure-relief protection, were maintained on the tank throughout the observations.

Data Obtained. The maximum breathing rates and corresponding information observed during the 14 months under various conditions are shown in Table 4. The contraction rate due to sudden cooling will be seen to be about 4 times as great as that for emptying, filling, solar heating, or combinations of conditions causing venting. No worth-while data on the efflux produced by mixing (by cycling contents) could be obtained other than that breathing rates so caused are not comparable to the maximum shown in Table 4.

Although not directly related to the subject, the data collected on the flammability of the vapor-air mixture were of interest. To show the relation between combustible contents and breathing action, Fig. 17 has been included.

For the most part (except for 3 months) the combustible-gas recorder operated in connection with the vent header at a point near its outlet. Flammable mixtures were present there at frequent intervals in an irregular pattern which was no doubt due to the lag in and large volume of the 600-ft long header. The interval from February 15, through February 26, 1940, Fig. 17, illustrates flammability within the header.

During June, July, and August, 1940, the combustible-vapor recorder operated directly in connection with the tank. It was found that explosive mixtures were present less frequently but for longer periods ranging up to 30 hr. In all, the tank vapors were within the flammable range 5 per cent of the time and "too rich to burn" 95 per cent of the time. The vapor-air mixtures when combustible were never in the lower limits, the gasoline content ranging from 2 to 53 per cent by volume, as based on laboratory analyses. Flammable limits of gasoline vapor-air mixtures are 1 to 6½ per cent by volume.[29]

All the recorded periods (seven in number) when the vapors within the tank were flammable are shown on the remainder of Fig. 17. It will be observed that in every case (except one of 45 min on June 17) the combustible mixture was produced by a combination of emptying and falling temperature. The exception was caused by a momentary in-breathing when a shower occurred while the vapors were warm (between 9 and 10 a.m.).

The use of flash arresters or inert-gas systems with atmospheric storage tanks containing volatile flammable liquids appears warranted by these observations.

Analysis. The data indicated that the maximum normal breathing requirement is that due to rapid contraction of the contained vapors. The quantity rate of contraction of a gas due to heat transferred to a colder tank wall is

$$Q = \frac{10.72FS(T - T_w)^{5/4}}{C_pMP} \quad \ldots\ldots\ldots\ldots [18]$$

in which Q is in cubic feet per hour, F is a function of the physical properties of the vapor (0.27 for air at atmospheric conditions),[30] S is the surface of the tank roof and shell enclosing the tank vapor in square feet, T is the initial vapor temperature in deg F, T_w is the final tank wall temperature (average) in deg F, C_p is the specific heat of the vapor, M is the molecular weight, and P is the average absolute pressure during contraction in pounds per square inch (14.736 internal for atmospheric tanks).

If the properties of air which constituted the greater percentage of the mixture ordinarily, and nearly the whole occasionally (air ranged 47 to 98 per cent by volume), and the observed temperatures from Table 4, Case 1, are used in Equation [18], maximum values of Q will be obtained. (For comparison with values for other vapors, see the evaluation of $\left(\frac{F}{C_pM^{1/2}}\right)^{1/2}$ in the Appendix of this section.) This value (cubic feet per hour) is then very nearly equal to $S/0.290$ as in Equation [16].

The capacity of the relief connection (a short tube) at pressures in this range is

$$Q = 4340d^2\sqrt{\frac{\Delta PT}{MP}} \quad \ldots\ldots\ldots\ldots [19]$$

in which Q and M are the same as in Equation [18], d is in inches, ΔP is pounds per square inch gage, P is pounds per square inch absolute, and T is the temperature of the vapor flowing in deg F absolute.

During the cooling process, the capacity of the relief connection must be equivalent to the rate of contraction at the permissible working pressure (1 in. water external). So, if Equation [18] is equated to Equation [19] at the observed conditions (Case 1), the required diameter will result as in Equation [17] $d = \sqrt{Q/921}$.

Derivation of Equations [18] and [19] will be found in the Appendix of this section.

Discussion. Although the contained vapors are not perfect gases and some condensation does take place during cooling, the comparison between observed breathing rates and those computed as for a gas on the basis of the rate of change of absolute temperatures is favorable and indicates results in the direction of safety.

The venting rate, $Q = S/0.290$, is based on a difference between initial vapor and final average tank-wall temperatures of 47 deg F and is equivalent to a fall in the vapor temperature of

Conditions	Hail Storm	Sudden Showers	
Temperatures:	April 8, 1940 11:50 a.m. to 12:10 p.m. Case 1	July 29, 1940 3:40 p.m. Case 2	May 31, 1940 2:05 p.m. Case 3
Atmospheric	73° to 54°F. in 20 min.	104° to 74°F. in 45 min.	78° to 65°F. in 30 min.
Vapor Contents	103° to 62°F. in 20 min.	146° to 84°F. in 1 hr.	95° to 67°F. in 30 min.
Maximum rate of change (vapor)	98° to 70°F. in 7 min.	119° to 111°F. in 2 min.	92° to 74°F. in 15 min.
Liquid Contents	52° to 56°F. in 20 min.	80° to 82°F. in 1 hr.	58°F. constant
Final Tank Wall about Vapor Space	56.0°F. (estimated average)		
Recorded Vapor Flow Rate (Max.)	4300 cu.ft. per hr. when 1 1/2 oz. per sq. in. vacuum seal blown	2650 cu.ft. per hr., when seal blown	*4450 cu.ft. per hr.
Liquid Level	10'-7 5/8" (constant)	19'-0" (constant)	0'-9" (constant)
Vapor Space Quantities	Volume 45,200 cu. ft. Surface (S) 5170 sq. ft.	Volume 28,800 cu.ft. Surface(S) 3860 sq.ft.	Volume 64,600 cu.ft. Surface(S) 6720 sq.ft.
Rate of Volume Change (Proportional to maximum abs. temp. rate as a gas).	18,850 cu. ft. per hr.	12,000 cu.ft. per hr.	*8400 cu.ft. per hr.
Proposed Breathing Rate (Based on S/0.290 as derived. Pump rate to be added).	17,830 cu. ft. per hr.	13,300 cu.ft. per hr.	23,200 cu.ft. per hr.
Reid Vapor Pressure (lb. per sq. in. at 100°F.)	8.3 lb. per sq. in.	8.3 lb. per sq. in.	5.6 lb. per sq. in.
Weather	Bright sun preceding storm, cloudy thereafter.	Hot sun shining before & after heavy rain storm.	Cloudy with intermittent sun before shower; bright sun thereafter.
Remarks:	Maximum condition (largest temperature drop in appreciable period found) used as basis of S/0.290.		

* Discrepancy between observed breathing rates and proportional rates of volume change is considered largely due to the pressure drop and lag in the recorded vapor flows were corrected to 60 F, the maxima at flowing

98 F to 70 F, in 7.86 min, when the vapor is assumed to be a gas. No additional temperature differential is considered necessary for a margin of safety. The vent sizes resulting are shown in Fig. 15, curve 2, which have a satisfactory service record of a number of years over a broad section of the country. As a matter of fact, a large number of comparable atmospheric tanks so vented were exposed to the same hailstorm cited, without giving any evidence of having been subjected to pressure above 1 in. of water external.

The capacity of a short tube, Equation [19], was derived from the adiabatic flow of an ideal gas through an orifice. It incorporates an orifice coefficient of 0.70 for flows where the ratio of upstream to downstream absolute pressure is less than 1.05.[31] Also, this is the coefficient used by the National Fire Protection Association under these conditions.[32] Tests were run on a typical tank and connection as a check on the formula derived. Actual flows were found to be 99 per cent of the theoretical within the atmospheric tank pressure range (0 to 3 in. water) and to be 100 per cent at a pressure of 5 in. of water (see Fig. 20 in the Appendix of this section).

[31] "Kent's Mechanical Engineers' Handbook," ref. 14, pp. 1–11.
[32] "Handbook of Fire Protection,"[9] p. 108.

Conclusion. The conclusions as outlined under *Summary* are adequate for the conditions specified and conform to the proposals of the National Board of Fire Underwriters up to 800,000 gal capacity, above which increased vent sizes as shown are suggested. Apparently, the average practice is to use vent sizes considerably smaller than this service-proved proposal (refer to Fig. 15).

Proposed sizes of connections with minimum capacities (based on 1 in. water external pressure) for the normal relief requirement for atmospheric tanks are listed in Table 5.

Relief capacities, concluded in Table 5, are not adequate for the condition of fire exposure now to be discussed and under which the relation of normal and emergency venting will be clarified.

To avoid excessive internal pressure due to accidental overfilling, the normal relief area should not be less than that of the fill pipe.

Requirements for Emergency Relief Due to Fire Exposure

Introduction. From the standpoint of emergency venting, atmospheric tanks (usually large) present a separate problem because of the very low safe working pressure (about 3 in. water

1300000 to 1800000	8	58450
1800000 to 2000000	2–6	65800

[a] Units of 2-in. vent size for tanks are usually the smallest standard manufacture.
[b] One 6-in. vent unit may be cheaper than the two small units, but they have the mechanical advantage of multiple devices.
[c] Similarly, one 8-in. vent unit may be cheaper than one 6-in. and one 4-in. size.

internal), the relatively large vapor space, the lessened possibility of complete envelopment in flame, and the lengthened (time) exposure required to produce maximum vaporization. The effect of the first two of the factors mentioned is such as to result in calculated relief areas which are impractical. The latter two are the basis of reasonable assumptions to be made which result in more economical designs.

Summary. The required diameter of a relief connection to limit internal pressure (not to exceed 0.50 psig) within vessels when the volatile contents are absorbing heat at 20,000 Btu per sq ft per hr of wetted surface exposed is

$$d = \sqrt{\frac{0.913\, S_w}{\sqrt{P(P + 14.7)}}} \quad [20]$$

If the pressure limit be 3 in. of water, as for atmospheric storage tanks, Equation [20] becomes

$$d = \sqrt{0.721 S_w} \quad [21]$$

and if the atmospheric tank be vertical cylindrical with bottom resting on pad or foundation, Equation [21] becomes

$$d = \sqrt{2.265\, DH} \quad [22]$$

in which (Equations [20], [21], and [22]) d is the internal diameter of the connection in inches, S_w is wetted surface exposed to fire in square feet when nominally full, P is the pressure limit

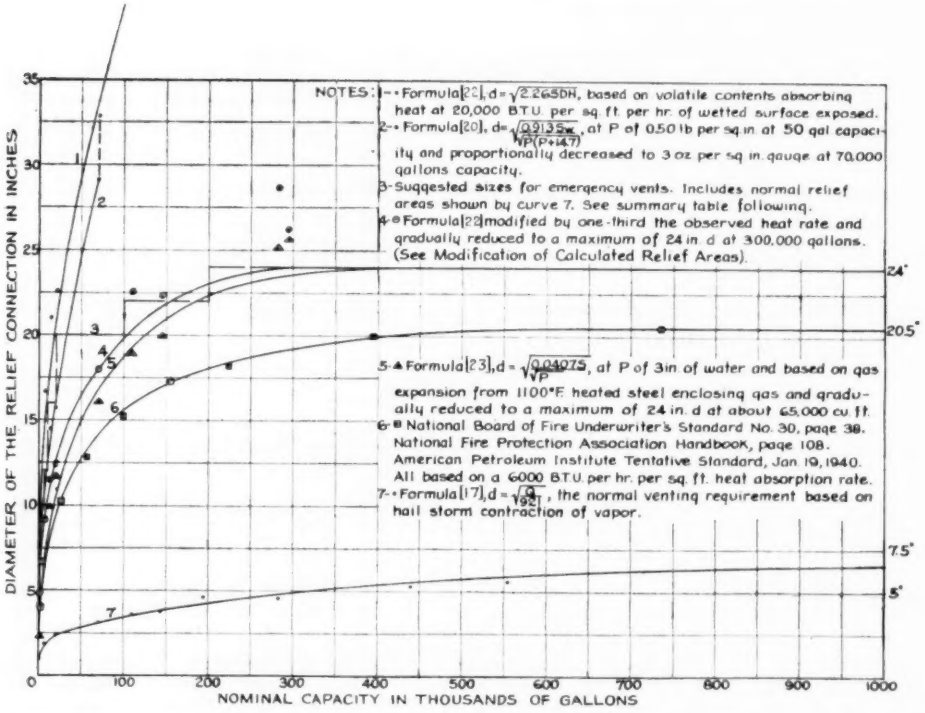

FIG. 18 COMPARISON OF REQUIRED DIAMETER OF RELIEF CONNECTION FOR ATMOSPHERIC STORAGE TANKS WHEN EXPOSED TO FIRE (1 in. water external, 3 in. water internal, pressure.)

in pounds per square inch gage (0.1083 for 3 in. water), D is the diameter of the tank in feet, and H is the height in feet of the contents on the exposed tank wall when it is nominally full.

For vessels in gas service only at pressures not to exceed 0.50 psig, the required diameter of the relief connection to limit internal pressure to a specified maximum is

$$d = \sqrt{\frac{0.0407\,S}{\sqrt{P}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [23]$$

in which d is the internal diameter of the connection in inches, S is the square feet of surface which may be exposed including unprotected roofs, and P is the maximum pressure permitted in pounds per square inch gage.

The origin of these formulas will be found in the Appendix of this section.

The formulas for liquid service, Equations [20], [21], and [22], should be applied to all vessels in the pressure range below 0.50 psig up to and including 15 ft diam; it then appears expedient for practical reasons to reduce the calculated relief sizes and to limit them to a maximum of 24 in. diam. These modifications are clarified as the discussion proceeds and are summarized under the heading, *Modification of the Calculated Relief Areas.*

Relief diameters for atmospheric tanks have been graphed in Fig. 18. The curve of Equation [22] is shown in relation to the same equation when modified by a heat rate one third of that concluded in Part 1. Between the two will be noted the suggested choice of vent size. For comparison, the proposal of the National Board of Fire Underwriters, the National Fire Protection Association, and the American Petroleum Institute is shown. Also appearing is the required size for normal venting which, though provided for in the emergency area, is not large enough to reduce it one pipe size over the entire range of tank capacity. Also observe that a contained gas or vapor will expand when in relatively large proportions, as in empty atmospheric tanks and when exposed to tank walls heated to 1100 F by external fire, at a rate nearly equivalent to the vaporization rate of volatiles.

Analysis and Method. The requirements for emergency relief of atmospheric tanks and low-pressure gasholders are based on the same reasoning as that for unfired pressure vessels as detailed in Part 2 of this paper. The physical conditions (pressure, temperature, and relative size) are merely different, necessitating the use of a different fluid-flow formula, a different value for the contents factor, and modification of calculated relief sizes as graphically suggested in Fig. 18.

As previously described, a vessel surrounded by fire absorbs heat and the temperature of its contents rises. If the content is liquid, its vapor pressure steadily increases and eventually boiling will occur; if a vapor or gas, progressive expansion takes place. (So-called empty tanks, equipped with adequate normal venting apparatus, have been observed to fail when involved with sudden, intense fire, although ignition of contents did not occur until after rupture.) Now, in either case, the relief apparatus must be of capacity equivalent to the rate of vaporization or the rate of volume increase. When the weight rate of the relief connection (at these low pressures) is equated to the weight rate of vaporization, the following Equation [24] results, which is the origin of Equations [20], [21], and [22]:

$$d = \sqrt{\frac{IS_w}{405\sqrt{P(P+14.7)}}}\left(\frac{T}{Mr^2}\right)^{1/4} \quad \ldots\ldots\ldots [24]$$

When the weight rate of expansion of a gas or vapor is equated to the weight rate of the relief connection, a second expression, Equation [25], results, which is the origin of Equation [23], namely

$$d = 0.0186 \cdot \frac{S^{1/2}}{\Delta P^{1/4}} \cdot \frac{(T_w - T)^{5/8}}{T^{0.325}} \quad \ldots\ldots\ldots [25]$$

In these equations, d is the internal diameter of the connection in inches, I is the heat-absorption rate in Btu per square foot per hour, S_w is wetted surface exposed in square feet, ΔP is the maximum pressure in pounds per square inch gage (0.1083 for 3 in. water), and S is total surface exposed in square feet. The terms $\left(\frac{T}{Mr^2}\right)^{1/4}$ and $\frac{(T_w - T)^{5/8}}{T^{0.325}}$ are the contents factor and gas expansion variable, which are reduced to constants, as described under subsequent headings. Equations [24] and [25], which are similar to Equations [8] and [9] in Part 2, are derived and simplified in the Appendix of this section to the useful Equations [20], [21], [22], and [23].

As in Part 2, the relief capacity is proposed in terms of area of the relief connection, because the designer is primarily interested in selecting an adequate fitting of standard size for the vessel to be constructed, and because of the variation in capacities of commercial relief apparatus. The vent apparatus may then be selected of a capacity, based on approved flow test, to pass the flow capacity of the calculated area, as will be shown.

Weight Rate of a Relief Connection. The vapor capacity of a short tube in pounds per hour at pressures not exceeding 0 5 psig is

$$W = 405\, d^2 \sqrt{\frac{MP(P + 14.7)}{T}} \quad \ldots\ldots\ldots\ldots [26]$$

in which W is the weight rate in pounds per hour, d is the internal diameter of the connection in inches, M is the molecular weight of the fluid, P is the inlet pressure in pounds per square inch gage, and T is the temperature of the fluid in deg F absolute.

This is the same formula used previously in this section for the determination of the normal breathing requirement, except that it was there given in cubic feet per hour. As stated before, it was shown to be accurate, and its derivation found in the Appendix of this section will be seen to conform to the procedure outlined by the American Gas Association.[33]

Contents Factor F, $\left(\frac{T}{Mr^2}\right)^{1/4}$. This term is identical with that derived and fully explained in Part 2 of this paper under the same heading. It is, as before, that which relates the properties of liquid contents. Since the developments in this section are limited to the pressure range of atmospheric to 0.50 psig, a single numerical value of the factor may be selected which would be adequate for any compound to be contained at these pressures.

For the present development, the value $F = 0.136$ has been used, for which reference is made to Fig. 12, Part 2. This value is considered adequate for any liquid which may be contained at these pressures, other than carbon tetrachloride. For this compound, use 0.155 for the contents factor in Equation [24].

Gas Expansion Variable, $\frac{(T_w - T)^{5/8}}{T^{0.325}}$. The rate of volume increase is dependent upon the rate of temperature rise within the vapor contents. Again, this is proportional to the value of the gas-expansion variable. If the formerly assumed maximum temperature difference of 1100 deg F, between initial vapor and final tank-wall temperatures is considered reasonable and adequate, the term reduces to the constant 10.85 (refer to Part 2, under the same heading as in this section).

As will be seen in the Appendix of this section, the variable was based upon the properties of air which apparently gives maximum values as therein demonstrated.

Flow Capacity in Terms of Area. If the relief diameters (not the next larger pipe size) as determined above, the molecular weight of contents, the relieving pressure, and the vapor temperature, are inserted in the weight rate of flow, Equation [26], of a short tube, the necessary capacity of the relief device may be computed. The apparatus may then be selected of a capacity (based on approved flow test) to pass the calculated rate which is as follows:

$$W = 405\, d^2 \sqrt{\frac{MP(P + 14.7)}{T}} \text{ lb per hr of vapor} \ldots [26]$$

$$Q = 156{,}000\, d^2 \sqrt{\frac{P(P + 14.7)}{MT}} \text{ cfh of free vapor at 68 F} \ldots [27]$$

$$Q = 29{,}000\, d^2 \sqrt{\frac{P(P + 14.7)}{T}} \text{ cfh of free air at 68 F} \ldots [28]$$

In Equations [26], [27], and [28], d is in inches, P is in pounds per square inch gage, and T is in deg F absolute.

For conditions of fire exposure, T is approximately the normal boiling point of the liquid contents. For vessels in gas service, T is about the temperature necessary to raise the pressure in the vessel from the absolute working pressure and temperature to the absolute set pressure of the relief device, as computed by the gas law, $T/P = T'/P'$.

A mathematical clarification of these equations is given in the Appendix of this section.

Time Element. The time required when exposed to intense fire for the liquid contents of a steel vessel to reach a specified average temperature may be estimated by applying the formula

$$\theta = \frac{V\rho C_p(T - 70)}{IS_w} + \frac{4.87t(T + 20)}{I} \quad \ldots\ldots\ldots [29]$$

in which θ is time in hours, V is the volume of contents in cubic feet, ρ is the density in pounds per cubic foot, C_p is the specific heat, T is the specified temperature in deg F, I is the heat-absorption rate in Btu per square foot per hour, S_w is the surface wetted by the product and exposed to fire in square feet, and t is the thickness in inches of the (steel) tank wall. This was introduced and derived in Part 2 of this paper. If this Equation is applied to vertical cylindrical flat-bottom tanks, it becomes (see Appendix of this section)

$$\theta = \frac{D\rho C_p(T - 70)}{4I} + \frac{4.87\, t(T + 20)}{I} \quad \ldots\ldots\ldots [30]$$

in which D is the diameter of the tank in feet. Results calculated by Equation [30] compare favorably with time-temperature observations in Part 1, Table 1.

From Equation [30], it is seen that the time required for the contents to absorb heat at any given rate is principally dependent upon the diameter of the tank. For illustration of the approximate time required to reach 100 F at the observed heat rate, Fig. 19 is shown. The tanks were assumed to be nominally full and of dimensions conforming to many tanks being used at this time. Calculations were made employing properties of compounds having a contents-factor value of 0.136, as shown in Fig. 19. Products having such properties are about as volatile as any stored at atmospheric pressure. Under the assumed conditions, a minimum time element and a maximum venting rate may be expected.

When vessels are in gas or vapor service and exposed to intense fire, the maximum venting rate will be reached in an even shorter time. Fig. 2, Part 1, illustrates the rapid expansion of tank vapors due to fire exposure.

Effect of "Outage." The term "outage" is used in literature pertaining to containers to indicate the proportion of a tank which contains vapor rather than liquid. Thus a tank which is only 40

[33] "American Gas Association Standards," New York, N. Y.

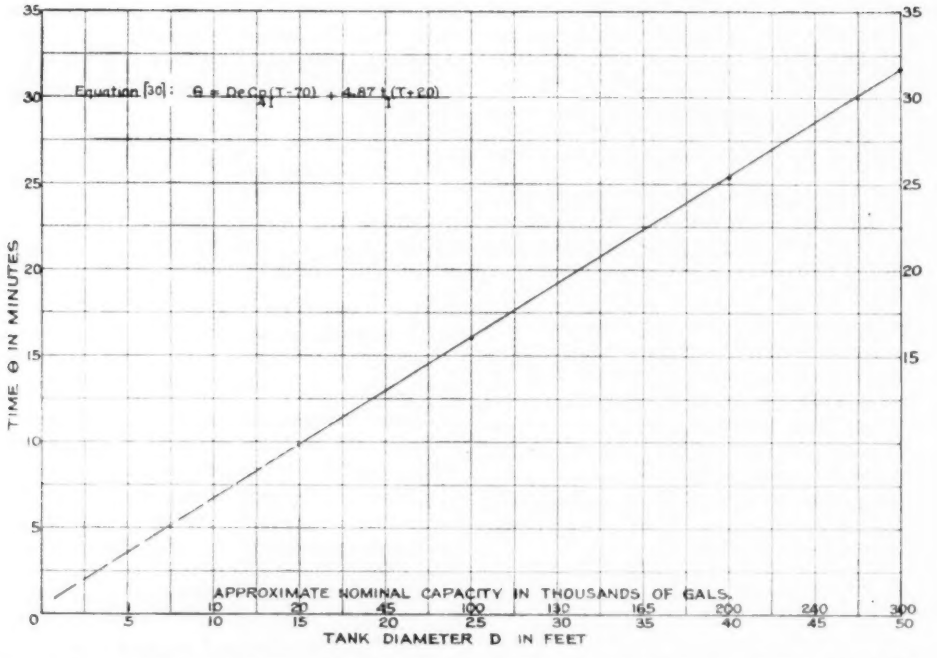

FIG. 19 ESTIMATED TIME FOR VOLATILE-LIQUID CONTENTS OF ATMOSPHERIC STORAGE TANKS TO REACH 100 F WHEN ABSORBING HEAT AT 20,000 BTU PER SQ FT PER HR

(Products of properties of $F = 0.136$; $T = 104$ F; $M = 74$; $r = 149.5$ Btu; $C_p = 0.447$; $\rho = 54.7$ lb.)

per cent filled would have an "outage" of 60 per cent. Although this term does not appear in the developed formula, it has been considered. If the wetted height of the tank is used rather than the nominally full wetted height, the effect of outage is taken care of. It is true that as the outage increases, the unwetted wall temperature will rise, but heat will be lost by conduction and radiation to the colder portions of the tank, and the temperature of the hot wall will probably not rise above the "critical" point of about 1100 F. When the outage is large, the wetted height is small, and the rate of vaporization is low; and, although the vapor temperature will be higher than the temperature corresponding to the boiling point, it can be shown that the highest venting rate will occur when a tank is full of liquid.

The time required for a completely empty steel tank to reach 1100 F in a fire of intensity I would be approximately

$$\theta = \frac{5114\,t}{0.8\,I} \text{ or } 0.320\,t \text{ for 20,000 Btu input rate} \ldots\ [31]$$

in which θ is time in hours for tank wall to reach 1100 F; t is thickness of tank wall in inches; I is intensity of fire in Btu per hour per square foot. Thus, in a fire of observed intensity of 20,000 Btu per hr per sq ft, a tank made of 1/4-in. steel would reach 1100 F in about 5 min.

$$\theta = 0.320 \times 0.25 = 0.080 \text{ hr} = 4.8 \text{ min}$$

This agrees very closely with time-temperature observations made by the Underwriters' Laboratories, Inc., in their tests described in Part 1. The source of this formula will be found in the Appendix of this section.

Emergency and Normal Relief. The requirements for relief of overpressure due to fire exposure represent an abnormal condition and are greatly in excess of those set forth for normal breathing and displacement. The emergency requirement is adequate for both conditions, and it appears both practical and economical to combine them into one device on the smaller vessels, as tabulated in the Summary for Use.

However, a separate apparatus for the normal requirement has the advantage of greater mechanical dependability over the much larger sizes needed for the combined requirement. Where flash arresters are needed, a further objection arises to large combined units. Efficiently designed arresters, as generally known today, would become huge and expensive, whereas the emergency requirement may be fulfilled separately by merely installing a vaportight hinged cover which may also be used as a manway. (These are available commercially.) If this cover be set to open above 3 in. water pressure, say 2 oz to 4 oz per sq in., no flash arrester would seem needed on this connection. When the emergency valve operated at such pressures, vaporization would already be considerable, and also the vapor would be "too rich to burn," until mixed with external air. Further, flows at 4 oz pressure for compounds having properties of $F = 0.136$ through ordinary vent connections, are of velocities ranging above 25 fps, which is more than the propagation rate of flame in a gas-air mixture at atmospheric pressure.

Modification of the Calculated Relief Areas. The discussion has now progressed so that the suggested reduction of the calculated relief sizes, as shown in Fig. 18, may be clarified.

It will be seen in Fig. 19 that the volatile contents of a 15-ft-diam tank (20,000 gal) may reach 100 F, in a matter of 10 min after being surrounded by intense fire. For this reason, the emergency-vent capacities should be compatible with the 20,000 Btu heat-absorption rate for all tanks from zero through at least 15 ft diam. For tanks above this diameter at these low pressures, the calculated relief areas become rapidly unreasonable (refer to Curve 1, Fig 18), but the likelihood of complete envelopment with fire of sufficient depth (probably about equal to the tank radius) to maintain the heat-input rate, observed in Part 1, becomes less and the time element larger. With these considerations in mind, the suggested vent size (Curve 3, Fig. 18) has been permitted to approach (at 100,000-gal capacity) the curve based on a 6000-Btu heat rate, which curve (the latter) has been gradually flattened to a maximum of 24-in. diam relief size at 300,000 gal capacity. If tanks of this capacity are of 40 to 50 ft diam, as is common, the time element for 100 F is in the neighborhood of

½ hr for severe conditions, which is perhaps sufficient time to employ protective (cooling or extinguishing) equipment reducing the exposure, or abandonment of the vessels.

Conclusion. The conclusions as outlined under *Summary* of this section apply only for the conditions specified.

Equations [20], [21], and [22] are not considered adequate for carbon tetrachloride, are not adequate to vent internal explosion, and are not intended to provide for internal reaction. No reduction in the area of the relief connections is considered for vessels covered with substantial noncombustible insulation, although allowance may be made for this protection in the capacity of the relief devices, which may be changed if the service becomes more severe from the viewpoint of fire exposure, see Proposed Summary for Use.

Equation [23] is not intended to apply to floating-type water-seal gasholders which have, by inherent design, adequate relief for fire exposure.

Suggested sizes of relief connections with necessary capacities for the emergency requirement for atmospheric tanks are given in Table 6 (based on 0.5 psi at 50 gal, proportionally reduced to 3 in. water pressure at 70,000 gal).

TABLE 6 SUGGESTED SIZES OF RELIEF CORRECTIONS FOR EMERGENCY REQUIREMENTS OF ATMOSPHERIC TANKS

Tank capacity, gal	Relief size, in. I.P. size	Minimum capacity, cu ft per hr of air at 60 F. and atmospheric pressure
50	2	13380
50 to 100	3	30100
100 to 300	4	54500
300 to 1000	6	120500
1000 to 2000	8	212000
2000 to 4000	10	326500
4000 to 10000	12	453000
10000 to 20000	16	753000
20000 to 100000	20	1048000
100000 to 200000	22[a]	744000
200000 and up	24	886000

[a] Not a standard pipe size.

Proposed Summary for Use

1 Minimum sizes of relief connections for vessels at pressures not to exceed 1 in. water external, or 0.50 psig internal: All vessels should be provided with relief area (or areas) in the form of connections or hatches. This area should be adequate for both normal breathing and emergency venting generated by exposure to fire.

(*a*) For the normal (based on contraction due to cooling and limited to 1 in. of water internal) requirement for vessels in volatile-liquid service use

$$a = \frac{Q}{1172} \text{ or } d = \sqrt{\frac{Q}{921}} \quad \ldots\ldots\ldots\ldots [1]'''$$

in which a is the relief area in square inches, d is the internal diameter of the relief connection in inches, and

$$Q = \frac{S}{0.290} + \text{emptying rate} \quad \ldots\ldots\ldots\ldots [2]'''$$

In Equation [2]''' Q and the emptying rate are in cubic feet of air per hour at 68 F, and atmospheric pressure, and S is the area of the tank roof and shell in square feet.

(*b*) For the emergency requirement (based on 0.50 psi at 50 gal proportionally reduced to 3 in. water internal pressure at 70,000 gal) for vessels not to exceed 15 ft diam in liquid service use

$$a = \frac{0.717\,S_w}{\sqrt{P(P+14.7)}} \text{ or } d = \sqrt{\frac{0.913\,S_w}{\sqrt{P(P+14.7)}}} \quad \ldots [3]'''$$

If the pressure limit be 3 in. of water as for atmospheric tanks, Equation [3]''' becomes

$$a = 0.566\,S_w \text{ or } d = \sqrt{0.721\,S_w} \quad \ldots\ldots\ldots [4]'''$$

and if the atmospheric tank be vertical cylindrical with bottom resting on pad or foundation, Equation [4]''' becomes

$$a = 1.78DH \text{ or } d = \sqrt{2.265\,DH} \quad \ldots\ldots\ldots [5]'''$$

in all of which a is the internal area and d the internal diameter of the relief connection in inches, S_w is the surface in square feet wetted by the contents when nominally full and exposed to fire, P is the relieving pressure in pounds per square inch gage (0.1083 for 3 in. water), D is the diameter of the tank in feet, and H is the height in feet of the contents on the exposed tank wall when nominally full.

For practical reasons, the emergency-vent sizes for all vessels in liquid service above 15 ft diam and, as calculated by Equations [3]''', [4]''', and [5]''' should be modified to conform to a lowered (below 20,000 Btu per sq ft per hr) heat-absorption rate, as proportionally represented by curve 2, Fig. 14, or curve 3, Fig. 18. The ultimate size should be limited to 24 in. diam.

The vent sizes and relief capacities for the normal and emergency requirements (basis as just given) for vertical, cylindrical, above ground (bottom resting on pad), atmospheric storage tanks are given in Table 7.

TABLE 7 VENTING REQUIREMENTS FOR ATMOSPHERIC STORAGE TANKS EXPOSED TO FIRE

Tank capacity, gal	Relief size (I.P. size) Normal; vent, in.	Relief size (I.P. size) Emergency; cover, in.	Minimum capacity, cu ft air per hr at 60 F and atmospheric pressure: Normal[d] (at 1 in. water flowing pressure)	Minimum capacity, cu ft air per hr at 60 F and atmospheric pressure: Emergency (at 3 in. water flowing pressure)
50	...	2[a]	...	6150
50 to 100	...	3[a]	...	13400
100 to 300	...	4[a]	...	24600
300 to 1000	...	6[a]	...	55400
1000 to 2000	1–1½	1–8	1920	98500
2000 to 4000	1–2	1–10	2805	153800
4000 to 10000	1–2	1–12	3660	221500
10000 to 20000	1–3	1–16	6180	344000
20000 to 50000	1–3	1–20	8230	615500
50000 to 100000	1–4	1–20	12500	615500
100000 to 150000	1–4	1–22[e]	14620	744000
150000 to 200000	1–4, [b] 1–3	1–22[e]	18100	744000
200000 to 400000	1–4, [b] 1–3	1–24	22820	886000
400000 to 800000	1–6	1–24	32900	886000
800000 to 1100000	1–6, 1–3	1–24	41100	886000
1100000 to 1300000	1–6, [c] 1–4	1–24	47500	886000
1300000 to 1800000	1–8	1–24	58450	886000
1800000 to 2000000	2–6	1–24	65800	886000

[a] The first four items of "Emergency relief size" are given in terms of "in. vent," all others in terms of "cover, in."
[b] Although one 6 in. may be cheaper, the two units have the advantage of multiple devices.
[c] Although one 8 in. may be cheaper, the two units have the advantage of multiple devices.
[d] To be used for selection of the normal relief devices. This capacity is included in that for the emergency requirement.
[e] Not a standard pipe size.

(*c*) For the emergency relief requirement for vessels in gas service not to exceed 40 ft diam use

$$a = \frac{0.03195\,S}{\sqrt{P}} \text{ or } d = \sqrt{\frac{0.0407\,S}{\sqrt{P}}} \quad \ldots\ldots\ldots [6]'''$$

in which a is the relief area in square inches, and d is the internal diameter of the relief connection in inches, S is the surface of the tank in square feet which may be exposed including the roof, and P is the relieving pressure in pounds per square inch gage.

Emergency relief connections for vessels in gas service above 40 ft diam should be modified to conform to a lowered heating rate as proportionally represented by curve 5 in Fig. 18, and limited to a maximum of 24 in. diam at 65,000 cu ft capacity.

(*d*) *General.* The relief area should be at least equivalent to

the area of the inlet connection to avoid excessive internal pressure due to accidental overfilling.

In all cases cited, the next larger pipe size should be used as the vent connection, which preferably should be located at the top of the tank vapor space.

No reduction in the size of the relief connection should be made for vessels covered with substantial noncombustible insulation, or provided with reliable cooling systems, although allowance may be made for this protection in the capacity of the relief device. When vessels are so equipped with an adequate relief connection, the relief apparatus may be changed if the service becomes more severe from the standpoint of operation or fire exposure.

2 The relief capacity of the required areas in terms of rate of fluid flow; liquid or gas service: To select a relief device or devices of adequate capacity, based on approved flow test, other than those capacities previously listed for atmospheric tanks, use the area a (not the next larger pipe size), as determined in paragraph 1 in any of the following formulas as the case may require

$$W = 516\,a\sqrt{\frac{MP(P+14.7)}{T}} \text{ or } 405\,d^2\sqrt{\frac{MP(P+14.7)}{T}} \quad [7]'''$$

lb per hr of vapor contents

$$Q = 198{,}500\,a\sqrt{\frac{P(P+14.7)}{MT}} \text{ or } 156{,}000\,d^2\sqrt{\frac{P(P+14.7)}{MT}} \quad \ldots\ldots [8]'''$$

cu ft per hr of vapor at 68 F, and atmospheric pressure

$$Q = 36{,}900\,a\sqrt{\frac{P(P+14.7)}{T}} \text{ or } 29{,}000\,d^2\sqrt{\frac{P(P+14.7)}{T}} \quad \ldots\ldots [9]'''$$

cu ft per hr of air at 68 F, and atmospheric pressure

In all of which a is the internal area in square inches, d is the diameter of the relief area in inches, P is the relieving pressure in pounds per square inch (not to exceed 0.50 lb), M is the molecular weight and T is the vapor temperature of the contents in deg F absolute.

For conditions of fire exposure, T is approximately the normal boiling point of the liquid contents. For vessels in gas service, T is about the temperature necessary to raise the pressure in the vessel from the absolute working pressure and temperature to the absolute set pressure of the relief device, as computed by the gas law, $T/P = T'/P'$.

Allowance may be made in the capacity of the relief device for vessels covered with substantial noncombustible insulation or provided with reliable cooling systems proportional to the reduction effected in the heat-transfer rate through the tank wall, if it is deemed advisable from a practical and economical standpoint.

3 Normal and emergency relief devices: It is preferable, as explained in the section, *Emergency and Normal Relief* that separate relief devices, when needed, be used for the venting requirement for normal operation for all vessels above 1000 gal capacity. The additional relief area required for fire exposure may be in the form of a vaportight hinged cover, hatch, or simple valve, each of which is considered more practical than a weak head seam.

Uncontrolled internal reaction and explosion in vessels of the subject category are emergency relief requirements to which this development does not apply. However, weak seams have been advantageous under such circumstances. The hazard of internal explosion may be minimized by the use of inert gas, grounding the vessel, or provision of flash arresters.

4 If relief capacity is inadequate for the contingency of fire exposure, additional protective features should be provided for the vessel and exposures. These may consist of fire-protective or extinguishment equipment, process-cooling systems, construction of dikes or walls, provision of drains, or fireproofing supports, etc.

5 Back pressure: In this low-pressure range, any back pressure on the downstream side of the relief device will reduce its flow capacity, as calculated by Equations [7]''', [8]''', and [9]''' proportional to the $\sqrt{P\,(P+14.7) - P'\,(P'+14.7)/P(P+14.7)}$ in which P' is the back pressure. Also, the opening pressure of the relief device must be adjusted to counteract the back pressure or the intended maximum pressure in the vessel will be exceeded.

6 Time element: The time required for the liquid contents of a vessel when exposed to fire to reach the boiling point (or any given average temperature) may be estimated by the following formula

$$\theta = \frac{V\rho C_p(T-70)}{IS_w} + \frac{4.87t(T+20)}{I} \quad \ldots\ldots [10]'''$$

in which θ is the time in hours, V is the volume of the contents in cubic feet, ρ is the density of contents in pounds per cubic foot, C_p is the specific heat of contents, T is the temperature reached in deg F, I is the heat-absorption rate in Btu per hour per square foot, and t is the thickness of the steel tank wall in inches. If Equation [10]''' is to apply to vertical, cylindrical, flat-bottom tanks, it becomes

$$\theta = \frac{D\rho C_p(T-70)}{4I} + \frac{4.87\,t(T+20)}{I} \quad \ldots\ldots [11]'''$$

in which D is the diameter of the tank in feet.

If θ is $^1/_2$ hr or more (approximate time for very volatile materials to reach 100 F, when contained in 40 to 50-ft-diam atmospheric tanks surrounded by intense fire) and there is assurance that effective cooling or fire-extinguishing equipment will come into play during the $^1/_2$-hr period, the emergency-relief (device) capacity may be reduced to the vaporization rate produced by the calculated temperature rise within the $^1/_2$ hr. For vessels exposed to fire in gas service, the maximum venting rate will occur within such a short time as to permit no modification of the calculated emergency relief.

Conclusion

The conclusions as outlined under *Summary* in the first of this section of the paper and as detailed under Summary for Use are based upon the foregoing theory which is mathematically expressed in the Appendix of this section.

The formulas proposed provide relief capacities greater than those provided by present average practice which capacities are not adequate for the abnormal condition of fire exposure.

For examples of use of the formulas see the Appendix.

Proposals herein presented hold only for pressures not to exceed 0.50 psig. For vessels to operate at pressures from 0.50 to include 15 psig, Part 4 of this paper will be presented at a later date. For pressures above that refer to Part 2.

Appendix for Part 3

Derivation of General Equations [24] or [3]^{iv}, and [25] or [15]^{iv}

1 Vapor weight rate of a short tube (at pressures not to exceed 0.50 psig), Equation [26]

$$V = C\sqrt{2g\Delta H}$$

$$Va = Ca\sqrt{2g\Delta H}$$

$$Va\rho = Ca\rho\sqrt{2g\Delta H}$$

$$3600Va\rho = 3600Ca\rho\sqrt{2g\Delta H}$$

$$W = 3600Ca\rho\sqrt{2g\Delta H}$$

When differential is pounds per square inch

$$\Delta H = \frac{\Delta P\ 144}{\rho^*}$$

$$\Delta H = \frac{\Delta P \times 10.72 \times T \times 144}{MP^*}$$

$$W = 3600 \times 0.70 \times \frac{0.7854d^2}{144} \times \frac{MP}{10.72T}\sqrt{\frac{64.35 \times \Delta P \times 10.72 \times T \times 144}{MP^*}}$$

$$W = 405\,\frac{d^2\,MP}{T}\sqrt{\frac{\Delta PT}{MP^*}}$$

$$W = 405\,d^2\sqrt{\frac{\Delta PMP}{T}} \quad \ldots\ldots\ldots\ldots [1]^{\text{I-V}}$$

In the development of Equation $[1]^{\text{I-V}}$ the following nomenclature was used:

V = velocity, fps
g = gravitational constant, 32.17
ΔH = differential head in ft of fluid*
C = coefficient of discharge
C = 0.70 when $p_1/p_2 < 1.05$ (see footnote 31)
a = area of short tube, sq ft
ρ = density of fluid, lb per cu ft
ρ = MP/RT for a gas
R = gas constant, 10.72
W = weight rate, lb per hr
M = molecular weight
P = absolute pressure, psi
T = absolute temperature, deg F
ΔP = differential pressure, psi
d = diameter of a short tube, in.

2 Weight rate vaporized

$$\frac{Q}{S_w} = \frac{Wr}{S_w} = I$$

$$W = \frac{IS_w}{r} \quad \ldots\ldots\ldots\ldots [2]^{\text{I-V}}$$

in which

Q = total heat input, Btu per hr
S_w = wetted surface heated, sq ft
r = latent heat of vaporization, Btu per lb
I = unit heat input, Btu per hr per sq ft
W = liquid vaporized, lb per hr

* It is theoretically correct to express the differential head ΔH in terms of the downstream density and so the P in the denominator in downstream pressure. Cancelling this P into the upstream pressure simplifies the equation, avoids confusion, and yet maintains theoretical accuracy within 0.36 per cent at 3 in. water pressure (1.7 per cent at 0.50 lb per sq in. gage). Note the comparison between calculated and actual flows in Fig. 20.

3 Required diameter of a short tube to pass the weight rate vaporized, Equation [24] or $[3]^{\text{I-V}}$:

Equate $[1]^{\text{I-V}}$ to $[2]^{\text{I-V}}$

$$405\,d^2\sqrt{\frac{\Delta PMP}{T}} = \frac{IS_w}{r}$$

$$d^2 = \frac{IS_w}{r \times 405}\sqrt{\frac{T}{M\Delta PP}}$$

$$d = \sqrt{\frac{IS_w}{405\sqrt{\Delta PP}}}\left(\frac{T}{Mr^2}\right)^{1/4} \quad \ldots\ldots [3]^{\text{I-V}} \text{ or } [24]$$

To apply Equation $[3]^{\text{I-V}}$

d = diameter of relief connection, in.
I = 20,000 Btu per sq ft per hr
S_w = wetted surface exposed, sq ft
ΔP = relieving pressure, psig
P = relieving pressure, psia
T = boiling point of contents at P, deg F abs
M = molecular weight of contents
r = latent heat of vaporization at T, Btu per lb

4 Weight rate of expansion or contraction of gas or vapor due to heat transferred to or from the tank wall:

$$wC_p\frac{dT}{d\theta} = \frac{Q}{\theta} \quad \ldots\ldots\ldots\ldots [4]^{\text{I-V}}$$

$$hS\Delta T = \frac{Q}{\theta} \quad \ldots\ldots\ldots\ldots [5]^{\text{I-V}}$$

$$w = V\rho = V\frac{MP}{RT} \quad \ldots\ldots\ldots\ldots [6]^{\text{I-V}}$$

From Equations $[4]^{\text{I-V}}$ and $[6]^{\text{I-V}}$

$$V\rho C_p\frac{dT}{d\theta} = \frac{Q}{\theta} \quad \ldots\ldots\ldots\ldots [7]^{\text{I-V}}$$

$h = F\overline{\Delta T}^{1/4}$ (see Part 1, ref 5)

From Equation $[5]^{\text{I-V}}$

$$F\overline{\Delta T}^{1/4}\,S\Delta T = \frac{Q}{\theta} \quad \ldots\ldots\ldots\ldots [8]^{\text{I-V}}$$

Equate $[7]^{\text{I-V}}$ to $[8]^{\text{I-V}}$

$$V\rho C_p\frac{dT}{d\theta} = FS\overline{\Delta T}^{5/4}$$

$$\frac{dT}{d\theta} = \frac{FS\overline{\Delta T}^{5/4}}{V\rho C_p} \quad \ldots\ldots\ldots\ldots [9]^{\text{I-V}}$$

From Equation $[6]^{\text{I-V}}$

$$dw = \frac{-VMP}{R}\cdot\frac{dT}{T^2} \quad \ldots\ldots\ldots\ldots [10]^{\text{I-V}}$$

$$-dw = \frac{w}{\theta}\cdot d\theta \quad \ldots\ldots\ldots\ldots [11]^{\text{I-V}}$$

Equate $[10]^{\text{I-V}}$ to $[11]^{\text{I-V}}$

$$\frac{VMP}{R}\cdot\frac{dT}{T^2} = \frac{w}{\theta}\cdot d\theta \quad \ldots\ldots\ldots\ldots [12]^{\text{I-V}}$$

$$\frac{dT}{d\theta} = \frac{w}{\theta}\cdot\frac{RT^2}{VMP} \quad \ldots\ldots\ldots\ldots [13]^{\text{I-V}}$$

Equate $[9]^{iv}$ to $[13]^{iv}$

$$\frac{FS\overline{\Delta T}^{5/4}}{V\rho C_p} = \frac{w}{\theta} \cdot \frac{RT^2}{VMP} \quad \ldots\ldots\ldots\ldots [14]^{iv}$$

In the development of Equations $[4]^{iv}$ to $[14]^{iv}$ the following nomenclature was used:

w = weight of contained gas or vapor, lb
C_p = specific heat of gas or vapor
dT = change in temperature
$d\theta$ = change in time
Q = total heat transferred, Btu
θ = time, unit hr
h = heat-transfer coefficient Btu per hr per sq ft per deg F
S = tank surface exposed, sq ft
ΔT = difference between tank wall and contained gas, deg F
V = volume of contents gas or vapor, cu ft
ρ = density of contents gas, lb per cu ft
M = molecular weight of gas or vapor
P = pressure, psia
R = gas constant, 10.72
T = temperature of gas or vapor, deg F abs
F = function of physical properties of gas
dw = change in weight
$W = \frac{w}{\theta}$ = weight rate, lb per hr

5 Required diameter of a short tube to pass the weight rate of a gas expanded or contracted due to heat transferred to or from the tank wall; Equation [25] or $[15]^{iv}$ (same nomenclature used as in section 4 preceding; also $\rho = MP/RT$):

Insert Equation $[1]^{iv}$ in $[14]^{iv}$

$$405\, d^2 \sqrt{\frac{\Delta PMP}{T}} \cdot \frac{RT^2}{VMP} = \frac{FS\overline{\Delta T}^{5/4}}{V\rho C_p}$$

$$d^2 = \frac{FS\overline{\Delta T}^{5/4}}{V\rho C_p} \cdot \frac{VMP}{RT^2\, 405} \sqrt{\frac{T}{\Delta PMP}}$$

$$d^2 = \frac{F}{C_p M^{1/2}} \cdot \frac{S}{405} \cdot \frac{\overline{\Delta T}^{5/4}}{T} \sqrt{\frac{T}{\Delta PP}}$$

$$d = \left(\frac{F}{C_p M^{1/2}}\right)^{1/2} \cdot \frac{S^{1/2}}{\sqrt{405}} \cdot \frac{\overline{\Delta T}^{5/8}}{T^{1/4}} \cdot \frac{1}{\Delta P^{1/4} P^{1/4}}$$

$$d = \frac{0.375 P^{1/4}}{T^{0.783}} \cdot \frac{S^{1/2}}{\sqrt{405}} \cdot \frac{\overline{\Delta T}^{5/8}}{T^{1/4}} \cdot \frac{1}{\Delta P^{1/4} P^{1/4}}$$

$$\left(\text{Refer to the following paragraph for } \frac{0.375\, P^{1/4}}{T^{0.0783}}\right)$$

$$d = 0.0186 \cdot \frac{S^{1/2}}{\Delta P^{1/4}} \cdot \frac{(T_w - T)^{5/8}}{T^{0.325}} \quad \ldots\ldots\ldots [15]^{iv} \text{ or } [25]$$

To apply equation $[15]^{iv}$

d = diameter of relief connection, in.
S = tank surface heated, sq ft
ΔP = relieving pressure, psig
T_w = temperature to which tank wall is heated or cooled, deg F abs
T = initial temperature of contents vapor, deg F abs; if T_w is less than T, reverse the signs

The term $\left(\frac{F}{C_p M^{1/2}}\right)^{1/2}$ in this section, relating the properties of the vapor contents, was replaced by its maximum value $0.375 \cdot \frac{P^{1/4}}{T^{0.0783}}$. This is justified in the following manner: The value of F, a function of the physical properties of a gas, varies with both temperature and pressure as will be seen. The value C_p specific heat at constant pressure varies with temperature. Inasmuch as pressure and temperature are working conditions to remain in the relief diameter Equation $[15]^{iv}$, it is desirable to express the subject variable in terms of P and T. Now

$$F = D\left(\frac{\rho^2 B C_p k^3}{Z}\right)^{1/4} \quad \text{(Part 1, ref. 5, Equation [20], p. 242)}$$

$$\left(\frac{F}{C_p M^{1/2}}\right)^{1/2} = D\left(\frac{\rho^2 B C_p k^3}{C_p{}^4 M^2 Z}\right)^{1/8} = D\left[\rho^2 Z^2 \cdot \frac{B}{M^2}\left(\frac{k^3}{C_p{}^3 Z^3}\right)\right]^{1/8}$$

Since B, M, and the ratio $C_p Z/k$ (Part 1, ref. 5, p. 417) are independent of P and T, we may write

$$\left(\frac{F}{C_p M^{1/2}}\right)^{1/2} = D'(\rho^2 Z^2)^{1/8}$$

and ρ for a gas is MP/RT, then

$$\left(\frac{F}{C_p M^{1/2}}\right)^{1/2} = D'\left(\frac{M^2 P^2}{R^2 T^2} \cdot Z^2\right)^{1/8}$$

Again M and R are independent of P and T, so

$$\left(\frac{F}{C_p M^{1/2}}\right)^{1/2} = D''\left(\frac{P^2}{T^2} \cdot Z^2\right)^{1/8}$$

$$= D''\left(\frac{P^2}{T^2} \cdot T^{1.398}\right)^{1/8}$$

$$= D''\left(\frac{P^2}{T^{0.602}}\right)^{1/8}$$

$$\left(\frac{F}{C_p M^{1/2}}\right)^{1/2} = D''\left(\frac{P^{1/4}}{T^{0.0753}}\right)$$

When $P = 14.7$ psia, and $T = 528$ deg R, $C_p = 0.24$, and $F = 0.27$ for air

$$\therefore D'' = \left(\frac{0.27}{0.24 \times 29^{1/2}}\right)^{1/2} \times \frac{(528)^{0.0753}}{14.7^{1/4}}$$

$D'' = 0.375$ and $\left(\frac{F}{C_p M^{1/2}}\right)^{1/2} = 0.375\, \frac{P^{1/4}}{T^{0.0753}}$

The nomenclature used in the foregoing derivations follows:

F = 0.27 for air at 68 F, and atmospheric pressure
D = proportionality constant
k = thermal conductivity
C_p = specific heat
ρ = density
B = coefficient of thermal expansion
Z = viscosity
M = molecular weight
R = gas constant

Z^2 varies with T for air as follows:

T, deg R	Z	Z^2
460	0.0162	0.000262
528	0.018	0.000323
660	0.021	0.000440
860	0.025	0.000625
1060	0.029	0.000840
1260	0.032	0.001050
1460	0.036	0.001295
1560	0.038	0.001444

$$\left(\frac{1560}{460}\right)^n = (3.39)^n = \frac{1.444}{0.2625} = 5.50$$

$$n = 1.398$$

TABLE 8 VALUES OF F FOR SEVERAL GASES

Gas	k[a]	C_p[a]	Z[a]	M[a]	$\frac{k^3C_pM^3}{Z}$	$\left(\frac{k^3C_pM^3}{Z}\right)^{1/4}$	F	$\frac{F}{C_pM^{1/2}}$
Air	0 0161	0.24	0.018	29	0.0468	0.465	0 270	0.209

[a] "Heat Transmission," by W. H. McAdams,[1] various pages.

Now it is also necessary to show that $\left(\frac{F}{C_pM^{1/2}}\right)^{1/2}$ gives higher values for air than for any other gases whose properties were available in the reference literature. To do this, we use McAdam's Equation [20][14] again which is

$$F = D\left(\frac{\rho^2BC_pk^3}{Z}\right)^{1/4}$$

and in which the nomenclature is as before. Again, $\rho = MP/RT$ and $B = 1/492$. Then, at a constant pressure and temperature it would be expected that F would vary for different gases as follows.

$$F = D'\left(\frac{M^2C_pk^3}{Z}\right)^{1/4}$$

At 1 atm pressure and 20 C, $F = 0.27$ and $\left(\frac{M^2C_pk^3}{Z}\right)^{1/4} = 0.465$ for air, so that the F value for any other gas, whose molecular weight, specific heat, thermal conductivity, and viscosity are known, may be determined from the relation.

$$F_g = \frac{0.27}{0.465}\left(\frac{k^3C_pM^3}{Z}\right)_g^{1/4}$$

in which the subscript g applies to the gas other than air. On this basis the F value for a number of representative gases has been calculated as shown in Table 8. It will be noted that the value of $\left(\frac{F}{C_pM^{1/2}}\right)^{1/2}$ for air is greater than for any of those so obtained, and for many others such as ammonia, nitrogen, and oxygen whose properties were considered but not listed in the table.

Simplification of General Expressions to Formulas For Use

1 The diameter of a short tube to limit internal pressure (not to exceed 0.50 psig) within vessels when the volatile-liquid contents are absorbing heat at 20,000 Btu per sq ft per hr of wetted surface exposed, Equations [20], [21], and [22], is derived as follows, the nomenclature being the same as used previously

$$d = \sqrt{\frac{IS_w}{405\sqrt{\Delta PP}}}\left(\frac{T}{Mr^2}\right)^{1/4} \quad \ldots\ldots [3]^{1/2} \text{ or } [24]$$

in which $\left(\frac{T}{Mr^2}\right)^{1/4}$ = contents factor, evaluated from Fig. 12, Part 2.

$$d = \sqrt{\frac{20{,}000\,S_w}{405\sqrt{P(P+14.7)}}} \times 0.136$$

$$d = \sqrt{\frac{0.913S_w}{\sqrt{P(P+14.7)}}} \quad \ldots\ldots [16]^{1/2}$$

If P be 3 in. water, 0.1083 lb

$$d = \sqrt{\frac{0.913S_w}{\sqrt{0.1083 \times 14.8083}}} = \sqrt{0.721S_w} \ldots\ldots [17]^{1/2}$$

If the tank be vertical cylindrical with bottom on pad

$$d = \sqrt{0.721\pi DH} = \sqrt{2.265DH} \ldots\ldots [18]^{1/2}$$

2 The diameter of a short tube to limit internal pressure to a specified maximum (not to exceed 0.50 psig) within vessels when the vapor contents absorb heat from the enclosing shell heated to 1100 F, Equation [23], is derived as follows, the nomenclature being the same as previously used:

$$d = 0.0186\,\frac{S^{1/2}}{\Delta P^{1/4}} \cdot \frac{(T_w - T)^{5/8}}{T^{0.325}} \ldots [15]^{1/2} \text{ or } [25]$$

in which $\frac{(T_w - T)^{5/8}}{T^{0.325}}$ = gas expansion variable. Then substituting the following values:

$T_w = 1100 + 460 = 1560$ deg F abs

$T = 0 + 460 = 460$ deg F abs

$(T_w - T)^{5/8} = 79.5$

$T^{0.325} = 7.33$

$(T_w - T)^{5/8}/T^{0.325} = 10.85$

$$d = 0.0186 \times \frac{S^{1/2}}{\Delta P^{1/4}} \times 10.85$$

$$d = \sqrt{\frac{0\,0407\,S}{\sqrt{P}}} \ldots\ldots [19]^{1/2}$$

when P is gage pressure.

3 The diameter of a short tube to limit external pressure on a tank to 1 in. of water when the vapor contents are contracted from the loss of heat to a colder tank wall, Equations [16], [17], [18], and [19], is derived as follows, the nomenclature being the same as previously used.

The weight rate of contraction is

$$W = \frac{FS\Delta T^{5/4}}{V\rho C_p}\,\frac{VMP}{RT^2} \ldots\ldots [14]^{1/2}$$

$$Q = \frac{FS\Delta T^{5/4}}{C_p} \cdot \frac{MP}{RT^2} \cdot \frac{R^2T^2}{M^2P^2}$$

$$Q = \frac{10.72\,FS(T - T_w)^{5/4}}{C_pMP} \text{ cu ft per hr}$$

in which

[14] Part 1, ref. 5, equation [20], p. 242.

$$\frac{\text{Weight rate, } W}{\text{Unit weight, } \rho} = \text{quantity rate, } Q$$

$$\rho = MP/RT$$

Applying the temperatures from Case 1, Table 4, and the properties of air

$$Q = \frac{10.72 \times 0.27 \times S(563 - 516)^{5/4}}{0.24 \times 29 \times 14.736}$$

(14.736 = average pressure during contraction)

$$Q = S/0.291 \text{ cu ft per hr} \ldots\ldots\ldots\ldots [20]^{\text{IV}}$$

When Equation $[20]^{\text{IV}}$ is used, the emptying rate must be added to provide for maximum in-breathing.

The weight rate of a relief connection (nomenclature as previously used) is

$$W = 405\, d^2 \sqrt{\frac{\Delta PMP}{T}} \ldots\ldots\ldots\ldots [1]^{\text{IV}}$$

$$Q = 405\, d^2 \sqrt{\frac{\Delta PMP}{T}} \cdot \frac{RT}{MP}$$

again $Q = \dfrac{W}{\rho}$

$$Q = 4340\, d^2 \sqrt{\frac{\Delta PT}{MP}} \text{ cu ft per hr} \ldots\ldots\ldots [21]^{\text{IV}}$$

(see Fig. 20).

Then the quantity rate of air at 68 F is

$$Q = 4340\, d^2 \sqrt{\frac{0.0361 \times 528}{29 \times 14.736^*}} = 918\, d^2 \text{ at 1 in. water pressure}$$

$$d = \sqrt{\frac{Q \times 14.7}{918 \times 14.736}} = \sqrt{Q/921} \text{ at atmospheric pressure } [22]^{\text{IV}}$$

Applying the surface from Case 1, Table 4, to Equations $[20]^{\text{IV}}$ and $[22]^{\text{IV}}$

$$Q = S/0.290 = 5170/0.290 = 17{,}830 \text{ cu ft of air}$$

$$d = \sqrt{Q/921} = \sqrt{17{,}830/921} = 4.40 \text{ in.}$$

Check by applying Equation $[15]^{\text{IV}}$ to Case 1, Table 4

$$d = 0.0186 \times \frac{S^{1/2}}{\Delta P^{1/4}} \times \frac{(T - T_w)^{5/8}}{T^{0.325}} \ldots\ldots [15]^{\text{IV}}$$

the following values being used:

$$S^{1/2} = \sqrt{5170} = 71.9$$

$$\Delta P^{1/4} = \sqrt[4]{0.0361} = 0.436$$

$$T^{0.325} = (563)^{0.325} = 7.82$$

$$T_w = 516 \text{ F abs}$$

$$(T - T_w)^{5/8} = (47)^{5/8} = 11.1$$

$$(T - T_w)^{5/8}/T^{0.325} = 1.425$$

then

$$d = \frac{0.0186 \times 71.9 \times 1.425}{0.436}$$

$$d = 4.37 \text{ in.}$$

A discrepancy exists of 3 parts in 438.5 between results by Equations $[15]^{\text{IV}}$ and $[22]^{\text{IV}}$. This is considered due to the average temperature difference between the tank vapor and external air during in-breathing for which Equation $[15]^{\text{IV}}$ does not provide.

4 The capacity of the relief areas in terms of fluid flow, Equations [26], [27], [28], [7]‴, [8]‴, and [9]‴.

The weight rate of vapor flow of a short tube is

$$W = 405\, d^2 \sqrt{\frac{MP(P + 14.7)}{T}} \text{ lb per hr} \ldots\ldots [1]^{\text{IV}}$$

The quantity rate is

$$Q = \frac{W \times 10.72 \times 528}{M \times 14.7}$$

where

$$Q = W/\rho$$

$$\rho = MP/RT$$

$$\rho = M\ (14.7)/10.72\ (528)$$

$$Q = 156{,}000\, d^2 \sqrt{\frac{P(P + 14.7)}{MT}} \ldots\ldots [23]^{\text{IV}}$$

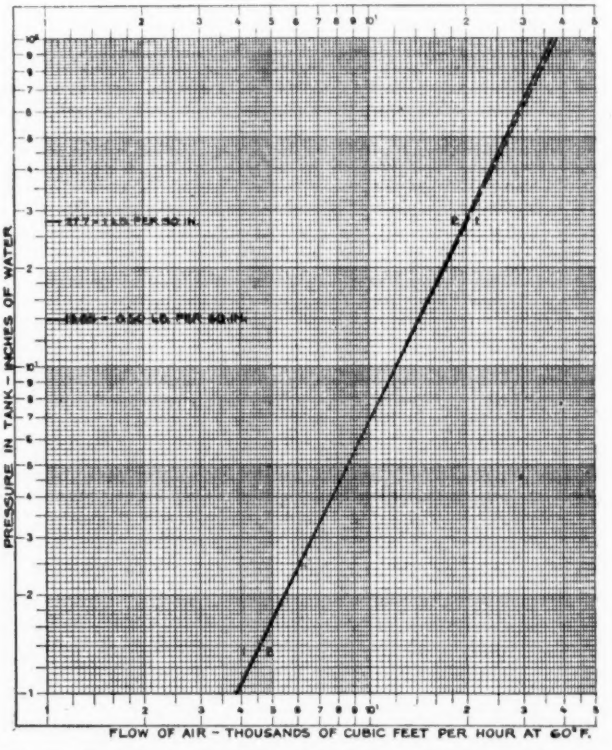

FIG. 20 COMPARISON OF THEORETICAL FLOW CAPACITY OF SHORT TUBE WITH THAT OF TYPICAL TANK CONNECTION AT LOW PRESSURES

NOTES: 1 Actual flows through a calibrated orifice to the tank.

2 Theoretical flow capacity equation $Q = 4340\, d^2 \sqrt{\dfrac{\Delta PT}{MP}}$ (coefficient of flow 0.70).

Refer to Part 3, "Relief of Vessels Exposed to Fire."

Capacity of a standard 2-in. nipple 6 in. long located in top head of 4 ft diameter by 5 ft high vertical cylindrical tank with inlet in lower shell. Actual flows were 99 per cent of theoretical at 1 in. water pressure.

* Actually, the external pressure during contraction cannot rise above 14.7 lb per sq in. absolute. Flows computed using 14.736 as P are within the accuracy illustrated by Fig. 20. Use of the P (14.736) is more than compensated for by using $Q = S/0.290$ instead of $S/0.291$.

cu ft per hr at 68 F and atmospheric pressure

The quantity rate of air is

$$Q = 156{,}000\, d^2 \sqrt{\frac{P(P + 14.7)}{29\, T}}$$

$$Q = 29{,}000\, d^2 \sqrt{\frac{P(P + 14.7)}{T}} \quad \text{.....[24]}^{\text{IV}}$$

cu ft per hr at 68 F and atmospheric pressure

At a flowing temperature of 104 F such as for compounds of $F = 0.136$

$$Q = 29{,}000\, d^2 \sqrt{\frac{P(P + 14.7)}{564}}$$

$$Q = 1222\, d^2 \sqrt{P(P + 14.7)} \quad \text{.....[25]}^{\text{IV}}$$

cu ft air per hr at 68 F and atmospheric pressure

When $P = 0.1083$ lb, 3 in. water

$$Q = 1550\, d^2 = 1972a \quad \text{.....[26]}^{\text{IV}}$$

cu ft air per hr at 68 F and atmospheric pressure

Derivation of Time-Element Formulas

1 Estimated time for the liquid contents of a vessel to reach a given temperature, Equations [29] and [30]

IS_w = total heat input, Btu per hr

$\frac{V\rho C_p \Delta T}{\theta}$ = heat absorbed by liquid contents, Btu per unit time

$\frac{St\rho C_p \Delta T}{12\,\theta}$ = heat absorbed by tank, Btu per unit time

$$IS_w = \frac{V\rho C_p (T - 70)}{\theta} + \frac{St\, 487 \times 0.12\, (T + 20)}{12\,\theta}$$

$$(S_w \leq 0.85\, S)$$

$$\theta = \frac{V\rho C_p\, (T - 70)}{IS_w} + \frac{4.87\, t(T + 20)}{I} \quad \text{.....[27]}^{\text{IV}}$$

(Liquid contents of an average temperature of 70 F and tank steel of an average of 60 F before exposure. Tank shell after heating of an average of 100 F hotter than liquid, although this will vary with the contents.)

If tank is vertical cylindrical with bottom on pad, $S_w = \pi DH$

$$\theta = \frac{D\rho C_p (T - 70)}{4\, I} + \frac{4.87\, t\,(T + 20)}{I} \quad \text{.....[28]}^{\text{IV}}$$

in which

I = heat absorption rate, Btu per sq ft per hr
S_w = surface wetted by contents exposed to fire, sq ft
V = volume of liquid contents, cu ft
ρ = density, lb per cu ft (487 for steel)
C_p = specific heat, 0.12 for steel
ΔT = temperature difference, deg F
θ = time, hr
S = surface of vessel heated, sq ft
t = thickness of tank shell in inches
T = temperature of contents, deg F
D = diameter of vessel, ft
H = height of contents on exposed wall, ft

2 Estimated time for an empty steel tank to reach the "critical" temperature of 1100 F, Equation [31], the foregoing nomenclature being used

$$IS_w = \frac{St}{12} \times \frac{487 \times 0.12\, (T - 50)}{\theta}$$

$$I = \frac{4.87\, t(1100 - 50)}{\theta}$$

$$\theta = \frac{5114\, t}{0.8\, I} = 0.320\, t \quad \text{.....[29]}^{\text{IV}}$$

(During the period of heating to 1100 F, the input I will be only about 80 per cent effective due principally to reradiation losses.)

Examples of Use of the Formulas

1 Assume an acetone tank (110,000 gal nominal capacity) 30 ft diam by 24 ft high, cylindrical shell with umbrella-type roof and flat bottom. The relief devices are to operate at 1 in. water external and 0.50 psi internal pressure.

(*a*) The normal breathing requirement (based on in-breathing) was determined as explained and tabulated in the Summary for Use in this section of the paper. This was done as follows

$Q = (S/0.290)$ + emptying rate ..... [2]'''

$Q = (3013/0.290) + 300$ gal per min
$Q = 10{,}400 + 2408$ cu ft per hr
$Q = 12{,}808$ cu ft air per hr at 68 F

$$Q = 12{,}808 \sqrt{\frac{520}{528}} = 12{,}710 \text{ at } 60 \text{ F}$$

$d = \sqrt{Q/921}$ .....[1]'''

$d = \sqrt{12{,}808/921} = 3.73$ in. (specify 4-in. standard I.P. size)

In this

$S = \pi D(H + 0.266D)$
H = height of straight shell
$S = \pi\, 30\, (24 + 0.266 \times 30)$
$S = 3013$ sq ft

The 4-in. size indicated is that recommended for this tank since it may be used at atmospheric pressure. However, the requirement may be figured more exactly (provide for the difference between 3 in. water and 0.50 psi internal pressure) as follows:

$$Q = \frac{S}{0.291 \times \frac{14.932}{14.736}} = S/0.295$$

See Equation [20]IV

$Q = (3013/0.295) + 2408$
$Q = 12{,}623$ cu ft air per hr at 68 F
$d = \sqrt{Q/921}$ ..... [1]'''
$d = \sqrt{12{,}623/921} = 3.70$ in. (use 4 in. as before)

(*b*) The emergency vent size at 3 in. water pressure is also tabulated in the Summary for Use of this section of this paper and is that recommended. Considerations involved in its selection are as follows

$$d = \sqrt{\frac{0.913 S_w}{\sqrt{P(P + 14.7)}}} \quad \text{.....[3]}'''$$

$$d = \sqrt{\frac{0.913 \times 2260}{\sqrt{0.50(15.2)}}} = 27.37 \text{ in.}$$

where

$S = \pi\, DH$
$S = \pi \times 30 \times 24$
$S = 2260$ sq ft

This is seen to be larger than the 24 in. maximum diam recommended (based on the lengthened time element and lessened pos-

sibilities of completely effective total heat absorption) for any vessel. It incorporates the observed 20,000 Btu per sq ft per hr heat-absorption rate.

The size (22 in.) recommended was based on a modified rate at 3 in. water pressure which rate may be obtained as follows

$$d = \sqrt{\frac{IS_w}{405\sqrt{P(P+14.7)}}}\left(\frac{T}{Mr^2}\right)^{1/4} \quad \ldots\ldots [24]$$

$$\sqrt{484} = \sqrt{\frac{I \times 2260}{405\sqrt{0.1083(14.808)}}} \times 0.136$$

$$I = \frac{484 \times 405 \times 1.268}{2260 \times 0.0185} = 5{,}950 \text{ Btu}$$

On the same modified rate basis, d for 0.50 psi relief pressure would become

$$d = 27.37\sqrt{\frac{5950}{20{,}000}} = 14.92 \text{ in.}$$

If this is used and the tank becomes involved with fire, the possibilities of rupture are greater.

If the recommended 22 in. be provided, the designed heat-absorption rate at 0.50-psi relief pressure is

$$I = 5950\sqrt{\frac{0.50(15.2)}{0.1083(14.808)}} = 12{,}950 \text{ Btu per sq ft per hr}$$

The relief capacity of the 22-in. connection at 3 in. water flowing pressure is

$$Q = 1222\, d^2\sqrt{P(P+14.7)} \quad \ldots\ldots [25]^{IV}$$

$$Q = 1222 \times 484\sqrt{0.1083 \times 14.808}$$

Q = 750,000 cu ft of free air per hr at 68 F (based on 104 F flowing temperature)

Compared with acetone vapor

$$Q = 4340\, d^2\sqrt{\frac{\Delta PT}{MP}} \quad \ldots\ldots [19]$$

$$Q = 4340 \times 484\sqrt{\frac{0.1083 \times 593}{58 \times 14.808}}$$

Q = 575,000 cu ft of acetone per hr at 3 in. water and 133 F

$$Q = 575{,}000\sqrt{\frac{528 \times 14.808}{593 \times 14.7}} = 544{,}000 \text{ cu ft of free vapor per hr at 68 F}$$

(*c*) Estimated time required to reach the boiling point at the observed (20,000 Btu) heat-absorption rate is

$$\theta = \frac{D\rho C_p(T-70)}{4I} + \frac{4.87\, l(T+20)}{I} \quad \ldots\ldots [11]'''$$

$$\theta = \frac{30 \times 49.5 \times 0.51(133-70)}{4 \times 20{,}000} + \frac{4.87 \times 0.375(133+20)}{20{,}000}$$

$$\theta = 0.5965 + 0.0140$$

$$\theta = 0.6105 \text{ hr} = 36.6 \text{ min}$$

2 Assume that the same vessel has been emptied and is then surrounded with intense fire:

(*a*) The shell metal would reach 1100 F in about

$$\theta = 0.320\, t = 0.320 \times 0.375 \quad \ldots\ldots [31]$$

$$\theta = 0.12 \text{ hr} = 7.2 \text{ min}$$

(*b*) After the heating period, the required size of vent to discharge the expanding vapor at 3 in. water pressure would be

$$d = \sqrt{\frac{0.0407\, S}{\sqrt{P}}} \quad \ldots\ldots [6]'''$$

in which

S = 3013 sq ft

$$d = \sqrt{\frac{0.0407 \times 3013}{\sqrt{0.1083}}} = 19.3 \text{ in.}$$

The necessary capacity of the relief device would be

$$Q = 1550\, d^2 \quad \ldots\ldots [26]^{IV}$$

Q = 578,000 cu ft of free air per hr at 68 F

Q = 9620 cu ft of free air per min at 68 F

Discussion

T. A. Gadwa.[35] The proposed constant heat-input rate of 20,000 Btu per sq ft per hr is considerably higher than the "Wartime Recommendations of Safety Valve Standardization Conference," which also considers a variable rate, depending upon the total surface of the vessel. The concept of wetted surface is a logical basis for calculation of exposed surface. Since the heat rate and wetted surface are the major factors affecting the relief-valve size, it would be desirable to have the conference review their recommendations with respect to these latest data.

The suggestion in the paper of considering the relief-valve connection as a short tube orifice is questionable. In order to obtain a 0.97 coefficient, a tapered nozzle is necessary, so that the inlet connection is always larger than the orifice, and both are established by the manufacturer. It is important always to connect the relief valve directly to a nozzle on the vessel rather than by means of a length of pipe, otherwise the pressure drop in the line will limit the capacity of the safety valve.

It is interesting to note that the code equation does not hold for pressures below approximately 15 psig and a different equation is necessary. When a relief valve operates at sufficiently high pressure, application of the gas-law deviation factor to the gas density will reduce the required orifice area. The code equation does not include this factor, although its use is suggested by the conference. Here again, possibly as a wartime measure, the API-ASME code could be revised to include the gas-deviation factor.

The heat rate for a vessel with insulation would be very useful since most fractionating towers would be in this category. Inasmuch as the recommended procedure requires orifice sizes larger than present methods, the question of whether test conditions duplicate the actual conditions must be considered before revisions are in order.

A. B. Guise.[36] The writer was especially interested in Part 1 of this paper, Observed Rate of Heat Absorption, because this is not only the key to the entire problem of adequate relief vents, but the subject of greatest controversy. When a member of the Flammable Liquid Committee of the NFPA, the writer became interested in the derivation of the tables of emergency-relief vents for tanks of various sizes and examined into the origins of these tables. As the authors mentioned, it was found that the only heat-absorption rate given was that of 6000 Btu per sq ft per hr, which applied only to large vertical tanks. In the course

[35] The Lummus Company, New York, N. Y.

[36] Vice-President, in Charge of Development, DuGas Engineering Corporation, Marinette, Wis.

of this committee's work, information was obtained from the Standard Oil Company of New Jersey on exposure fires around 1000-gal tanks in which heat-absorption rates of 24,000 Btu per sq ft per hr were obtained. These tests were not mentioned in the paper, so the assumption is that the authors were unaware of them. However, the figures check excellently with those found in the tests described in the paper.

Subsequently, the writer became curious as to the accuracy of the emergency-relief-vent tables when applied to pure compounds, such as benzol, alcohol, and acetone, and derived an equation similar to Equation [9] of the paper. However, simplification of this equation was never undertaken by the use a "contents factor," with which the authors have done such an excellent job of making this equation more readily usable.

It is noted that the vessels are assumed to be 90 per cent full of material when exposed to fire. In the writer's calculations, the same assumption was made, and he agrees thoroughly that this is the best condition to use for computations.

All of us who have struggled under the necessity of using our "best judgment," in place of the authoritative information and thoroughgoing analysis of the subject as given in this paper, will be pleased to have a logical basis upon which the fire protection engineer can attack his problems.

About 2 years ago such information would have been invaluable to the writer, when he was informed that a certain organization recommended the use of 3000 Btu per sq ft per hr as the heat input to a 38-ft-diam butadiene sphere. In his calculations, the value 12,000 Btu per sq ft per hr was used and fortunately his advice was followed in this case.

F. L. MAKER.[37] The authors have evidently done a very great amount of work in preparing this paper. Usually the results of so much labor should entitle the authors to some amount of grateful commendation from those whose future labors would be eased by the presentation of fundamentals completely worked out. In this case, however, it would appear that they brought most of the work on themselves by the fact that an essentially simple problem has been unbelievably complicated. The resulting recommendations, which do not necessarily follow from the facts presented, are in a form that is unsatisfactory from several points of view.

Time has not permitted preparation of a complete discussion of the entire paper, and the following remarks are concerned with the first two parts of the paper only, i.e., relief for vessels under pressure over 15 psi.

The test data presented in the first part include a description of tests run by Fetterly, the Underwriters Laboratory, by the Aluminum Company of America, and by the authors, in regard to maximum rates of heat absorption. As conclusions from these results, the authors recommend that the heat-absorption rate of 20,000 Btu per sq ft of wetted surface be adopted as the criterion for determining the relief capacity.

The authors recognize that this heat-absorption rate appears high when compared to over-all absorption rates on boilers and tube stills and point out that much higher rates are experienced in combustion chambers of radiant absorption sections of boilers. They are correct in regard to the much higher radiant-absorption rates in boilers; and even in oil stills rates in excess of 20,000 Btu per sq ft per hr on the surface most directly exposed to the fire are not uncommon. A point that was overlooked is that in oil stills the absorbing surface is deliberately arranged to limit the maximum heat-absorption rate to avoid coking or overheating of the oil on the inside of the tubes.

That such rates of heat absorption are possible is not new. The authors make reference to the Liquefied Petroleum Gas Safety Orders of the California Industrial Accident Commission. These were prepared about 9 or 10 years ago, and the writer suggested the particular form of the provision for safety valves that was adopted. A memorandum discussing the particular provision was presented at the time. This included the following:

"One of the most common emergency situations, particularly in the oil industry, is concerned with the possible exposure of a volatile fluid to fire. Tanks containing gasoline, casing head gasoline, butane, etc., may develop rather high vapor pressures at fairly moderate temperatures. In the case of a fire surrounding the vessels, which may occur due to breakage of lines, or perhaps from broken connections or leaks in the container itself, heat may be absorbed through the walls of the container that will cause vaporization of the volatile contents. In order to determine what amounts of vaporization might have to be taken care of, tests were run by the General Engineering Department of the Standard Oil Company of California some years ago (about 1925), in which a horizontal tank of water was surrounded by a fire in a pool of gasoline inside a dike and the quantity of vapor generated was measured. Heat-absorption rates were found as high as 25,000 Btu per sq ft of wetted surface; the tank being approximately half full of water."

The authors' 20,000 Btu per sq ft per hr would not be out of line for vessels completely exposed to fire. However, it does not appear reasonable to apply this same rate in all situations. The tests cited by the authors were in some cases run under conditions where the tank was pretty well enclosed. This condition might easily occur in a building, and for such cases the suggested rate would appear reasonable. The authors are apparently also interested primarily in vertical tanks. Most of the storage of products of high volatility in refinery and natural-gasoline processing plants, where the storage is within the plot limits of the plant, is usually in long horizontal tanks, running from 6 to 14 ft in diam, and lengths up to 100 ft. For such tanks the probability of the entire surface being exposed to maximum heat-absorption rates is small, particularly where they are installed in the open air and not inside of a building. Consequently, some deduction in average heat-absorption rate would appear to be reasonable. The suggestion made in connection with the California Liquefied Petroleum Gas Safety Orders was based on the following:

"For small containers, which are much more likely to be surrounded by fire, this maximum rate would probably be used as a basis for relief capacity. For larger containers it is unlikely that the entire surface will be surrounded by fire, so that lower rates appear reasonable. For butane tanks of sizes in the neighborhood of 1000 gallons capacity a rate of 20,000 Btu per sq ft per hour on 60 per cent of the total area of the tank (equivalent to 12,000 Btu per sq ft per hour on the entire surface of the tank) has been proposed. On very large tanks, and on those in which exposure on the entire tank might appear impossible, smaller rates yet may be used. In the case of butane tanks installed away from a source of fuel, except for a leak in piping, a rate of 25 per cent of the foregoing amounts was recommended. This amounts to 3000 Btu on the entire surface of the tank. D. V. Stroop, secretary of the API Fire Protection Committee, has proposed a somewhat similar condition in the form of a curve, which when plotted on logarithmic paper became almost a straight line. Making the substitution of a straight line leads to a formula of the following form

$$\frac{Q}{A} = \frac{48{,}000}{A^{1/4}}$$

where

Q = total amount of heat absorbed by vessel per hour
A = total area of vessel

[37] Designing Engineer for Refinery Plants, Standard Oil Company of California, San Francisco, Calif. Mem. A.S.M.E.

"The total heat absorbed by the vessel is therefore
$Q = 48{,}000\ A^{1}/_{1}$ Btu per hr"

This formula is admittedly arbitrary. On the other hand, it would appear more reasonable for large storage vessels than using the same rate of heat absorption regardless of size. If the vessel is so enclosed that it is possible for it to be entirely surrounded by fire, which implies a limited size, the use of a maximum absorption rate of 20,000 Btu per sq ft does not appear unreasonable.

In the case of the California Liquefied Gas Safety Orders, the formula was further simplified, because only two commercial products, namely, commercial butane and propane fuel, were being considered, and the corresponding pressure conditions for vessels constructed under the safety order were limited.

From this point on, the paper becomes more difficult to follow. The objective of the authors is not quite clear, nor is it clear just what provision they are finally recommending. They suggest that their recommendations be embodied in official codes. Before this could be done, however, the presentation would have to be considerably simplified and clarified, and the various suggestions involved separated, so that they could be evaluated on their own merits.

After considerable study of the text and the derivation of formulas in the Appendix to Part 2, it appears that what the authors are proposing is to determine the size of a nozzle to put on a vessel. They also seem to be concerned with the fact that after a pressure vessel is built, it is frequently found later to contain other than the product it was originally designed for, and they apparently have in mind that the so-called, "contents factor F," will in some way give them a nozzle that would be large enough for a number of different products.

In addition they superpose a further suggestion that these nozzles be designed in sizes only for a limited number of pressures, namely, 15, 60, 150, 250, and 500 psi.

The entire problem involved would appear to be much simpler than the amount of mathematics presented in this paper seems to indicate. It seems to involve only the following steps:

1 Determine the amount of heat absorption to be provided for.

2 Determine the maximum pressure at which the discharge through the emergency relief device is to be computed, and the corresponding temperature.

3 Determine, for the particular product concerned, the number of pounds per hour that would be vaporized for this total heat absorption.

4 Choose a suitable emergency-relief device having a capacity sufficient to discharge the amount of vapor thus computed.

There is no advantage in attempting to accumulate all these steps into one all-embracing formula, and particularly to do this only for a limited number of pressure ranges. Rather, such an over-all formula tends to hide the results of the individual steps and renders any check of their reasonableness difficult.

In regard to the total amount of heat to be absorbed, the rate of 20,000 Btu per sq ft per hr on a wetted surface appears reasonable for small containers that can be entirely surrounded by flame, or even for fairly large vertical containers that may be so enclosed that they are likely to be entirely surrounded by flame in case of fire. For containers installed outdoors, some reduction is reasonable to take care of the unlikelihood of an entire vessel of large size being surrounded by an intense fire. The relation previously given, as used by the API, appears reasonable. It is admittedly arbitrary and might be improved upon. It is, however, convenient to use, it is qualitatively in the right direction, and in view of lack of evidence to the contrary, it is suggested that it continue to be used.

The next step is to determine the pressure at which the relief should be computed. This, of course, depends indirectly upon the product concerned, in that the pressure vessels presumably are made strong enough to hold the contents under normal conditions, with some leeway above the vapor pressure that would be reached in normal operation to prevent frequent poppings. Actually the vessel will be stronger than required to maintain the product at the vapor pressure corresponding to its normal temperature. The vessel will usually have some additional thickness, due to the use of commercial thicknesses of plate, and while relatively new, to the provision of some corrosion allowances. In the case of vessels for fluids of low vapor pressures, such as less than 50 psi at ordinary operating temperature, it will generally be found that the minimum thickness for which it is desirable to make the vessel will give a safe working pressure that may be considerably higher than the normal vapor pressure of the contents. In this case economy will be achieved by taking advantage of the maximum working pressure of the vessel and designing the emergency relief for this pressure. The corresponding temperature can be obtained from a vapor pressure-temperature curve of the product, which will either be available or can be approximated by general rules, such as a line drawn on a Cox chart from a given boiling point at atmospheric pressure. A safety valve should be set at this maximum allowable pressure, and if this is the only provision for emergency relief, its capacity should be computed on the basis of whatever "accumulation" or increase above the initial popping pressure is permissible for the maximum discharge rate. The A.S.M.E. Unfired Pressure Vessel Code allows 10 per cent accumulation. However, it should not be overlooked that the emergency condition being provided for is hoped to be very unusual, and that there appears no good reason why a maximum accumulation up to the pressure at which the vessel has been hydrostatically tested (generally at least 50 per cent above the design pressure) should not be permitted. Even above this pressure the safety factor of the vessel provides further leeway before the vessel might be expected to explode.

If a safety valve is provided of such size that it can take care of only normally expected conditions, further emergency fire relief can be provided by some form of bursting disk. Bursting disks have the disadvantage, however, that they cannot be designed to have bursting pressures very close to the normal operating pressures and have a reasonable life. A bursting disk that will burst at a pressure twice or 1.5 times the normal maximum pressure can be expected, however, to have a reasonable life. If the normal operating pressure is close to the design pressure of the vessel, it is suggested that bursting disks added for emergency fire exposure, in addition to a safety valve set at the design pressure, be arranged to have their bursting pressure at 150 per cent of the design pressure of the vessel.

For bursting disks, which are relatively cheap compared to safety valves, it is usually simple to provide plenty of capacity.

The purpose of the "contents factor F," used the the authors, is not at all clear. Partly, it seems to be introduced in order to reduce the determination of relief provision size to a single formula. The advantage of this is doubtful, as it succeeds admirably in hiding the reasonableness of each step in the process. Partly also, an impression is gathered that the authors proposed this factor because of some doubt that data on latent heat of vaporization would be readily available, and that by use of Fig. 12 it would be easier to guess the value of the "contents factor F" than it would be to guess the latent heat of vaporization. It is much more accurate to estimate the value of the latent heat than to choose the correct value of the more complicated value F.

Time has not permitted checking the curves of Fig. 12 to see what provision the authors have included for variation of the

latent heat of vaporization with temperature, nor is any table given showing how the various points were computed. This is one of the disadvantages of the use of an all-embracing formula, in that there is no ready way of checking the reasonableness of an important value used in the formula. The authors mention the use of Trouton's rule. Actually a curve based on Hildebrand's rule, that covers vaporization at other than atmospheric boiling points, should be used. Such a chart has been published.[38]

With the heat absorption, the discharge pressure, the temperature, and the latent heat of vaporization fixed, the quantity to be handled can be easily computed and the necessary size of the safety device chosen.

The dimensions of the relief device will depend upon what kind it is. The formula used in the API-ASME Code, due to Davidson and MacArdle, is devised primarily for hydrocarbons having a considerable number of atoms in the molecule. It will be on the safe side by about 10 per cent for a simpler molecule, such as ethane and propane, and other gases having few atoms in the molecule; these have higher values of the ratio of specific heats. The formula includes a coefficient of 0.97 for a tapered nozzle, because the originators of the formula worked for a company making a safety valve of the nozzle type, for which this coefficient applied. This same coefficient might not apply for other types of safety valves, particularly the low-lift type, previously in common use on boilers and air tanks.

The authors modify this formula to apply to a short tube having a coefficient of 0.83 instead of 0.97. At this point again, the reasoning becomes vague. It is not quite clear from here on what the authors mean to do with the diameter thus found. They talk about using the diameter thus determined for the "relief connection size," implying that they mean the actual nozzle attached to the vessel and not the nozzle that may be part of the safety valve, nor the diameter of any bursting-disk device. If this is what they have in mind, the nozzle so determined will be too small. The actual connection to the vessel in the safety valve or other relief device should be considerably larger in diameter than the limiting discharge orifice. If this is not the case, the entrance to the nozzle constitutes in effect a second orifice in series with the principal relief orifice, and when the flow starts, the pressure drop will not be almost entirely concentrated at the relief orifice, but will be divided between the relief orifice and entrance losses and friction in the connecting pipe between the vessel and the safety valve. This may cause the pressure at the safety valve to drop below the pressure at which it reseats, causing the valve to chatter. When a safety valve is used, the normal procedure is to choose the size of the safety valve from tables, furnished by the manufacturers, or to take the size a manufacturer recommends for the conditions, and then make the pipe connection correspond to the inlet flange on the safety valve. This will be usually several times the diameter of the actual nozzle in the safety valve. The discharge connection will be even larger.

The authors apparently also have the idea of making such computations only for a limited number of pressures. Their Fig. 12, for example, indicates pressures of 15, 60, 150, 250, and 500 psig, and they give four formulas, Equations [1]′, [2]′, [3]′, and [4]′, for particular pressures. Presumably they are trying to make it easy for an inspector or a designer to pick the nozzle sizes. Actually deciding upon safety-valve sizes by steps in this manner will cause considerable trouble. For example, Equation [2]′ is suggested for working pressures from 60 to 200 psig. Presumably, therefore, it is based on 60 psig. If it is used to determine the area of a safety valve operating at 100 psig, it will require a larger-size safety valve than is actually needed. This may increase the expense very considerably in the case of the original installation, and even more if the rule is applied to an existing installation. A safety valve might be entirely adequate for the actual discharge pressure and yet not be large enough for the assumed lower pressure arbitrarily used for convenience. Such a provision is quite objectionable. The amount of time saved over computing the requirements for the actual operating conditions is inconsiderable, and the amount of extra expense in the installation may be of large magnitude.

As a general conclusion, the authors' suggestion that their recommendations be used as a basis for official codes probably will be emphatically disagreed with by most designers who have been using the API-ASME Code, because of its failure to allow for the less likelihood of exposure to fire of an entire area of a large tank, because of the lack of clarity of just what the authors are actually computing in their relief-device size, and because of the complicated way in which the result is arrived at, with the steps so combined that the implied values are not immediately evident for check as to their reasonableness.

T. McLean Jasper.[39] While the writer does not feel competent to discuss this paper so as to add constructive information or criticism, it is easily recognized that this type of information has positive value in analyzing a very important problem. It supplies data which will tend to reduce the danger. The particular tribute the writer wishes to pay to the authors is the resort to a practical approach to the problem, and this after all is the superior method for any intricate matter.

The next step is to devise a simple workable plan for placing safety valves or disks and connections which will evacuate inflammable liquids from fires when they occur, thus rendering them less hazardous and thereby safeguarding working personnel and property.

F. L. Newcomb.[40] On January 4 and 5, 1943, a meeting of safety-valve manufacturers and users in the petroleum industry was called by the Petroleum Administration for War to draw up recommendations for wartime standardized petroleum safety valves, including their application. At that time, a heat-input curve was submitted to the Petroleum Administration and adopted for the duration. This heat-input curve was prepared by the Standard Oil Development Company and was a modification of the curve proposed by D. V. Stroop of the American Petroleum Institute. Both this curve and the one proposed by Mr. Stroop have been referred to previously. The Standard Oil Development Company curve was the result of recommendations from process engineers concerned with the design of furnaces and other heat-transfer equipment and was the result of long and careful consideration.

Through membership on the API Subcommittee on Relief Valve Capacities, there was available to the writer some data on actual fires which had occurred in the petroleum industry where the safety valves had prevented overpressure during a fire. By assuming that the safety valves blew to capacity and knowing the characteristics of the contents of the container, it was possible to figure the maximum heat input per square foot of exposed area. If the safety valves were not discharging at full capacity, the heat input would have been less than computed, and therefore the assumption was on the safe side. When these calculations were made and plotted against the curve submitted to the Petroleum Administration for War, in every case the maximum heat input was less than required by the curve. The matter of heat input and numerous other features are under consideration

[38] Ref. (12) of authors' paper, p. 13.

[39] Engineer, A. O. Smith Corporation, Milwaukee, Wis. Mem. A.S.M.E.

[40] Senior Specialist, Standard Oil Development Company, Elisabeth, N. J. Mem. A.S.M.E.

by the API Subcommittee, and this curve has also been submitted to them as a proposal for a starting point in their work. It is possible that when time permits this committee to become more active and more data are obtainable, it may be advisable to modify the curve. It has, however, been in use for a number of years and there has never been any evidence that it has not been adequate. The lack of failures due to fire exposure of vessels reasonably protected with safety valves in the petroleum industry indicates that the present practices are adequate. It is felt that the recommendations contained in the paper under discussion would require unreasonably high safety-valve relieving capacity and place an entirely unnecessary burden on pressure-vessel users.

It is not felt, however, that the work done by the authors preparing this paper should, in any way, be overlooked in further studying the matter of safety-valve relieving capacity, but should be given due consideration along with all other data and experience which may be available.

R. C. Werner[41] and S. T. Russell.[41] This discussion has been limited to Part 1 on "Observed Rate of Heat Absorption." Each of the four groups of experiments was studied in turn and certain points were noted which were thought to have a vital bearing on the acceptance of a 20,000 Btu per hr per sq ft heat-absorption rate as a basis for sizing relief valves for vessels exposed to fire.

In regard to the test reported by J. F. Fetterly, Bureau of Explosives, 1929, the authors' use of 5.9 min as the time factor in calculating the rate of heat absorption of 23,300 Btu per hr per sq ft of wetted surface may be open to question.

It is reported by Fetterly: "It was intended that the safety valve should open to the full extent of its relief area, and when once opened to that area it should remain open until the contents of the container were discharged without exceeding 375 pounds per square inch gage pressure."

The irregularities in the pressure curve in Fetterly's publication may be explained entirely by Venturi effect, if the piping was arranged as in Fig. 3 of the paper under discussion, and the piping was of certain sizes. Fetterly's paper does not give details of the arrangement of the equipment. If it were assumed that the relief valve, once open, did not shut, the heat-absorption rate would have been 11,850 instead of 23,300 Btu.

It is plausible to reason that the temperature curve reported by Fetterly represents the condition at the bottom of the cylinder, and that vaporization might be taking place at the surface in spite of the temperature at the bottom being less than the theoretical boiling point of propane. If the propane contained some lower boiling material this effect would be more marked.

If one assumes that the mechanism outlined by the authors is correct the rate of heat absorption would vary as follows:

Time, min	Rate, Btu per sq ft per hr
0 to 3.7	1530
3.7 to 9.4	8410
9.4 to 15.3	23300

Fetterly's report does not indicate any physical basis for such a wide variation in rate of heat absorption.

In general, it may be said that it appears difficult to arrive at a correct value of the rate of heat absorption on the basis of the test data in Fetterly's publication.

In regard to the test made by the Underwriters' Laboratories, Inc., as reported in N.B.F.U. Bulletin of Research No. 3, 1938, the following three points are noted:

1 The introduction of a water film on the surface of a plate on the fire side increases the heat absorbed from the fire. A second test was performed with identical conditions except that no water film was present. From the dimensions of the vertical plate and the rate of the average temperature rise, the maximum rate at which heat was absorbed by the plate without the water film was calculated to be 461,000 Btu per hr, as compared to 776,000 Btu per hr with the water film. These results bring out the fact that if the quantity of heat absorbed is measured by a water film on the outside of the tank a considerably higher result will be obtained than for the case where no water film exists. This should be taken into account when applying other test data.

2 A considerable error may be introduced if one applies the results obtained from a small-scale test to commercial installations. As the oxygen supplied to burning fuel is increased to the theoretical quantity, the flame temperature increases rapidly. Therefore a fire with excess oxygen will generally be hotter than where a deficiency of oxygen exists. A small fire may well be the hotter because of its size, since an excess of oxygen over that needed for complete combustion can be easily obtained, but in the case of a fire of large area, it is difficult for the center portion to obtain any oxygen at all.

3 The size of the tank should also be considered. Although the actual initial flame temperature in two different cases may be identical, the larger tank will absorb a greater portion of the total heat in the flame and thus have a lower average flame temperature adjacent to the tank than for the other case. Small tanks and areas will, therefore, receive heat at a greater rate than large tanks or areas.

In regard to the report of the 1930 tests of the A.P.I. on aluminum-alloy tanks for tank trucks, the following points are noted:

1 To assume that a measure of the total heat supplied to the gasoline is the amount of heat needed to vaporize completely the gasoline may result in considerable error, particularly in the case of small tanks. Gasoline may leave the tank in the form of a liquid as entrainment. This can be gathered from the original data on this test. The vapors from the tank ignited at 4 min 20 sec after the start of the fire. At 6 min the fusible plug in the fill cap melted and atomized gasoline was observed to issue from the opening for several seconds. Since both openings are in the same cap it is possible that gasoline was atomized (leaving as a liquid) for the full period of 1 min 47 sec through the vent and probably longer but at a reduced rate.

2 To assume that the liquid level in the tank can be measured by the abrupt temperature rise as recorded by the thermocouples located at different elevations may result in error. The thermocouples were located on lugs on the outside surface. The temperature of the liquid on the inside of the tank would differ by the temperature gradient needed to transfer the heat from the outside surface through the metal walls and inside film to the liquid. This temperature gradient would vary from 30 to 200 F. With such a temperature gradient the inside temperature may be related to the thermocouple readings, but it would be difficult to determine the exact relationship.

On checking the original data, a difference was discovered between the recorded temperatures in the table and a plot of the temperatures. The value for the thermocouple No. 10 at 14 min is recorded as 355 F but plotted as 255 F. Replotting the temperature curve for thermocouple No. 10 with the correction given, it would appear that the abrupt temperature rise for both the No. 10 thermocouple (at 50 per cent level in the tank) and No. 11 thermocouple (at 75 per cent level in the tank) occurred at approximately the same time, i.e., 12 min from the start of the fire. Since both thermocouples rose abruptly at the same time, they do not seem to have given a very good indication of the liquid level.

[41] Blaw-Knox Construction Company, Pittsburgh, Pa.

A reasonable explanation may be obtained for this abrupt rise in temperature from the photographic record of the test in the original report. The photographs as a rule were taken every 3 min. At 9 min there was only a slight indication of any wind blowing. This could be observed from the burning vent gases. At 12 min a slight breeze was blowing the flame from the burning vent gases toward the end of the tank on which the thermocouples were mounted, which were those reported in this paper. The thermocouples on the second tank on the opposite side at no time indicated such a sharp rise although the tank was only one half full to start and was exposed to the same fire. It will be noted from the photographs that the flame was blown away from the second tank by the wind. The abrupt temperature rise, therefore, seems to be dependent upon whether or not the thermocouples were exposed to the radiation from the burning vent gases, and not primarily to the liquid level in the tank.

3 To assume, after rapid ebullition is started, that the only heat needed is for evaporation seems to be an error. From the properties of the gasoline used in the test the initial distillation point is 95 F, and the 51 per cent distillation point is 284 F. The heat needed to evaporate the gasoline is that heat required for the latent heat of evaporation plus that needed as sensible heat to raise the temperature of the remaining gasoline to a rising boiling point.

4 The data on the other 150 gal tank should have been considered. This second tank was directly attached to the first and was exposed to the same fire. The charge consisted of only 75 gal of which 30 gal remained after the test. In all, only 45 gal were vented as compared to 129 gal for the tank reported in the paper under discussion. This marked difference cannot be explained by the difference in exposed area only. Additional explanation may result in the consideration of entrainment. The half-full tank would have on an average a lower liquid level thus resulting in less entrainment.

5 In applying the results of these tests to the design of a relief valve to be attached to a storage tank located in the open, a correction factor should be used with the test data since a windshield was used. Theoretically the radiation from the shield to the tank may be almost as great as from the flame alone. Windshields also help the natural convection of the fire and increase the per cent air to a possible excess. In the case of burning gasoline spread over a large area, there would be a deficiency of air, and therefore a much lower flame temperature.

In regard to the test made by the authors of the paper under discussion, the following points are noted:

1 It is questionable whether the asbestos shield around the tank approaches the condition of a flame of considerable depth. The emissivity of asbestos is higher than can be reached in a flame, and a flame of considerable depth probably would be of a much lower temperature, due to the difficulty of oxygen reaching all parts of the flame. Therefore the heat-transfer rate with the asbestos shield would be higher than could be obtained by a tank surrounded by a large-area fire. The authors were aware of this fact, but believed that the strong updraft between the cylinder and the tank tended to offset the increased radiation.

2 However, it seems questionable whether the strong updraft between the cylinder shield and the tank has the indicated effect. This strong updraft increases the natural convection to the tank and probably causes an increase in the air supply giving a more theoretical mixture and thus a higher flame temperature, as compared to a large-area fire which would have a deficiency of oxygen in many places.

3 On checking the information presented for runs Nos. 2 and 3, it appears that the heat which the authors designate as latent heat absorbed is not a measured quantity but rather the difference between the actual measured sensible heat absorbed and the calculated theoretical possible heat absorbed. Therefore, the calculated rate of heat absorption is actually a theoretical value and should not be confused with the values reported in runs Nos. 1 and 4, which are actual measured rates.

4 The results obtained in run No. 4 are questionable due to the reduction in area used in the calculation by the assumption that a band of the wetted surface 2 ft wide is not exposed to the flame. By using the full wetted area a value of 12,630 Btu per sq ft per hr is calculated. If the authors' assumption is used, a value of 16,850 Btu per sq ft per hr is obtained which is 33.4 per cent higher. Since the actual measured flame temperature is higher than for runs Nos. 2 and 3, it is questionable whether such an assumption which results in a 33.4 per cent increase should be made without at least more test data.

5 As was pointed out in regard to the test made by the Underwriters' Laboratories, Inc., and which is observed when comparing runs Nos. 1 and 4 (25,900 as against 16,850 Btu per sq ft per hr) the tank or plate with water flowing on the surface facing the flame will absorb heat at a considerably higher rate than if the water film is omitted. This would indicate, as mentioned before, that a water film increased the absorption rate and therefore such test data cannot be applied to a dry tank.

6 In calculating the results of run No. 1, the authors have assumed a mechanism whereby the tank metal receives the radiation and then transfers the heat to the water film. This assumption is open to question. The measure of absorptivity of a material to radiation is its emissivity. McAdams reports the maximum emissivity of iron and steel at around 0.75, whereas for water a value of 0.96 is reported. This would indicate that the water film is more absorptive to heat radiation than steel.

Underwriters' Laboratories, Inc., reports in its test; "A simple experiment to gage the properties of water film may be performed by viewing a flame through a thin sheet of glass. The difference in heat energy sensed by the face or hand with or without the glass is not appreciable; but when an unbroken film of water is caused to pass over the glass surface the difference in the heat transmitted through the combination is quite perceptible, although translucency is not materially altered." However, in the authors' test the tank metal became hotter than the water film. This appears to be in contradiction to Underwriters' Laboratories, Inc., observation and to theory. More data along this line are therefore needed.

In summarizing there seem to be three experimental procedures of major importance which should first be evaluated before the results obtained by using such procedures are adapted to a relatively large storage tank located in the open and heated by flame such as a large-area open fire.

1 The use of a water film on the outside of a tank to measure the quantity of heat absorbed. The water film in two of the reported cases greatly increased the amount of heat absorbed.

2 The use of the quantity of material which is vented from the tank as a measure of the quantity of heat absorbed when it is assumed that the material was vented as a vapor. In one particular case, atomized gasoline was observed to issue from the tank.

3 The use of a windshield to control the fire. The emissivity of the shield is generally higher than the possible flame emissivity and thus greatly increases the radiation to the tank. In all the reported cases some type of windshield was used.

In conclusion, the authors of this paper should be congratulated for their contribution to the field of design and safety. It is good to see that even during a period of accelerated production the field of safety has not altogether been forgotten.

WALTER SAMANS.[42] Because of lack of time for adequate study of this paper, it would be an unwarranted presumption on the writer's part to make any off-hand comments on the authors' findings. However, their correlation of formerly existing test data with theory indicates that more tests were very much needed to confirm the theories. The chemical industries particularly will appreciate this report, and the authors' employers, who fostered the tests, in absorbing the costs for the equipment and personnel engaged, are entitled to commendation jointly with the authors themselves. The data thereby presented should prove the best possible source for the formulation of a more standardized practice in determining the required safety valves supplemented by relief disks or cups, and similar devices.

The writer's comments will apply principally to large vertical storage tanks. The authors have recognized a difference between test fires around small pressure vessels and fires in commercial plants where the hindrance offered to complete envelopment by flame will materially cut down the total heat absorbed. They have acknowledged this difference in Part 1 of their paper for the test reported by Fetterly, and those conducted for the A.P.I. and N.F.P.A. They have acknowledged the justification for a reduced heat input on vertical storage tanks over 15 ft diam, approaching a rate of 6000 Btu per sq ft per hr for a 100,000-gal-capacity tank, and reaching the maximum 24-in. size of relief vent for tanks of 300,000 gal (7000 bbl approximately) and arger, in Part 3, Fig. 18.

Although this appears to be a concession to the experience in actual tank fires, and purports to be a reasonable interpretation of test results, this may not prove a sound reason for discarding the present practices for petroleum storage tanks, as shown by curve 6 of Fig. 18. This stand is taken both because of the character of the hydrocarbon flame encountered when pools of petroleum, as crude, reduced crude, intermediates, or gasoline are on fire in a tank pit, and because vertical storage tanks do rupture at the edge of the roof without destructive explosion.

Assume that burning oil on the ground is a heavy petroleum product and that there is no appreciable wind (rain is not a consideration); there will be lots of smoke which screens the tank from radiant heat, except where the inrushing air enters the vapor. Inside of that boundary there is incomplete combustion, because of insufficient air, and consequently a lower temperature. Above the top of a tank 30 ft or more in height, the radiant heat has little effect on the roof. It is quite possible that the equivalent of only 1/6 of the wetted shell surface need be computed at a heat input of 20,000 Btu per sq ft per hr. In the case of burning gasoline, the flame may be almost free of smoke, or at least will appear so on the outer boundary of the burning cloud of vapor. There could not be a sea of fire over an area having an annular width equal to the radius of a large tank that could be "seen" by the wetted tank surface as the interior of the burning vapor cloud is not clear. Smoke does form.

Because of the greater area on fire, the inrushing air will carry the flame higher, but by attenuation of the flame, the radiant-heat effect will be reduced with height, radiating less total heat per average square foot on higher tanks, and to the tank roof. Intermediate oils, between heavy fuel and gasoline, will show "in-between" effects.

When there is a wind blowing, there is no great difference in rate of heat input until its velocity is higher than the air drawn to the fire by the draft. There can never be the chimney effect produced by the authors' tests, because there the gasoline was sprayed into the rising current of air to produce a hot continuous flame with resulting excess air, as far as the photographic cuts indicate.

To simulate a storage-tank fire, tests might be made by burning gasoline poured on top of a pool of water around the tank The screen or shield should be placed outside of the basin that holds or receives the cooling water, and air admitted through a sufficiently large clearance under the screen. The effect should be similar to that obtained in the trial runs using gas fuel, shown in Fig. 8, except that, gasoline vapor having a higher molecular weight, and the flame being screened, a higher rate of heat input may be expected.

In this connection the authors' "unfortunate experiences" with small tanks should not affect conclusions based upon good experience with large vertical oil-storage tanks. To evaluate the screening effect of the width (i.e., horizontal depth) of flame on the heat radiated to the surface of the tank, the Underwriters' Laboratory test made on a flat plate might be reproduced, but shielding the boundaries of the plate from flame contact so that the air-vapor mixture will not take place near the test plate. Obviously, the results should give a low rate of heat input, when a heavy fuel oil is burned and not as high a rate as on the authors' test recorded in the paper, when burning gasoline.

The statements just given are also intended to verify the authors' conclusion that open-air combustion cannot be compared with controlled combustion in a boiler furnace. In the latter, only the wall tubes and radiant-heat surface are comparable, but the type of furnace flame, with little obstruction, and that due to haze, is seldom reproduced in industrial fires. It is expected that the subject of vertical storage-tank fires, covered by this contribution to the discussion, will be amplified by the actual experience of some of the many oil men in California who have combated fires in oil refineries and field storage tanks. The record so obtained should be combined with the results of the authors' studies and tests and formulated into the best possible procedure for determining the protective venting needed for large tanks.

Another point which appears to need clarification is the statement in the Summary at the beginning of the paper: "So far as can be learned, there is no substantial theory or evidence to support the limiting of heat-input rates to any particular height. There are some indications to the contrary, that is, high flame temperatures apparently exist at relatively great heights above the fuel during large fires."

There appears no reason for this reversal of published "Fire Fighter" opinion, i.e., not by the text of the authors' paper, and there being no other publication referred to in this thesis, possibly the authors will say why this statement was made in the Summary of Part 1, where reported tests did not develop "relatively great heights," unless other records made and cited in the original reports were not herein reproduced. The wording of the statement referred to may be unintentionally misleading. "High gas" temperatures will exist wherever they are found, and what was no doubt meant was that high temperatures are radiated to relatively great heights, provided the fire is intense and large enough. As mentioned in this discussion on fires around oil tanks inrushing air over an annular flaming oil area surrounding a tank, "attentuates" the flames and, for the case herein considered, will hasten the completion of vapor combustion. Obviously, the larger the area covered by fire, the higher the flame will reach, and the greater the intensity of radiation in the most favorable directions. Reverting to the original statement on "the limiting of heat-input rates to any particular height," the authors' tests did not simulate an open-air fire and on such fires the radiation effect of flames above a pool of oil on the ground will diminish rapidly upward as the intensity decreases.

[42] Sun Oil Company, Philadelphia, Pa.; member of the A.S.M.E. Boiler Code Committee; Chairman of the API-ASME Committee on Unfired Pressure Vessels; Vice-Chairman, API-Oil Storage Tank Committee. Mem. A.S.M.E.

The authors' theories are presented in a usable manner by the formulas, and the derivations are of practical form. They seem well substantiated by the tests. The authors have also recognized the varied degree of exposure encountered with special protection that may be provided in the construction. It now remains for interested authorities, as represented by state inspectors, insurance engineers, and recognized technical committees to formulate reasonable assumptions of departure from test conditions, to which the authors' correlation between tests and theories may be properly applied to give adequate protection for each type and size of vessel or tank.

The authors' work was well worth while. The resulting forward steps have anticipated similar work by other organizations that was no doubt postponed because of the existing war emergency. The authors' continued work for the furtherance of their ideas should be aided and encouraged in all ways possible.

H. R. ZEIGLER.[43] The derivation of the fundamental equation is very simple and logical. The authors start with the formula given in the API-ASME Code which is used for determination of capacities of pressure-relieving safety devices. They claim that this formula is universally employed and is of proved accuracy. By substitution, factors for heat input, wetted surface, and latent heat are introduced to complete the formula.

A novel feature of the paper is a chart which shows "contents factors" for many compounds. This chart may be read and the reading substituted in place of one expression in the formula which involves temperature of the substance, molecular weight, and latent heat of vaporization of the substance.

In addition to the basic equation, the authors offer a few other equations, the purpose of which is not particularly clear. However, all of these equations are extremely easy of solution, whereas the well-known Fetterly formula is quite difficult of solution and offers many possibilities of error.

One novel suggestion is that relief valves be made the same size on all vessels of the same capacity and pressure range. This is to promote interchangeability of use of such vessels and, consequently, a high "content factor" is used.

The authors concede indirectly that the size of the tank has an influence, if the writer interprets the paper correctly. This statement is based on the fact that they treat of four pressure ranges for vessels not exceeding 10,000-gal capacity, and one formula only for vessels above that size. However, another way of looking at this is that they may consider it uneconomical to bother with different relief areas for vessels of many differ nt working pressures. The four pressure ranges are 15–60, 60–200, 200–700 psig and finally, pressures above 700 psig. Incidentally, in O. M. Setrum's study of the subject of relief valves, he suggested that the external temperature of tanks of 10,000 gal and larger should be 1000 F, instead of the 1200 F used for smaller tanks.

In leading up to the equation recommended, the authors exert all their efforts to establish a heat-input rate of 20,000 Btu per hr per sq ft of wetted surface. In reviewing previous work they point out that the API Committee on Fire Prevention prepared a chart 12 or 14 years ago for gasoline tanks exposed to fire. This chart shows capacity and size of relief devices for heat-input rates of 21,000 to 6000 Btu per hr per sq ft, but there was no practical basis presented for this choice of a heat rate. The relief standards contained in N.B.F.U. pamphlet 30 are based on heat input of 6000 Btu per hr per sq ft of wetted surface. They regard the work of Fetterly as outstanding and, therefore, discuss it at some length.

In discussing Fetterly's formula, the authors show that judged by modern methods of calculation, his coefficient of heat input was remarkably accurate. They then show that, since his estimate of surrounding temperature was 1200 F, the heat-input rate was about 14,000 Btu per hr per sq ft of wetted surface. However, they advance the idea that 1400 F is a more probable surrounding temperature and, therefore, according to Fetterly's coefficient the heat-input rate would be 23,000 Btu per hr per sq ft of wetted surface. The writer believes this disregards the fact that Fetterly's coefficient must have been obtained empirically from a calculated input rate and, therefore, the premise is untenable. It is also felt there were some other distortions of Fetterly's test data in the authors' analysis. Finally, the authors proved to their satisfaction that vaporization was in excess of relief-valve capacity in spite of the fact that the fire test on which Fetterly based his paper was satisfactorily performed.

The authors summarize their tests as follows: "When a tank is surrounded by an intense fire having an effective temperature of about 1400 F, heat is absorbed from the flames at a rate of the order of 20,000 Btu per hr per sq ft of wetted surface exposed."

The tests do not make out a very good case for either heat input of 20,000 Btu per hr per sq ft of wetted surface, or for the effective temperature of 1400 F. The tabulated results for three runs out of four were 25,900, 17,300, and 18,700 Btu and 1510, 1270, and 1315 F. These effective temperatures were measured at the center of the flame region under well-shielded conditions, and it is the writer's opinion that, unless a tank were installed within a building, windage would discount the effective temperature and, consequently, the heat-input rate very considerably.

The formula recommended by the authors seems to have only one weakness, namely, the heat-input rate which they have tried so hard to establish at 20,000 Btu per hr per sq ft of wetted surface.

The writer has worked out the following relief-valve areas for an 82.5-in-ID (7-ft-OD) × 42-ft T.L. tank. This tank was chosen because it has a nominal capacity of 10,000 gal and a total surface of 1000 sq ft. The working pressure is 200 psig, and this is chosen because it is a pressure very commonly used by the writer's company. This size and working pressure give an opportunity to show several different solutions for relief area.

Equation [2]′ covers vessels between 60 and 200 psig and is developed from Equation [4]′, being simplified by the insertion of 66 psia, and the wetted surface is expressed as 85 per cent of the total surface.

Equation [3]′ covers vessels between 200 and 700 psig and is developed in the same manner except that 220 psia is used.

Although Equation [4]′ will not be used, it is necessary to point out that this is based on the assumption that tanks should be equipped with relieving devices of sufficient capacity to promote interchangeability.

Equation [5]′ covers vessels larger than 10,000 gal. By inference the preceding equations are for vessels less than 10,000-gal capacity.

Equation [2]′ $a = 0.0192S = 19.2$ sq in.

Equation [3]′ $a = 0.01112S = 11.12$ sq in.

Equation [5]′ $d = \sqrt{\frac{97.3S_w}{(P+14.7)}} \left(\frac{T}{Mr^2}\right)^{1/4} = 2.715$ in...

.....$a = 6.15$ sq in.

Fetterly's formula using 1400 F.....$a = 4.91$ sq in.

Fetterly's formula using 1200 F.....$a = 3.52$ sq in.

$D \times U$ table where $D = 7$ and $U = 45$; $D \times U = 315$ and $a = 3.10$ sq in.

In Equation [5]′ S_w = wetted surface, sq ft

T = temperature F absolute of vapor

P = gage pressure (R.V. setting pressure)

[43] Phillips Petroleum Company, Bartlesville, Okla.

M = molecular weight of vapor
r = latent heat, Btu per lb

The writer feels that the authors have not proved their constants sufficiently for adoption, in view of the success of the present practices recommended by the National Board of Fire Underwriters in Pamphlet 58.

The authors have not proved the inadequacy of Fetterly's formula.

In general, the authors offer a very intelligent basic formula for the solution of relief-valve-area problems and, if their constants for heat input and surrounding temperatures can be adjusted downward to produce more reasonable results, the writer would like very much to see this basic formula adopted.

T. C. Smith.[44] The authors of this paper are to be congratulated for this excellent paper with its summary of fire tests conducted by themselves and others. Particular attention should be directed to the method used for cooling the test tank and recognition given to this type of protecting against overpressure or overheating of the tank surface in the vapor space.

It has been difficult to understand why the authors have chosen to determine the pipe size required for the relief-valve connection rather than the orifice area of the valve. Commercial spring-loaded relief valves have an orifice area ranging from 25 to 30 per cent of the connecting-pipe area, hence it would appear that the orifice should be of primary concern and the inlet-pipe connection of secondary interest.

Also, consideration should be given to replotting the curves of "content factors" with the term "pressure" incorporated in the equation. This will permit a series of charts, each consisting of a family of curves for various groups of contents.

The authors present heat-input rates ranging from 20,000 to 30,000 Btu per sq ft per hr, as obtained from three different sets of tests. These values are not questioned. Next, they compare these results with established venting rules and create doubt as to their safety. Lastly, they call attention to the absence of specified heat-input rates in two well-known pressure-vessel codes, thereby inferring that this matter has been given scant attention by bodies interested in the formulation of safety standards.

The writer hastens to correct any doubts, on the deficiency of these venting rules, or impressions that this subject has been or is being neglected by groups engaged in the initial drafting of safety standards. These existing rules, although differing in form, employ definite heat-input values which have been established by experience. Also, these sponsoring groups receive many reports of tank and vessel failure which are studied to determine whether revisions in their standards are necessary. The heat-input rates and some of the current work being done is reported herewith as a matter of record.

The first venting rules, for the protection of equipment from overpressure when exposed to external fire, appear to be for oil-storage tanks operating at atmospheric pressure. The American Petroleum Institute was asked to suggest some kind of a venting schedule, and after reviewing the records of their industry where tanks were involved in fires, arbitrarily selected a unit-heat-input rule which was represented by their experience. This rule expressed mathematically is

$$Q/A = \frac{48{,}000}{A^{1/3}}$$

where

Q = total heat absorbed by tank per hour
A = wetted surface exposed to heat

[44] General Petroleum Corporation, Los Angeles, Calif.

The development of liquefied petroleum gases for commercial use brought out two venting rules intended for small- and moderate-size pressure tanks. The California Safety Orders for Liquefied Petroleum Gases gave a rule which was based on 20,000 Btu input on 60 per cent of the surface, or an average of 12,000 Btu per sq ft on the gross surface. The National Board of Fire Underwriter's rule was based upon a modification of Fetterly's formula, using a flame temperature of 1200 F for tanks having a capacity of 10,000 gal or less, and 1000 F for tanks of 30,000 gal capacity or more, with adjusted temperatures for tanks of intermediate capacity. The heat input by this rule will vary between 23,000 and 13,000 Btu per sq ft per hr.

The application of either the California or NBFU rule to extremely large vessels resulted in relieving areas that appeared to be excessive and caused them to be questioned. The American Petroleum Institute, because of its interest in pressure-vessel safety and fire prevention, became interested in the problem and referred the matter to a subcommittee for further study. This subcommittee was instructed to confine its initial efforts to large pressure storage tanks and determine if the previous A.P.I. rule for heat input to atmospheric tanks was satisfactory for pressure tanks, also what modifications might be necessary for other factors involved.

The assignment has been divided into three parts for study, namely, (*a*) the correlation of test data to actual fire conditions; (*b*) further tests, if necessary, to determine the scale effect for both horizontal and vertical vessels; and (*c*) a survey of fires involving pressure vessels to determine the maximum average heat input.

Some progress has been made on the last item. A questionnaire was issued to the petroleum industry for histories of external fires on pressure vessels. Cases have been selected where the vessel was full or nearly full of liquid hydrocarbons and both incoming and outgoing lines were closed. Such cases with pertinent detail data permit the estimation of the average heat input by assuming that the open relief valve is an orifice. This survey has produced heat-input data for two extreme cases as follows:

(*c*-1) More than 11,000, but less then 17,000 Btu per sq ft per hr, for small propane cylinders having a wetted surface of 16 sq ft. Approximately twenty-five cylinders exposed in ten or twelve fires failed from insufficient relief-valve area (0.062 sq in.). This experience prompted a program for changing the type of relief valve to one having a larger orifice (0.100 in.), and the results to date show that some twelve cylinders have successfully withstood severe fires. In at least two cases there were, in the same fire, cylinders with each type of valve, and some of those with the small orifice failed from excessive pressure while all of those with the large orifice came through without damage.

(*c*-2) Approximately 2300 Btu per sq ft per hr on a sphere having a wetted surface of 4363 sq ft. This was a 48-ft-diam sphere subjected to a severe fire for 1 hr 7 min. At times the vessel was completely enveloped in flame. The relief valves were adequate and prevented failure of the sphere.

(*c*-3) In addition to the foregoing, three intermediate cases can be cited as follows:

3600 Btu on a natural-gasoline tank; wetted surface = 319 sq ft
2050 Btu on a natural-gasoline tank; wetted surface = 900 sq ft
1350 Btu on a natural-gasoline tank; wetted surface = 990 sq ft

In all of these fires, the average heat input is estimated to be less than the value obtained by the previously mentioned API heat-input rule for oil-storage tanks.

Reports have been received on many other vessels, but unfortunately, the data do not permit an estimation of heat input because of open lines discharging liquid or vapor, or flame impingement on a surface in the vapor space which resulted in

overheating and failure of the metal. Such failures cannot be prevented by relieving devices which maintain, regardless of the size of the device, a fixed pressure on the tank.

Previously, it would be both improper and premature to predict the final recommendations of this subcommittee.

As noted previously, there are existing rules for venting in use in the petroleum industry, and so far as is known, there is no evidence that these rules where properly applied have been inadequate to maintain safe conditions. The authors of the paper under discussion propose that these rules be superseded on the basis of the evidence and conclusions which they have submitted. In the writer's opinion, this is not justified by their data.

The experimental accuracy of their data is not being questioned, but the interpretation and extrapolation thereof on which their recommendations are based is open to criticism. They have employed results from a very limited number of tests run on a narrow range of vessel sizes under conditions which do not duplicate, nor in some cases resemble, actual service conditions. They have used these as a basis for a proposal that a satisfactory experience record be discounted and supplanted. This is unsound.

The data that they have derived justify conclusions only within the range of exposure conditions covered by the reported tests. However, if correlated with other accumulated data they can aid in reaching a reasonable solution for the over-all problem and for this purpose they are of full value. It is recommended that they be considered at this time only as a contribution to the study being made by the API subcommittee mentioned previously.

Authors' Closure

Reply to Discussion by T. A. Gadwa

Herewith are the authors' comments on the questions raised by Dr. Gadwa in his discussion of their paper.

Effective Height of Flame. Dr. Gadwa's reference to 50 ft for a minimum height for protection against fire exposures is the highest about which we have learned and with which we are in agreement to this extent: We have experienced heat failures (1000 to 1200F) of unprotected structural steel at a 50-ft elevation in the open. However, under such circumstances, a good part of the fire fuel was about 20 ft above grade. We have had such failures in the open at 30-to-40-ft above-ground spillage fires, and this was a part of the basis for the suggestions near the end of Part 1 of the paper. We are convinced that the more generally used height of 20 ft is inadequate.

Input Rate of 20,000 Btu per Sq Ft per Hr. At this time, we have a record of ten tests by six separate concerns, and five analyses of actual fires which indicate that the constant rate of 20,000 Btu per sq ft per hr of surface wetted by the contents is a safe minimum for vessels enveloped with intense fire. We do, however, suggest a reduction of this rate for atmospheric tanks above 20,000 gal nominal capacity, as proportionately represented by curve 2, Fig. 14, or curve 3, Fig. 18, of the paper. The authors interpret the "Wartime Recommendations . . ." to specify heat rates of 10,700 Btu for 10 sq ft of surface downward to 4800 Btu for 1000 sq ft per hr of wetted surface. In the light of our fire experience, this is inadequate, and no attempt will be made to co-ordinate our results with these recommendations.

Effect of Insulation. We suggest allowance for insulation in the capacity of the relieving apparatus but not in the area of the relieving connection. This would depend upon the reduction effected in the flow of heat by the insulation when exposed to hot gas temperatures of 1400F. No data have been prepared on this as it is expected that only in rare cases will allowances prove economical and practical.

Conversion of API-ASME Code Equation. To clarify the reason for the conversion of the API-ASME orifice equation, reference is suggested to its derivation. This will be found in "Discharge Capacity of Relief Valves for Oil Stills," by K. S. M. Davidson and D. W. MacArdle.[21]

It will be seen in this reference that the equation was derived using a ratio of specific heats of 1.001, a critical pressure ratio of 0.6064, and a coefficient of discharge of 0.97. These superficial or ideal values (the first two) were employed to assure adequate relief capacities for any of the heavier hydrocarbons. Since the formula is so universally employed, well known, and of proved accuracy, it was considered wise to incorporate it in the paper rather than those which we had derived for synthetic organics, even though there was little difference.

Further, it is our method to compute all relief capacities in terms of free area and then select the relief device of a capacity based upon approved flow test to pass the calculated rate. Since we use valves having capacities which range from 14 to 60 per cent of the capacity of the relief connection of the same size, it is frequently necessary to choose a larger relief connection than the calculated free area. We do not figure the relief capacity of the valve orifice itself because only those capacities for valves which are essentially free-blowing orifices (top guided, high lift, full bore) can be calculated readily with practical accuracy.

Also, it will be found expedient for most cases that the necessary relief device for fire exposure be supplemental to the usual spring-loaded safety valve, and that this device be simple, inexpensive, and of relatively large capacity. Such apparatus is available with free areas practically equivalent to the pipe-size connection. Reference is suggested to paragraph 5, Proposed Summary for Use, Part 2 of the paper.

Reply to Discussion by F. L. Maker

In order to simplify the authors' reply to Mr. Maker's lengthy discussion, a summary of his comments is given as follows:

1 Mr. Maker's comments refer to Parts 1 and 2 of the paper.

2 He states that heat-input rates of the order of 20,000 Btu per sq ft per hr are not new.

3 He suggests continued use of $\frac{Q}{A} = \frac{48{,}000}{A^{1/2}}$.

4 He wonders why we refer to nozzle size rather than relief-device size.

5 He is confused by the "contents factor."

6 He suggests how the problem should be solved.

All of Mr. Maker's comments in which relief devices are mentioned should be ignored because our paper is concerned with the free-relief area rather than the relief device itself.

The following reply is more to the points summarized:

1 Although Mr. Maker's comments refer to Parts 1 and 2, the authors wish to point out that a fire is no respecter of the working pressure of a vessel. Therefore, although the fire experience to which the authors refer consists of observed failure of low-pressure vessels up to 10,000-gal capacity exposed to fire out in the open. the intensity of a fire around similar high-pressure vessels would be the same. Reference is made by Mr. Maker to the difference between vessels in refineries and those in other plants. The codes do not recognize this differentiation and the authors are of the opinion that the code should be specific about the size and shape of a vessel in relation to heat input in an exposure fire, or else vessels should be designed for the worst condition. The formulas given apply to any shape and working pressure.

2 The authors are aware that possible heat-input rates of 20,000 Btu per sq ft per hr are not new but they desire to point out that very little information has been given to the public to this effect in the 18 years since heat-absorption rates of this

magnitude were observed by Mr. Maker. Furthermore, because of the use of recommended values of from one sixth to one third of the observed heat-input rates many a tank has probably suffered damage during this period.

3 Mr. Maker suggests continued use of the arbitrary expression $Q/A = \frac{48{,}000}{A^{1/3}}$ as a relation between heat input and surface area of a vessel. This is an example of arbitrary rule which the authors feel can and should be replaced by a more practical and accurate expression. The absurdity of this expression may be brought out by equating the right-hand side to 20,000 Btu per sq ft per hr and solving for A, the area of a vessel for which a heat-input rate of 20,000 Btu per sq ft per hr would be recommended; thus

$$\frac{48{,}000}{A^{1/3}} = 20{,}000$$
$$A^{1/3} = 2.4$$
$$A = (2.4)^3 = 13.8 \text{ sq ft}$$

This is equivalent to a vessel about 18 in. in diameter and 36 in. long. Our tests and fire experience indicate that 20,000 Btu per sq ft per hr may be expected up to areas of approximately 200 sq ft and 600 sq ft respectively. We, therefore, emphatically deny that this expression is reasonable.

4 The reasons for basing relieving capacity on the free-discharge area of relief connections are detailed in the reply to the comments by Turner C. Smith.

5 Mr. Maker is confused by the "contents factor." The authors feel that they have been quite clear in stating that this factor may be calculated for each individual liquid to be stored or processed and have suggested two excellent methods of estimating latent heats of vaporization. However, we also feel that by use of the recommended general expression for the "contents factor" in terms of pressure, one need not be concerned with the nature of material to be stored; and that not only is a factor of safety provided for, but also the cost of resulting vent nozzle is negligible compared to the cost of one which would be required for some particular liquid.

6 Finally Mr. Maker suggests the procedure to follow in determining relief areas, namely:

1 Determine the amount of heat input.
2 Determine maximum pressure of discharge.
3 Determine the vaporization rate.
4 Choose relief device to discharge vapor.

This is precisely the method used by the authors as shown in the paper.

Under item 1, we suggest 20,000 Btu per sq ft per hr, except for atmospheric tanks, as outlined in Part 3 of the paper.

Under item 2, we use the code rule in the paper of 10 per cent greater than the working pressure for maximum discharge pressure.

Under item 3, we determine the vaporization rate by use of the "contents factor."

Under item 4, we show a relation from which the minimum diameter of a circular relief area to discharge the vapor may be calculated.

We still feel that an "all-embracing" formula simplifies the problem for the host of equipment manufacturers and regulatory bodies who would need to go through these four steps, and that we are not trying to cover up any steps or introduce any irrelevant factors which would give unreasonable relief connections.

In answer to Mr. Maker's general conclusion, which of course refers to pressure vessels, the authors wish to point out that, whereas the information supplied by the paper may lack in application to large-size vessels, the existing available information is seriously lacking in application to small-size vessels.

Reply to Discussion by F. L. Newcomb

All of the actual fires used as a basis for the test of the curve described may not have been fires of great intensity. This committee should have asked for information from other industries besides the petroleum industry. A number of cases were cited by the authors in which the existing design rate of 6000 Btu was found to be inadequate, to which cases reference is suggested.

The only instance of a large tank being exposed, which supported the recommended curve, was that given by Turner C. Smith as example *c*-2. The apparent fallacy in its application is described under the reply to Mr. Smith's discussion to which attention is invited.

Reply to Discussion by R. C. Werner and S. T. Russell

The authors disagree with the tabulation of paragraph 6 and the statement of paragraph 7 in the comments by Mr. R. C. Werner and Mr. S. T. Russell, for the following reasons:

1 The very physical construction of the fuel around the propane cylinder would account for a variable heating rate on the wetted surface of the tank. As the wood is consumed and the fire bed lowers, the flame in the vicinity of the wetted surface would be more intense.

2 Up to the time of vaporization, the heat-transfer process is in an unsteady state. Thus, the steel vessel which weighs about 1000 lb and the propane vapor in the vapor space absorb heat, but as the temperature of the steel shell rises the rate of heat absorption decreases. However, as the fire level drops, then a relatively steady state is reached in the transfer of heat to the boiling liquid and practically all of the heat absorbed by the wetted surface goes into vaporization of the liquid. The values 1530 and 8410 Btu per hr per sq ft in the tabulation are evidently based upon the rise in liquid temperature only, and this low rate of sensible heat absorbed would be expected because of the mass of wood which surrounds the tank during the first few minutes of the fire.

Since these critics doubt the accuracy of Fetterly's test setup, as shown in Fig. 3 of the paper, the authors will be glad to display further information on request, including photographs and the results of two other tests conducted by Mr. Fetterly, or the critics may refer to files of the Bureau of Explosives in New York, N. Y.

In regard to the first point raised on the Underwriters' Laboratory tests, note that 461,000 Btu per hr (the heating rate at 1-min exposure) is still equivalent to 19,200 Btu per hr per sq ft. The chart shows that the plate heated from 65 F to 340 F in $^1/_2$ min, which is a heating rate of about $122 \times 0.12 \times 275 \times \frac{60}{0.5} =$ 483,000 Btu per hr. The maximum heating rate must be higher than this and exists at the first instant when the plate is at its lowest temperature. When the plate is at 600F (the temperature at 1-min exposure), it is losing heat from the rear and absorbs heat at a slower rate because of its high temperature.

The second point is rather abstract but actual observations of fires and the damage therefrom leave little doubt that air does exist in large areas so that combustion is complete enough to result in high temperatures. Reference may be made to the NFPA Handbook[9] on fire severity. Note also that a 3000-gal tank is not a small-scale tank but rather a commercial-process installation.

The third point is provided for in Part 3 of the paper. We agree that large-size tanks will not receive heat at the same rates as small-size tanks.

The comments on the Aluminum Company tests although lengthy are merely opinions of Messrs. Werner and Russell, and the authors of the paper do not grant that these opinions are superior to their own on these tests.

In regard to Items 4, 5, and 6, under the test made by the authors, note that the heat available in the fuel for test No. 4 is only 28 per cent of the quantity available in test No. 1. The two tests are, therefore, not comparable as far as determination of effect of water film is concerned. The emissivities for oxidized iron and steel, painted surfaces, and so on, are also reported as 0.95 to 0.98. The figure of 0.96 for water is calculated. Very few commercial surfaces will maintain a low emissivity for a long period of time.

In the summarization paragraph, Messrs. Werner and Russell refer to a large-area oil fire. We wish to point out that such a fire would not be as intense as a large-area butadiene or acetone fire. Large storage tank and large-area fire are not defined. The authors have given consideration to various sizes of tanks in using the observed heating rates.

It is the opinion of the authors that the summary statements of Messrs. Werner and Russell do not in any way detract from the observed heat-input rate of 20,000 Btu per hr per sq ft because:

1 They have calculated the input rate to a dry plate of 19,200 Btu per hr per sq ft (Underwriters' Laboratory tests); and if they are correct in their emissivities of iron and water, run No. 1 of the authors' tests would yield $25{,}900 \times 75/96 = 20{,}200$ Btu per hr per sq ft.

2 Damage to tanks and equipment in actual fires shows that vent sizes are too small whether they are venting air, vapor, or a combination of vapor and liquid.

3 A tank surrounded by other tanks and equipment would present the same windshield effect in an actual fire.

The authors would also point out that when human life is a consideration, it is customary to provide a factor of safety in the transposition of observed data to actual practice. For instance, in the design of pressure vessels a factor of safety of 4 or 5 is used. In view of the evidence of test data and the many cases of destruction of equipment in actual fires it is difficult to understand why anyone would desire to interpret data on the low side, or to design for any but the worst conditions that can be conceived.

Reply to Discussion by Walter Samans

The type of constructive criticism received from Mr. Samans is appreciated. The authors are in agreement with most of his comments. The following reply is made to several questions which he raised:

Mr. Samans feels that a heating rate of the order of one sixth of the observed rate (20,000 Btu) should apply to large atmospheric vessels. Solution of curve 3 in Fig. 18 of the paper will show that a rate, ranging from 5000 Btu at 300,000-gal capacity to 2300 Btu at 1,000,000-gal capacity, has been applied.

It was said that the authors' tests did not simulate fires in the open. This is true, as acknowledged, to an extent not great enough to affect materially the rate of heat absorption. The authors would point out that the test results were confirmed by five other independent organizations.

The reasons for stating, "So far as can be learned, there is no substantial theory or evidence to support the limiting of heat-input rates to any particular height. There are some indications to the contrary, that is, high gas temperatures apparently exist at relatively great heights above the fuel during large fires," will be found under the heading Flame Temperatures and Effective Height, near the end of Part 1 of the paper. In addition to the evidence there given, the authors have recently observed structural steel destroyed 30 to 40 ft above the liquid fuel. This was in the open and the structure was carrying only its own weight. The failures were the drooping type necessitating temperatures of at least 1000 to 1200 F.

Reply to Discussion by T. C. Smith

The following reply is made to specific quotations from Mr. Smith's discussion:

Mr. Smith's Comment. "It has been difficult to understand why the authors have chosen to determine the pipe size required for the relief-valve connection rather than the orifice area of the valve. Commercial spring-loaded relief valves have an orifice area ranging from 25 to 30 per cent of the connecting-pipe area, hence it would appear that the orifice should be of primary concern and the inlet-pipe connection of secondary interest."

Quotation Pertaining From Authors' Paper. "The relief capacity is proposed in terms of area of the relief connection (or connections) because the designer is primarily interested in selecting an adequate fitting of standard size for the vessel to be constructed, and because of the great variation in the capacity of commercial relief apparatus. This connection is ordinarily an inserted short tube with a square inner edge, somewhat rough from the standpoint of fluid flow. The relief device may afterwards be selected of a capacity (based on approved flow test) to pass the vapor rate of flow computed from relief area, as will be explained later."

Authors' Additional Comment. To elaborate further, the authors point out that of many popular types of safety valves studied, capacities were found to vary from 14 to 60 per cent of the capacities of tank connections of the same pipe size. It is generally recognized that only those capacities for valves which are essentially free-blowing orifices (top guided, high lift) can be calculated readily with practical accuracy. Such valves are in the minority of the many types manufactured. To repeat, the necessary relief capacity can always be calculated in terms of free area of the relief connection, and the apparatus chosen of a capacity (based on approved flow test) to pass the calculated rate.

The wide variation in the capacities of commercial relief devices and the questionable value of calculated capacities of valves which are not essentially free-blowing orifices will be obvious if reference is made to recent literature[15] on this matter.

It is further believed that the relief apparatus necessary for fire exposure, in most cases, would be supplemental to the usual spring-loaded safety devices and would also be a more simple, inexpensive device of relatively large capacity. Reference is suggested to paragraph 5, Proposed Summary for Use, Part 2, of the paper.

The method of specifying relief capacities in terms of free area is that shown in the "Proposed Tentative Standards: API Venting Guide" (May, 1940, p. 4). After Table 2, which gives the diameters of free areas with capacities, will be found the following statement in paragraph 7.1: "Certified capacity curves of venting equipment shall be based on flow tests conducted by commercial testing laboratories of institutions of recognized technical standing." Further, in the "A.S.M.E. Code for Power Boilers" (1940 edition, p. 108), will be found Table P-14 giving minimum total areas of openings (square inches) in fire-tube boilers for safety-valve connections.

The authors, therefore, feel that they have followed a recognized and rational method in expressing relief capacities in terms of free area.

Mr. Smith's Comment. "Also, consideration should be given to replotting the curves of 'contents factors' with the term 'pressure' incorporated in the equation. This will permit a series

[15] "Safety Valve Capacity Tests" (in accordance with the rules formulated by the A.S.M.E. Boiler Code Committee), National Board of Boiler and Pressure Vessel Inspectors, Columbus, Ohio, 1940; "Steam Flow Through Safety Valves," by E. K. Falls, Ohio State University, Columbus, Ohio, 1942; and "Safety and Relief Valves for Refrigerants," by E. K. Falls, *Refrigeration Engineering*, April, 1943, p. 257.

of charts, each consisting of a family of curves for various groups of contents."

Authors' Reply. This comment is not fully understood. It will be seen, in Fig. 12 of the paper, that the contents-factor values were plotted against pressure. No attempt was made to plot values for a substantial percentage of the numerous compounds but only for those considered representative and for which latent-heat data were directly available in the literature referred to in conjunction with Fig. 12. It is believed these are sufficient for the purpose of showing the method of solution and illustrating the value of simplification.

If a series of charts, consisting of values for families of compounds, were made, the present worth of Fig. 12 would be further enhanced. When trial solutions were made for numerous other compounds, the contents-factor values were found to be within the range of those now shown on the graph. "Their use in individual cases would result in numerous vent sizes adequate only for materials of like properties at the same condition." No different pipe-size relief connections other than those shown in Table 2 would result.

To emphasize again; the suggestion of a simplified value of the contents factor varying with pressure "in no degree nullifies the value of Equation [9] in calculating the required relief diameter directly for any contents."

Mr. Smith's Comment. "The authors present heat-input rates ranging from 20,000 to 30,000 Btu per hr as obtained from three different sets of tests."

Authors' Reply. Described and analyzed in Part 1 of the paper are tests by four (not three) separate organizations; seven tests in all. In the "Conclusion" of Part 2, further confirming tests by another company are referred to; while, in addition, four accidental fire exposures are pointed out as having supported the test data.

In the supplementary remarks to this paper made at Los Angeles on June 17, 1943, the authors cited one further test and one further actual example. The paper thus had for its practical basis the analysis and development of 10 man-made fire-exposure tests by six separate organizations and 5 actual cases confirming the test data. At this time, 6 additional failures due to fire exposure are being studied for further data.

Mr. Smith's Comment. "The speaker hastens to correct any doubts, on the deficiency of these venting rules, or impressions that this subject has been or is being neglected by groups engaged in the initial drafting of safety standards."

Authors' Reply. Early in Part 1, and again near the end of Part 2, the authors explained that the existing proposals for emergency venting were found to be inadequate. We believe this evidence to be convincing and will not repeat or elaborate on it here, but further explanation will be given in supplementary remarks. No inference was made that the subject was being neglected, but it was stated that the necessary information could not be obtained from the regulatory bodies. The following are quotations from a letter dated November 7, 1942, from the engineering office of one of the regulatory bodies in reply to our inquiry for information on the subject of rates of heat absorption during fire exposure:

> The subject of emergency relief of internal pressure was headed up some twelve to fourteen years ago in the NFP A Committee on Flammable Liquids when the API Committee on Fire Prevention undertook to make studies and recommendations for inclusion in the NFPA Suggested Ordinance.
>
> One of the first steps was a theoretical study along the lines of the enclosed, 'The Rates of Vaporization in Gasoline in Storage Tanks Exposed to Fire,' which was ultimately used as the basis for the typical bulk marketing tank of approximately 20,000 gallons capacity. There was a consensus among our fire prevention engineers that for such a tank we might reasonably expect absorption of heat energy at the rate of 100 Btu per minute per square foot of wetted surface.
>
> More recently there have been fragmentary data which indicated much higher heating rates than 6,000 Btu per square foot per hour for the entire wetted surface of smaller tanks such as tank truck compartments. These data encouraged me to suggest a variable heating rate such as that represented by the red line on the chart. One oil company has recommended the use of this assumption in the form of the equation
>
> $$h = \frac{48{,}000}{A^{0.5}}$$
>
> where h = heat absorbed to cause evaporation—Btu per hour per sq ft.
>
> A = external area of vessel.
>
> We are lacking in data on larger tanks but there seems to be a general feeling among fire protection engineers that this assumption is reasonably safe, particularly for the larger sized tanks.

This letter is typical of the replies of other authorities on the subject, and this lack of data led to the independent study in an attempt to solve our own problem.

Mr. Smith's Comment. "The National Board of Fire Underwriter's rule was based upon a modification of Fetterly's formula, using a flame temperature of 1200 F for tanks having a capacity of 10,000 gal or less, and 1000 F for tanks of 30,000 gal capacity or more, with adjusted temperatures for tanks of intermediate capacity. The heat input by this rule will vary between 23,000 and 13,000 Btu per sq ft per hr."

Authors' Reply. If this reference (the last sentence quoted) is intended to apply to Fetterly's formula, it is not in agreement with the figures ("these values are not questioned") to be found under the heading Analysis of Fetterly's Formula and Test, in Part 1 of the paper, where Fetterly's work is analyzed and compared with present-day theory. There is shown the figure of 14,500 Btu per hr per sq ft of wetted surface for an effective flame temperature of 1200 F, and for 1000 F temperature, 8100 Btu will result.

Mr. Smith's Comment. The authors' paper was severely criticized for proposing a solution for large vessels without giving actual data on large-scale fire exposures. It should be noted that Mr. Smith cites only one large-scale analysis, which is as follows:

Example: "(c-2) Approximately 2300 Btu per hr per sq ft on a sphere having a wetted surface of 4363 sq ft. This was a 48-ft-diam sphere subjected to a severe fire for 1 hr 7 min. At times the vessel was completely enveloped in flame. The relief valves were adequate and prevented failure of the sphere."

Authors' Reply. The report of this same case, dated June 5, 1941, was received from one of the eastern refiners on November 6, 1942. In it will be found that the vessel was surrounded by fire for only 10 min. The result of 2300 Btu per hr per sq ft was the average for 1-hr exposure. Maximum rates of heat absorption may, therefore, have been 6 times as great (13,800 Btu) for which the relief devices should be adequate in order to limit the pressure rise. This is an excellent example but its maximum and not average values should be used as guidance toward safety.

As explained in Part 3 of the paper, it is expedient for practical reasons to lower the design heat-absorption rates for large atmospheric vessels. The vessel described contained 6000 bbl. When a solution is made of Equation [24] from curve 3, Fig. 18, of the paper, for a tank of this capacity, a heat-absorption rate of 3670 Btu per hr per sq ft of wetted surface results. This compares favorably with 2300 Btu average when it is considered that both are arbitrary assumptions, but the authors would use a much higher rate for the hazardous and expensive sphere under consideration in accordance with Part 2 of the paper.

For further evidence to support this reasoning, the authors have observed 17-ft-diam × 19-ft 4 1/2-in-high aluminum tanks

completely surrouned by fire and melted down in a matter of a few minutes. This metal had a melting point of 1216 F. An effective temperature of this magnitude is commensurate with a heat-absorption rate of 15,000 Btu per hr per sq ft. Actual effective hot gas temperatures were probably higher than 1216 F.

Reply to Discussion by H. R. Zeigler

In the paper we tried to avoid the discussion of relief devices, their relative merits, etc. Suggestions were, therefore, confined to relief areas or relief connections, and their calculated capacities. Mr. Zeigler's statements, "One novel suggestion is that relief valves be made the same size on all vessels of the same capacity and pressure," and ". . . it is necessary to point out that this is based on the assumption that tanks should be equipped with relieving devices of sufficient capacity to promote interchangeability," are misinterpretations. We did say: "It being proposed, as already inferred, that the relief connection be the same size on all vessels of given capacity and range of working pressure. When equipment is so provided with adequate relief area for volatile compounds in the form of relief connections, the relief devices may be replaced to provide for any change in contents or more severe working conditions from the standpoint of relief requirements." We feel that the relief apparatus should be selected to pass the calculated vent rate at the same conditions, and this choice will govern its size. This procedure is given in the section Proposed Summary for Use, of Part 2.

We were not aware that the National Board of Fire Underwriters' Pamphlet No. 58 applied to processing and storage equipment other than that for liquefied petroleum gases. We have used specifications for relief requirements from Pamphlet No. 30 but not from No. 58. For that reason we do not know and did not say that the relief areas in No. 58 are inadequate. We merely plotted specifications from the latter for comparison.

It is unfortunate that it appeared we were trying to prove the inadequacy of Fetterly's formula. As a matter of fact, the evidence indicates that his method has given more accurate results than any other. With a given latent heat (not calculated by $L = 0.185\ T\ (V1 - V2)\ dP/dT$ as he proposed) and for low pressures, our formula gives relief areas only 10 per cent less than Fetterly's. This comparison will be found plotted in Fig. 10. Fetterly's heat-absorption rate of 22,600 Btu per hr per sq ft is based on the vaporization of 1000 lb of propane taking place in the observed time of 5.9 min. The other figures are merely cited to support this rate, and it will be noted that there is reasonable agreement among them. This analysis was mailed to Fetterly for criticism but no reply was received.

Finally, the magnitude of the observed rate (20,000 Btu) of heat absorption is the principal contention. This is a long story about which we and our critics have written many pages. It may be pointed out that rates as high as 20,000 Btu have been confirmed by five other organizations besides ourselves. A number of critics are in agreement on this figure except for large vessels. A summary of the tests and experience on which the 20,000 Btu rate and 1400 F effective temperature are based has been published.[46] Further, it may be noted that the average rate for our four tests was 19,688 Btu per hr per sq ft at an average temperature for the flame of 1357 F (820 C being 1508 F).

We are confident that future tests and analyses of vessels exposed to accidental fire will prove the proposed heat rate to be of the correct magnitude.

Wood-Cloth and Wood-Paper Laminates

By JOHN DELMONTE,[1] LOS ANGELES, CALIF.

A growing tendency exists for the use of wood and resin-impregnated cloth or paper, which is an outgrowth of laminated - plywood developments. Combinations of cloth and paper with wood, in addition to serving as vehicles for the bonding glue in the manufacture of the laminates, also help stabilize the wood assemblies and provide structural advantages, as demonstrated by test data given in the paper. For example, when a reasonably large number of paper laminates are used, there is an apparent increase in the tensile properties of wood, attributable to prestressing of the wood resulting from differences in coefficients of thermal contraction as parts are cooled upon removal from the press. Dimensional stability in plywood faced with phenolic-resin-treated cloth and paper is found to be far superior to unprotected plywood.

A NATURAL consequence of laminated-plywood developments and laminated-plastic-material developments is a trend toward intermediate products combining wood and resin-impregnated cloth or paper. While it will be acknowledged that there are applications best served by wood alone or other applications best fulfilled by plastics materials, there are various properties developed by their combination that are not possessed fully by either material itself. There are not many evidences as yet of extensive adaptation of resin-impregnated cloths or papers with wood although a few are in the process of development for aircraft applications.

Examining the fundamental properties of wood, one will admit its superior advantages of low cost, light weight, and high strength although he will also recognize its anisotropic tendencies and susceptibility to moisture. Plywood developments were a logical evolution in that they balanced physical properties more evenly and reduced the effects of swelling. However, while resin-bonded plywoods were a step in the right direction, even these have not always possessed the necessary dimensional stability required of aircraft materials, in spite of synthetic-resin bonding agents, such as phenol formaldehyde, urea formaldehyde, and melamine formaldehyde. Elaborate finishing schedules offer some measure of protection to the plywood, but even these are beset by numerous practical problems (1).[2]

The most noteworthy developments for stabilizing plywood have been suggested by the Forest Products Laboratory (2, 3) in their publications upon resin-impregnated wood. This well-known technique involves a procedure of impregnating thin wood veneers with a water-soluble phenolic resin and curing the resin in the veneer by heat alone (Impreg), or by combination of heat and pressure (Compreg). Approximately 30 per cent resin diffused into the cell walls of the wood fibers has resulted in a decided improvement in wood-stabilizing characteristics, particularly against swelling effects of moisture. What few objections have been raised against these techniques include the following:

1 Increase in density without a substantial gain in strength.

2 Added difficulties in performing secondary gluing operations in aircraft as compared with unimpregnated plywood.

3 Problems of obtaining proper impregnation and its determination.

Also to be noted are the developments of superpressed plywood and multiple-phenolic-resin films which increase the ratio of resin to wood (4). High laminating pressures above 1000 psi have been employed to increase the penetration of resin into the wood. The cardinal advantage of this process is the development of superior shear strength in the plywood, which greatly increases for a slight increase in density. On the other hand, the rate of increase of tensile strength and compressive strength over density is only slight. This development is also significant in the technique of increasing resin content by adding multiple layers of phenolic-resin film, a procedure which would be unnecessarily prolonged if spraying were resorted to.

Both of these fairly recent developments in stabilizing plywood have taken into account the advantages of increasing the ratio of synthetic resin to wood in order to stabilize the wood. Ordinary synthetic-resin-bonded aircraft plywood contains anywhere from 10 to 25 lb per 1000 sq ft of dry-glue spread sufficient for good bonding, high shear strength, and good water resistance at the glue lines only.

The combinations of resin-impregnated cloth and papers with wood fulfill more than the function of vehicles for the glue; they also help to stabilize the wood assembly as well as make possible structural advantages as various test data disclosed in this paper will reveal. In addition, the wood-cloth and wood-paper laminates make possible more complicated assemblies and constructions, difficult with plywood alone.

Physical Test Conditions

Unless stated otherwise the various physical tests reported upon in this paper were performed upon wood-cloth or wood-paper laminates which had been conditioned at 50 per cent relative humidity for at least 48 hours in order to realize approximately 10 per cent moisture in the wood. Tests were performed under prevailing atmospheric conditions which, for the most part, were at room temperatures of 70 to 80 F, and relative humidities of 35 to 45 per cent. All tensile tests and flexural tests followed A.S.T.M. Standards for flat sheets of plastics materials (5). Specific-gravity determinations were made by measuring the volume of accurately machined samples and dividing this value into the weight. The moduli of elasticity reported were obtained by the simple cantilever-beam technique. This method is described elsewhere in its adaptation to plastics materials (6).

Test Laminates

The following laminates were prepared for physical tests and tests of dimensional stability under extremes of moisture condition. In Groups I and II the base material was standard-aircraft-grade 3-ply vertical-grain plywood with two birch faces and poplar core.

Group I:

(*A*) Plywood base, two birch faces, poplar core; over-all thickness 0.106 in.

(*B*) Resin-impregnated paper,[3] 2 layers on each face of plywood-base core (*A*)

(*C*) Resin-impregnated paper,[3] 5 layers on each face of plywood-base core (*A*)

---

[1] Technical Director, Plastics Industries Technical Institute. Mem. A.S.M.E.

[2] Numbers in parentheses refer to the Bibliography at end of paper.

Contributed jointly by the Rubber and Plastics Group and Aviation Division and presented at the Semi-Annual Meeting, Los Angeles, Calif., June 14–17, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

(*D*) Resin-impregnated paper,[a] 10 layers on each face of plywood-base core (*A*)

[a] Consolidated Water Power & Paper Company; phenolic-resin content, 35 per cent.

NOTE: Group I samples were laminated at 250 psi for 10, 15, and 20 min at 310 to 320 F, for increasing layers of paper.

Group II:

(*A*) Plywood base, two birch faces, poplar core; over-all thickness 0.106 in.
(*B*) Phenolic-resin-impregnated canvas,[b] 1 layer on either face of plywood-base core (*A*)
(*C*) Phenolic-resin-impregnated canvas,[b] 2 layers on either face of plywood-base core (*A*)
(*D*) Phenolic-resin-impregnated canvas,[b] 5 layers on either face of plywood-base core (*A*)

[b] 9-oz canvas duck, phenol-formaldehyde impregnating resin varnish (BV-1115), 38 per cent resin content.

NOTE: Group II samples were laminated at 250 psi for 20, 25, and 30 min at 310 to 320 F for increasing layers of cloth.

Group III:

(*A*) Three-ply birch veneer, 0.032 in. thick, core cross-grain; phenolic-resin bonding agent, PR-14 (Amberlite)
(*B*) Similar to (*A*) except 2 phenolic-resin-impregnated papers added between each ply
(*C*) Similar to (*A*) except 5 phenolic-resin-impregnated papers added between each ply

NOTE: Group III samples were laminated at 250 psi, and 325 F for 15 min. Plywood shear tests were performed in accordance with AN-NN-P-511b Army-Navy Specification for Plywood and Veneer, dated October 28, 1942.

Group IV:

Two parallel-grained birch veneers, 1/16 in. thick, between which are laminated:

(*A*) 1 phenolic-resin-impregnated paper
(*B*) 5 phenolic-resin-impregnated papers
(*C*) 10 phenolic-resin-impregnated papers
(*D*) 20 phenolic-resin-impregnated papers

Group V:

Two cross-grained birch veneers, 1/16 in. thick, between which are laminated:

(*A*) 1 phenolic-resin-impregnated paper
(*B*) 5 phenolic-resin-impregnated papers
(*C*) 10 phenolic-resin-impregnated papers
(*D*) 20 phenolic-resin-impregnated papers

NOTE: Groups IV and V were laminated at 250 psi and temperature of 320 F for 20 min (*A* and *B*), 25 min (*C*), and 30 min (*D*).

RESULTS OF TESTS ON PHYSICAL PROPERTIES

The results of tests on the laminated assemblies may be divided into two groups, i.e., physical properties and dimensional stability under extremes of moisture conditions. The physical properties are presented first.

Results of physical tests upon Group I and Group II laminates are shown in Table 1. In order to keep variables to a minimum, laminating pressures of 250 psi are employed for these laminates as well as the others. This pressure likewise is not too far removed from those employed in rubber-bag-molding operations. Data reported for the straight plywood (10 per cent moisture) compare favorably with those reported in other publications (7). The most obvious improvement in physical properties is apparent in the wood-paper laminates (Group I). Not only are values of the tensile strength and modulus of elasticity decidedly improved but also the specific tensile strength, which is equal to the ultimate tensile value divided by the specific gravity. These improvements are due largely to the excellent properties of the phenolic-resin-impregnated paper employed in conjunction with the plywood.

Manufacturers' specifications for laminates of paper alone at 250 psi are as follows:

Ultimate tensile strength (with grain) 36,000 psi
Modulus of elasticity (with grain) 3,000,000 psi
Specific gravity, 1.38
Water absorption, 6 per cent (24 hr)

Unless indicated otherwise the test data of this report were obtained in a direction parallel to the grain of the impregnated paper. It was further observed that properties for the straight laminated paper decreased somewhat (tensile strength at 33,000 psi, for example), when the material was conditioned for several days at 50 per cent relative humidity. It was pointed out earlier that all the wood laminates were conditioned in this manner.

Table 1 also reports the stiffness factors ($E \times I$) for the various laminates assuming, for purposes of comparison, a constant panel weight of 0.5 lb per sq ft and then estimating moments of inertia from

$$I = \frac{bh^3}{12}$$

where b = 1 in.
h = thickness which at specific gravity indicated in Table 1 will give 0.5 lb per sq ft
I = moment of inertia.

Plywood faced with a few sheets of impregnated paper shows slight gains in the stiffness factor. While plywood faced with resin-impregnated canvas does not register the gains shown for the wood-paper laminates, the data nevertheless demonstrate the versatility of plastic materials in securing moduli of elasticity at very much lower values than with plywood alone. To the stress engineer this suggests decreased stiffness factors, but to the fabricator of compound curvatures it suggests an easier material to fabricate plus the added advantage of better dimensional stability under adverse weather conditions.

The load distribution within the various components of wood-cloth and wood-paper laminates are basically dependent upon the moduli of elasticity of the different components. For pure tension and pure compression it is obvious that

$$\delta = \frac{S_1}{E_1} = \frac{S_2}{E_2}$$

Cross-grain birch:		
Faces 1, impreg; paper core	3220	137000
Faces 5, impreg; paper core	7640	170000
Faces 10, impreg; paper core	12200	250000
Faces 20, impreg; paper core	17670	491000

where δ = unit deformation in composite assembly of material No. 1 and material No. 2
S_1 and S_2 = unit stresses in No. 1 and No. 2
E_1 and E_2 = moduli of elasticity in No. 1 and No. 2

Likewise, for calculating stress at any point within the plywood panel, the formula developed for straight plywoods (8) may be applied to cloth-wood and paper-wood laminates, considering the layers of paper or cloth in the same category as a layer of wood veneer

$$S_L = \frac{E_L}{E_P} \cdot \frac{M_P C}{I_P}$$

where S_L = stress in layer or laminate in question
E_L = modulus of elasticity of that laminate alone
M_P = bending moment at point in question
C = distance from neutral axis to layer or laminate in question
E_P = apparent modulus of entire plywood panel (see Table 1)
I_P = moment of inertia of entire plywood panel

Group III laminates were prepared largely with the idea of observing the effects of impregnated paper upon the shear strength of plywood. Samples were cut in accordance with the Army-Navy Aeronautical Specification for plywood and veneer (9) and tests performed as required. Results of these tests, disclosed in Table 2, demonstrate that all the plywood samples with and without impregnated papers at the glue line, passed the minimum requirements of the specification. However, there was a small, but definite decrease, in shear strength with an increase in paper content. This was occasioned by the appearance of paper failure which was marked by a separation of the fibers of the paper. Dry shear tests were performed upon five samples for each reading record in Table 2, after 48 hr conditioning at 50 per cent relative humidity.

Groups IV and V laminates serve the purpose of revealing further fundamental data on the co-relationship of paper and wood. While the plywood-paper samples prepared are unbalanced in the sense of uniform grain direction for the wood, without the benefit of cross-plies, results on the load distribution within the wood and impregnated paper are interesting. In Fig. 1, the marked increase in tensile strength, for example, is to be expected from the excellent properties of the paper employed. As indicated earlier, the ultimate tensile strength of this particular laminated paper alone is 36,000 psi, after dry conditioning, and about 33,000 psi after 50 per cent relative-humidity conditioning. It is significant, however, that the increase in tensile strength of the wood is greater than would be expected upon the addition of the paper. This is illustrated on the right-hand side of Fig. 1. In other words, assuming constant tensile strength for the laminated paper, the apparent strength of the wood increases with greater amounts of impregnated paper. These data were obtained, for pure tension, as follows:

$$P_1 + P_2 = P = A_1S_1 + A_2S_2$$

where P_1 = portion of load carried by impregnated paper
P_2 = portion of load carried by wood veneer
A_1 = cross-sectional area of paper laminate
A_2 = cross-sectional area of wood veneer
S_1 = stress intensity in paper laminate
S_2 = stress intensity in wood veneer
P = total load

Using the foregoing formula and calculating load distribution for increasing amounts of paper laminate, the increase in P could not be accounted for solely by the increase in high-strength-paper content. However, it is possible that thermal-expansion coefficients vary and upon removal of the laminate from the hot plates of the press, the wood veneers were under initial stress due to greater shrinkage of the laminated phenolic-paper layer upon cooling. Then

$$P = A_1S_1 + A_2S_2 + KE_2A_2$$

where K = unit deformation due to thermal-expansion difference during manufacture
E_2 = modulus of elasticity of wood veneer

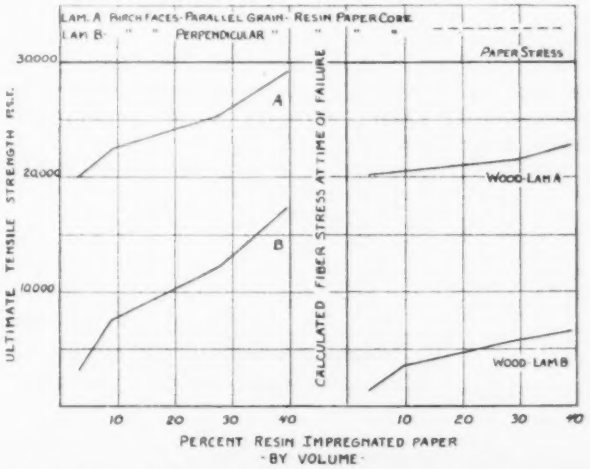

FIG. 1 ULTIMATE TENSILE STRENGTH OF WOOD-PAPER LAMINATES

In Table 3, are reported physical properties of Groups IV and V laminates after conditioning at 50 per cent relative humidity.

Results of Tests on Dimensional Stability

The effects of moisture gradients upon wood laminates are to bring about severe dimensional distortion. While the developments of synthetic-resin adhesives for the glue lines have created the so-called "waterproof" plywood, in the sense that shear failures would no longer be due to deterioration of the glue line the resin adhesives will not protect the wood structure itself. Faced with very large tangential and radial shrinkage in all wood veneers, plywood manufacturers are ever concerned with the avoidance of warping and distortion in plywood panels. Much care is necessary in preconditioning the wood veneers to uniform moisture content, and then in afterconditioning to compensate for loss of moisture in hot-pressing or the introduction of moisture from the glue.

As pointed out earlier, synthetic-resin impregnants have stabilized wood by greatly reducing the effects of moisture. Some stabilization is achieved by facings of impregnated canvas and impregnated paper on the outside of the plywood core (Groups I and II laminates) by creating a moisture barrier. The effectiveness of phenolic-resin-impregnated paper and cloth in stabilizing plywood may be determined by means of a test designed to measure distortion in plywood upon exposure to severe moisture gradients.

As shown in Fig. 2, one side of a plywood test sample was coated with a metal face, 1 mil in thickness, which extended up the sides of the test sample, excluding moisture from all surfaces except the top surface. Upon placing the plywood sample in a pan of water, immediate deformations are apparent as the plywood fibers in direct contact with the water begin to swell. This swelling or distortion in the 5-in. test length is measured with a depth gage, as shown in Fig. 2. Results are clear-cut and comparisons may be made in a short period of time, without any delay being necessitated for the less-significant percentage of water absorbed.

All test samples were conditioned at 50 per cent relative humidity for at least 48 hours prior to test, and distortion is less than would have occurred if the materials were started from a perfectly dry condition. However, the interest lies largely in the comparative results.

Data shown in Figs. 3 and 4 illustrate the distortion in plywood as a function of time. It is quite obvious that resin-treated papers and cloth greatly improve the dimensional stability of plywood by retarding the effects of moisture. The distortion curve for plywood alone demonstrates a peak value, indicative that moisture has diffused through the plywood and that the fibers nearest the protective metal foil have begun to swell counteracting the swelling on the exposed side. When the test is carried out for a long period of time the distortion in the plywood is largely recovered.

For purposes of comparison, the more conventional A.S.T.M.

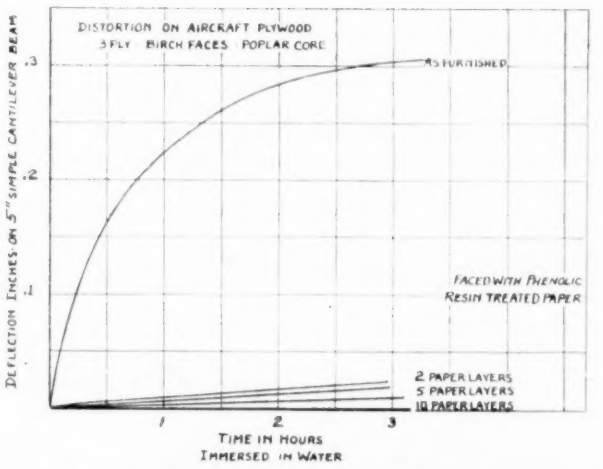

Fig. 3 Distortion in Plywood Faced With Phenolic-Resin-Treated Paper

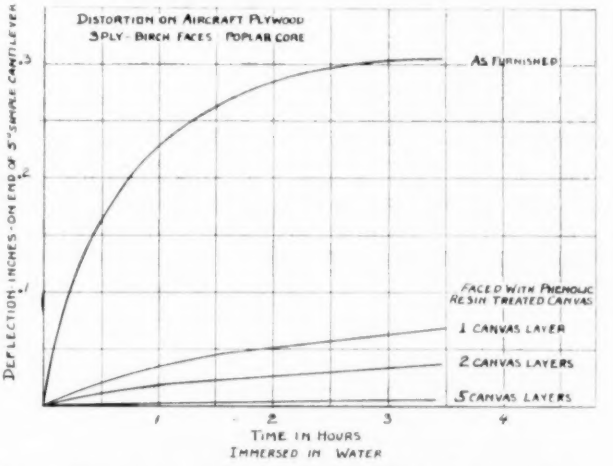

Fig. 4 Distortion in Plywood Faced With Phenolic-Resin-Treated Canvas

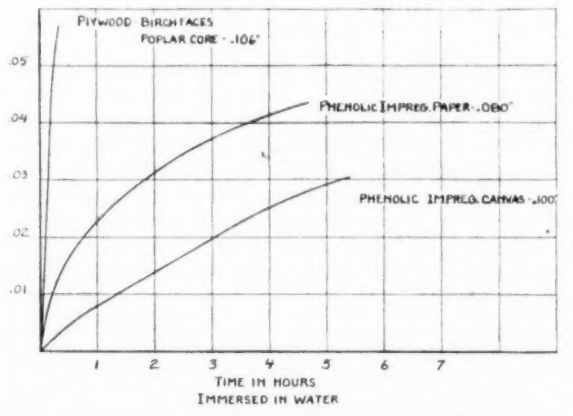

Fig. 5 Distortion of Laminated Canvas and Laminated Paper in Contact With Water

tests were performed upon plywood faced with one and two layers of phenolic-resin-treated canvas. Pieces which were dry-conditioned measured 1 in. × 3 in., the sides being protected against moisture by metal foils. The results follow:

Material	Water absorbed (in 24 hr), per cent
Plywood faced with one phenolic-resin-treated canvas	8.4
Plywood-faced with two phenolic-resin-treated canvas	3.1

As may be suspected, the plywood distortion in moisture may not be attributed to the plywood alone, but also to the resin-impregnated canvas and paper. This is borne out by the disclosures in Fig. 5 which show distortion of laminated canvas and laminated paper when they are brought in contact with water as shown in Fig. 2.

That some of the combinations with plywood show even lower distortions is explained by the greater over-all thicknesses of these assemblies.

Conclusions

It is apparent that there are physical advantages to be realized from the combinations of resin-impregnated paper and cloth with plywood; particularly for the high-strength paper employed in these tests. There is some evidence that when a reasonably large number of paper laminates are present there is an apparent increase in the tensile properties of the wood attributable to prestressing of the wood brought on by differences in coefficients of thermal contraction as parts are cooled upon removal from the press.

While resin-impregnated canvas did not add greatly to the physical properties of the plywood, the molders and fabricators of plywood parts would do well to recognize the benefits of canvas in its stretchability, allowing the attainment of smaller radii of curvature and a certain amount of drawing impractical in wood alone. This would suggest the usefulness of phenolic-resin-impregnated canvas in fulfilling discontinuities in a cloth-wood combination.

Dimensional stability in plywood faced with phenolic-resin treated cloth and paper is far superior to unprotected plywood. This advantage alone should suggest to manufacturers of aircraft plywood that a few facings of impregnated paper or cloth would improve the qualities of their products.

Acknowledgment

Acknowledgment is given to Mr. Foster Luce, Mr. E. Watkins, and Mr. W. F. Lusk of the Plastics Industries Technical Institute staff for assistance in preparation of some of the samples and performance of some of the physical tests, data for which are given in this paper.

Superchargers for Aircraft Engines

By R. G. STANDERWICK[1] AND W. J. KING,[1] WEST LYNN, MASS.

This is a comprehensive treatment covering the development of turbosuperchargers, which today are making possible the outstanding performance at high altitudes of United States military aircraft. The basic function of supercharging is to increase the intake-manifold air pressure in an engine, as a result of which the primary objectives are attained of (*a*) maintaining full (rated) power at altitude; (*b*) increasing power at sea level; (*c*) improving fuel economy for cruising. Fundamental design considerations cover the means for accomplishing these ends, with some indication of the power requirements, temperature effects, and the like. Types of superchargers are discussed, and their systems of drives, and then particular attention is devoted to the General Electric turbosupercharger, as used on the Boeing Flying Fortress, Consolidated Liberator bomber, and Lockheed Lightning, and Republic Thunderbolt pursuit ships. Final sections of the paper are concerned with a comparison of various types of superchargers, and the present and future prospects for this most important aircraft-engine auxiliary.

Fundamentals of Supercharging

THE basic function of supercharging is to increase the intake-manifold air pressure in an engine. This has two immediate results; (*a*) the density of the charge forced into each cylinder is increased, and (*b*) a favorable excess or differential is maintained in the intake manifold pressure with respect to the exhaust back pressure. These two effects are utilized to accomplish the primary objectives of supercharging aircraft engines, as follows:

1 To maintain full (rated) power at altitude.
2 To increase power at sea level ("ground boosting").
3 To improve fuel economy for cruising.

A further effect of supercharging, which is beneficial in each of these respects, is to promote fuel vaporization and uniform distribution of mixture to the individual cylinders.

In order to appreciate the nature of the problem, in reference to these objectives, it is first necessary to take account of a few of the elementary relationships underlying the performance of present-day aircraft engines.

Other things being constant, the indicated horsepower developed in an engine is directly proportional to the mass rate of air consumption (as pounds per minute). For a given speed this means that the power is proportional to the density of the air, which is a function of its pressure and temperature. As a fairly close approximation (1),[2] the brake horsepower of an engine varies directly with the absolute pressure, p, and inversely as the square root of the absolute temperature, T, of the carburetor inlet air, as expressed in the formula

$$\frac{\text{Bhp}_0}{\text{Bhp}_1} = \frac{p_0\sqrt{T_1}}{p_1\sqrt{T_0}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where the subscripts 0 and 1 refer to standard sea-level and altitude conditions, respectively.

Altitude Effects. Fig. 1 shows how these factors vary with altitude in a representative modern aircraft engine, except unsupercharged, using standard N.A.C.A. atmospheric data (2). A glance at this should suffice to indicate the occasion for supercharging military-airplane engines, where it is so vitally important for the engine to be capable of developing its full power at any level within its altitude range.

The significant fact here is that by the application of a suitable supercharger the same engine which gave less than 30 per cent

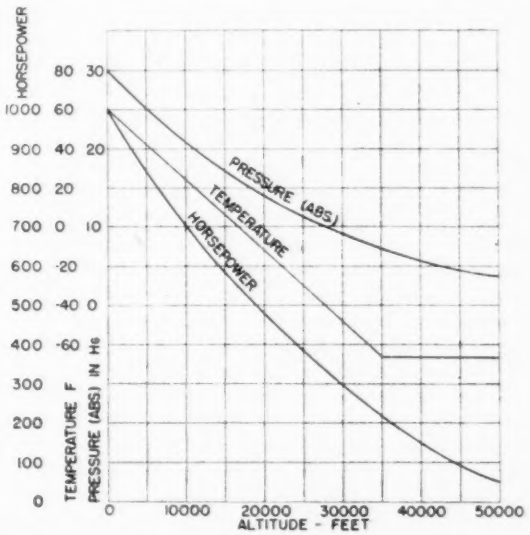

FIG. 1 VARIATION IN ATMOSPHERIC PRESSURE AND TEMPERATURE WITH ALTITUDE AND EFFECT UPON ENGINE POWER

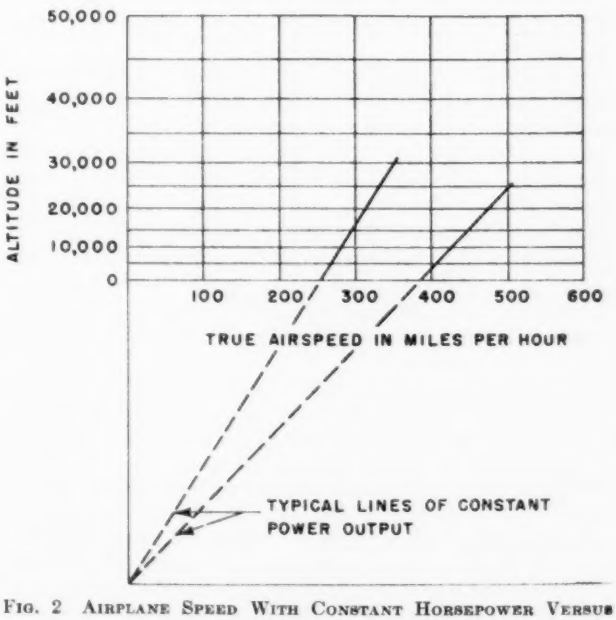

FIG. 2 AIRPLANE SPEED WITH CONSTANT HORSEPOWER VERSUS ALTITUDE

[1] Supercharger Engineering Division, General Electric Company.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Aviation Division and presented at the Semi-Annual Meeting, Los Angeles, Calif., June 14–17, 1943, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

of its full power at 30,000 ft can be made to deliver 100 per cent power all the way from sea level to that altitude, and beyond. With proper attention to such factors as propeller design, propeller and engine speeds, and type of supercharger, it is further possible to maintain substantially the same fuel-consumption rate (pounds per horsepower-hour) at altitude as at sea level.

These two facts have a direct bearing upon the curves in Fig. 2, which shows the variation in the speed of a given airplane with altitude, if the engine power output can be held constant. This chart is calculated from theory and assumes constant propeller and airplane efficiency. Under these conditions, it may be seen that a plane having a speed of 250 mph at sea level may attain a speed of 350 mph at 30,000 ft, for the same power and time rate of fuel consumption. Of course actual airplanes will not follow this chart exactly, but Kendall Perkins of Curtiss Wright states that, on the average, the speed of a plane will increase by 1 per cent for each 1000 ft of altitude (3). Very likely a higher figure can be realized in a suitably designed plane. At all events it is clear that the ability to maintain power at high altitudes results in marked improvements in peak performance of the plane, saving valuable time in military or commercial operations, and increasing the speed at which satisfactory over-all economy can be maintained.

Ground Boosting. Superchargers can also be used very effectively for ground boosting, i.e., increasing the sea-level power of the engine, since the indicated mean effective pressure (imep) and horsepower are proportional to the intake-manifold air pressure (map). With a moderate allowance for friction and accessory power loss in the engine, the brake-mean-effective-pressure values, (bmep) and brake horsepower (bhp) likewise increase very nearly linearly with the manifold air pressure. Of course, the power output of an engine can also be increased by increasing the compression ratio, but the interesting fact here is that a given increase in bmep and bhp can be obtained with a considerably smaller rise in maximum cycle pressure and temperature by means of supercharging. The result is that the manifold pressure can be boosted to yield a substantially greater power output before the allowable limit is imposed by stresses, temperatures, or detonation. It is entirely practicable, for example, to increase the output of an unsupercharged engine from 500 to 800 hp by boosting the manifold air pressure from 29 to 40 in. Hg abs, without changing the speed. This extra power is frequently of great value in facilitating take-off.

In all of the foregoing comparisons, the engine speed has been assumed to remain constant. The variation of power with speed is expressed by the formula

$$\text{Bhp} = \text{const} \times \text{bmep} \times \text{rpm} \quad [2]$$

High power is therefore commonly obtained by a combination of high speed and high bmep. High speed is attained by setting the variable-pitch-propeller governor to hold the desired revolutions by appropriate adjustment of the propeller-blade angle, and high bmep is secured by boosting the manifold pressure either by opening the throttle or increasing the speed of the supercharger (if the latter is controllable).

Cruising Power. For cruising, the power can be reduced either by reducing the speed or the bmep, or both. If the propeller efficiency is not impaired, it is definitely more economical to reduce power by reducing the speed, keeping the bmep as high as practicable. This is a consequence of the reduction in engine friction losses at the lower speeds. When the speed is reduced for this purpose at cruising altitudes, it is frequently found that the most economical values of map and bmep cannot be attained even with full opening of the throttle without a considerable amount of boosting from the supercharger. As an example to help make this clear, the following figures are cited for a hypothetical engine for which the value of the constant in Equation [2] is 0.0025:

Power	Cruising (maximum economy)	Full
Manifold air pressure, in. Hg	30	47
Brake mean effective pressure, psi	140	220
Speed, rpm	1200	2700
Power, bhp	420	1485

At 15,000 ft, the manifold pressure could not be more than about 16.5 in. Hg without supercharging. This would yield a bmep of approximately 77 in. Hg, which would require a speed of 2180 rpm to produce the 420 bhp for cruising. The fuel consumption at this speed would normally be appreciably greater than at 1200 rpm. To maintain 420 bhp at still lower speeds would probably require richening of the fuel-air mixture to avoid detonation, and the propeller efficiency might be considerably reduced.

Supercharger Operating Range. Another serious obstacle to the maintenance of high manifold pressures for cruising is the limited range of satisfactory operation of superchargers now in common use, as indicated in Fig. 3. In this figure, Q represents

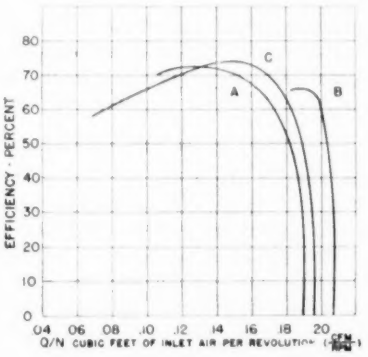

FIG. 3 TYPICAL RANGE CURVES OF SUPERCHARGERS

the volume flow of air supplied to the engine cfm, and is proportional to the engine power, at any given altitude; N is the supercharger speed, rpm, which is the chief factor in determining the pressure (map) supplied to the intake manifold. The useful operating range of a supercharger refers to the spread between the lower value of Q/N, usually established by the incidence of violent surging or instability, and the upper value beyond which the efficiency falls off very rapidly. Curve A is representative of the modern centrifugal supercharger. The significance of these curves will be discussed further. For the present purpose it will suffice to observe that curve A indicates the difficulty of attempting to reduce Q for very low power outputs while maintaining N at a relatively high level, in order to employ high manifold pressures. In addition to the fact that this tends to push the value of Q/N into the unstable region beyond the left end of the curve, a very flexible speed control is required to allow N to be maintained when the engine speed is reduced to less than one half of its maximum rating.

Differential-Pressure Effects in the Engine. Apart from its prime function of increasing the density of the charging air forced into the engine cylinders, supercharging has a further beneficial effect in promoting the scavenging of spent gases from the clearance volume, at the end of the exhaust stroke. Since the intake-manifold pressure is higher than the back pressure some of the hot residual gas is forced out during the "overlap" interval between the opening of the intake valve and the closing of the exhaust. This improves the volumetric efficiency, lowers the initial temperature of compression, and reduces the tendency to backfire with lean fuel-air mixtures.

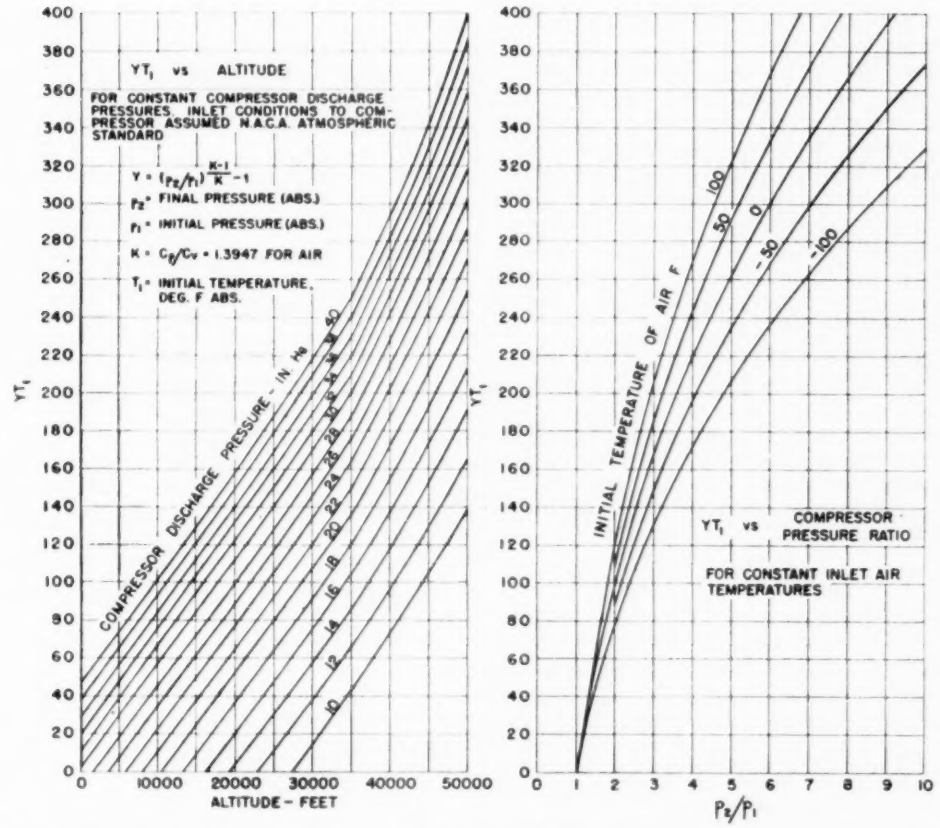

FIG. 4 VARIATION OF FUNCTION YT_1 WITH ALTITUDE, PRESSURE RATIO, AND INITIAL TEMPERATURE

The excess of the intake pressure over the exhaust must be taken into account in computing the effect upon the net engine power of the power required to drive the supercharger. A substantial portion of the latter, roughly 40 per cent, is returned to the engine in the form of "steam-engine power," which is the excess of the work done on the pistons during the intake stroke over the work done on the spent gas during the exhaust stroke.

Power Required for Driving Supercharger. Present-day aircraft engines consume about 0.12 lb of air per min per hp delivered. The power required to compress this air is determined chiefly by the ratio of the final to the initial absolute pressures, p_2/p_1, and the absolute temperature, T_1, of the inlet air. The theoretical power for isentropic compression is given by the formula (reference 4)

$$\text{Hp} = 0.00573\ YT_1 \text{ per lb air per min} \quad [3]$$

where

$$Y = (p_2/p_1)^{0.283} - 1$$

and T_1 is in deg F abs.

Values of the function YT_1 are given in Fig. 4. The curves on the left are based on the assumption that p_1 and T_1 correspond to the standard N.A.C.A. atmospheric values of Fig. 1, for each altitude. The curves on the right give the same function for the particular pressure ratio and inlet temperature involved in any case. To obtain the compressor-shaft-input power, the values obtained from Equation [3] must be divided by the efficiency.

In many practical cases p_1 may be assumed to be equal to the prevailing atmospheric pressure in flight, since the pressure drop in the upstream induction system is roughly balanced by the "ram" or kinetic pressure of the slipstream impinging upon the air scoop. For the typical internal-geared supercharger p_2 is the manifold pressure. Assuming a compressor efficiency of 70 per cent, the power required to develop 1000 hp at 10,000 ft with a manifold pressure of 32 in. Hg can then be obtained from Fig. 4 and Equation [3] as follows

$$YT_1 = 65$$

$$\text{Hp} = \frac{0.00573 \times 65 \times 120}{0.7} = 63.8$$

(This must again be divided by the mechanical efficiency of the drive train to obtain the power taken from the engine crankshaft.) The pressure ratio in this case is 1.55. For comparison, a supercharger to maintain 40 in. Hg of manifold pressure at 25,000 ft would have to develop a pressure ratio of 3.6, which would require an input of about 185 hp per 1000 hp of engine power.

The newcomer to this field sometimes finds it difficult to understand how a device which extracts such sizable blocks of power from the engine can be applied to sustain, or even increase, the net engine output. Perhaps this can be appreciated more readily from the analogy which it bears to the forced-draft blower of a stoker-fired furnace of a steam power plant, where a few hundred horsepower input to the blower enables the furnace to burn enough additional coal to generate several times the initial investment in power. Moreover, as mentioned, the supercharger compressor actually pumps a substantial portion of its shaft power back into the engine (5). For the electrical engineer the supercharger may be compared with the grid of an electronic tube, when the grid system is used to control the relatively large plate-circuit power in a regenerative hookup. The fact is that the supercharger is being employed to an increasing degree as the

primary means of controlling the power of an airplane engine, in place of the carburetor throttle.

Temperature Effects. Unfortunately, air cannot be compressed even with the perfect efficiency of an isentropic process, without a significant rise in temperature, unless the heat of compression is removed by cooling during the process. In aircraft superchargers it is not practicable to effect any appreciable amount of cooling in the compressor itself; in fact, the surface area is so small relative to the mass flow of air that the process is substantially adiabatic (and polytropic).

For an adiabatic process, the minimum temperature rise occurs in the case of reversible, isentropic compression, i.e., when the compressor efficiency is 100 per cent. In this case, the ideal temperature rise is numerically equal to the function YT_1 of Fig. 4

$$T_2 - T_1 = YT_1 \quad [4]$$

and the actual temperature rise in any case is this value divided by the compressor efficiency. This is the source of the very convenient and commonly used expression for compressor efficiency, otherwise known as the "temperature-rise ratio"

$$e_t = \frac{YT_1}{T_2 - T_1} \quad [5]$$

which should be equal to the actual shaft efficiency if there is no heat transfer to or from the surroundings.

Equation [4] and Fig. 4 can now be used to determine the temperature rise of the air in the foregoing examples of supercharger power. For the 32-in. manifold pressure at 10,000 ft

$$T_2 - T_1 = YT_1/0.7 = 65/0.7 = 93 \text{ F}$$

and for the 40-in. pressure at 25,000 ft

$$T_2 - T_1 = 188/0.7 = 269 \text{ F}$$

With an inlet-air temperature of —30 F, the manifold temperature in the latter case would be 239 F. This would be intolerably high, according to present standards, for reasons which will be discussed later. In practice, the total pressure ratio of 3.6 involved in this case would be divided between two stages of compression with an intercooler between them, as indicated in Fig. 5. With the conditions assumed in this illustration the manifold temperature would be reduced to 134 F.

Referring further to Fig. 5, the first-stage discharge pressure is commonly set at 31.67 in., in order to maintain standard sea-level pressure, 29.92 in., at the carburetor inlet, allowing for a drop of 1¾ in. Hg in the intercooler and ducting. The temperature rise in each stage was obtained from Equation [4], allowing for a compressor efficiency of 70 per cent. It will be observed that the first-stage pressure ratio, p_2/p_1, is 31.67/11.1 = 2.85, whereas the second-stage ratio is 40/28.6 = 1.4, in order to make

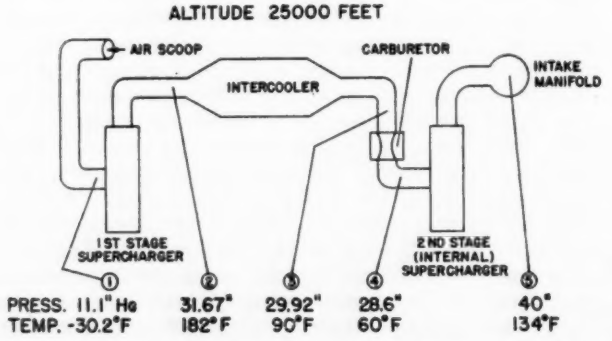

FIG. 5 PRESSURES AND TEMPERATURES IN A TYPICAL TWO-STAGE INDUCTION SYSTEM

more effective use of the intercooler. (Occasionally an aftercooler is used between the final stage and the manifold, but this is not convenient in radial engines.) The so-called "intercooler effectiveness" is the ratio of the drop in temperature of the compressed air to the initial temperature difference with respect to the ambient, or

$$\frac{t_2 - t_3}{t_2 - t_1} = \frac{182 - 90}{182 - (-30)} = 43.4 \text{ per cent}$$

which represents a compromise in performance to reduce cooler weight. The drop of 30 F in the carburetor is due to the absorption of latent heat by the evaporating gasoline. In some cases, most of this occurs in the passages of the internal supercharger, but the effect is about the same.

There are at least three reasons for limiting the manifold temperature to the lowest practicable level:

1 To avoid detonation or "knocking" in the engine, which has such a serious effect upon engine life as to constitute a major limitation to the allowable power rating. As the mixture temperature increases, fuel of higher-octane rating must be employed to maintain constant intensity of detonation.

2 To increase the density of the charge supplied to each cylinder, thereby increasing the power developed, as per Equation [1].

3 To reduce the combustion and exhaust temperatures of the engine.

These three results are promoted by improving the efficiency of the supercharger, which reduces the temperature rise during compression. In addition, any improvement in first-stage efficiency reduces the work of compression in a second stage by reducing the value of T_1 in Equation [3].

On the other hand, these same results can be promoted by increasing the effectiveness of the intercooler. In either case higher efficiency or effectiveness inevitably results in greater size and weight, at a given stage of the art. Optimum installation design therefore calls for a careful compromise of these factors to obtain best over-all performance, with due regard for total drag, power, and supercharger operating speed.

TYPES OF SUPERCHARGERS

Two basic types of compressors have been used to supercharge internal-combustion engines:

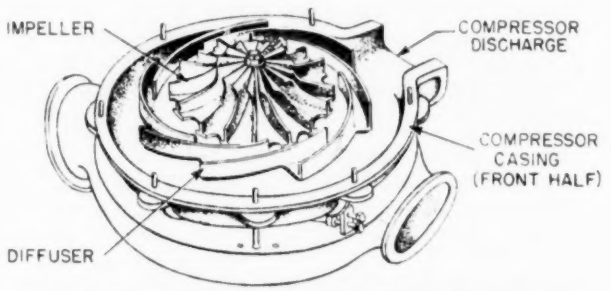

FIG. 6 CENTRIFUGAL COMPRESSOR IN TURBOSUPERCHARGER

1 The "positive-displacement" type, of which the Roots blower is a prominent example. This has two rotors carrying lobes which mesh with each other as do gear teeth, and which during their rotation open and close a displacement space between the dumbbell-shaped lobes. An excellent description of this blower was given by John L. Ryde in a recent S.A.E. paper (6). It has not been applied to the supercharging of airplane engines to any appreciable extent since the N.A.C.A. tests of 1930, reported by Oscar Schey (7). Other positive-displacement pumps,

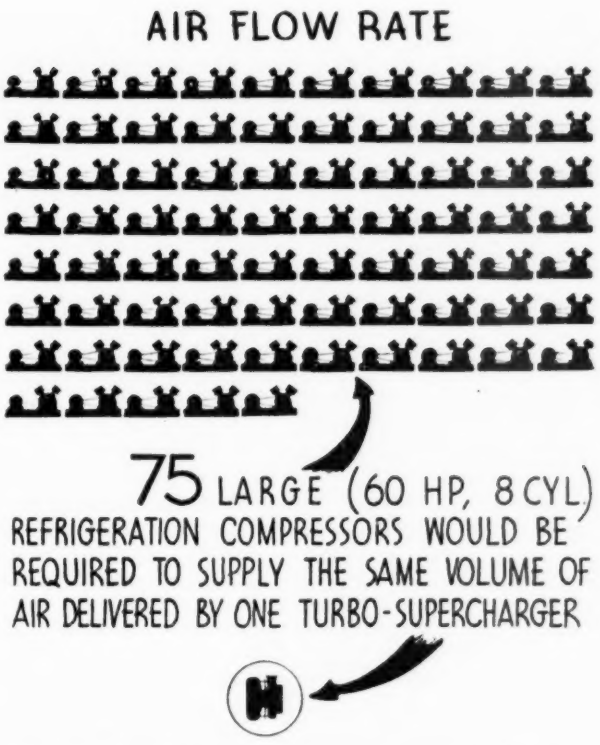

FIG. 7 CONTRAST BETWEEN SUPERCHARGER AND EQUIVALENT RECIPROCATING COMPRESSORS

such as the rotary-vane and reciprocating-piston types, have not been well adapted for use in aircraft, principally because of their relatively large size and weight for a given capacity.

2 The "centrifugal" type, the principal elements of which are a multivaned impeller and an annular diffuser, Fig. 6, enclosed in a suitable casing, which includes a collector or scroll surrounding the diffuser. The impeller is driven at speeds of the order of 20,000 to 30,000 rpm, with peripheral velocities or "tip speeds" commonly reaching 1100 or 1200 fps. The impeller imparts energy to the air principally by giving it violent peripheral and angular acceleration, roughly one half of this energy appearing as static pressure rise and half as kinetic energy at the exit (8). The function of the diffuser is to convert as much as possible of the velocity of the high-speed air streams into further increase in the static pressure, by a process of efficient deceleration. Because of its high speed of operation, the centrifugal supercharger has an exceptionally high volumetric capacity, which makes it especially well adapted for use in aircraft. By way of contrast, Fig. 7 shows graphically the relative size of a centrifugal supercharger (turbine-driven) as compared with the 75 conventional electrically driven reciprocating compressors which would be required to furnish the air for a 2000-hp engine.

The "axial-flow" compressor should be mentioned as another basic type, which has frequently been considered for supercharging engines (9). It is essentially a series of propeller-type fans, as many as 16 or 20, mounted on the same shaft, with a set of fixed turning vanes between stages, not unlike a multistage steam turbine. One of its limitations is its relatively narrow operating range, which has the character of curve *B* in Fig. 3, except that its peak efficiency may be appreciably higher. Its chief disadvantage is its large size, principally in axial length, due to the many stages required to produce a substantial pressure ratio. Mainly for these reasons, it has not been applied to aircraft engines, although it has been used commercially in gas-turbine power plants (10, 11).

CENTRIFUGAL-COMPRESSOR DESIGN FACTORS

In selecting a centrifugal compressor for a given supercharger application, the following factors must be taken into account: (*a*) Capacity, (*b*) maximum pressure ratio, (*c*) efficiency, (*d*) range, (*e*) impeller speed, (*f*) mechanical ruggedness, (*g*) size, (*h*) weight.

It is, of course, impracticable to discuss all of these factors exhaustively in a paper of this kind, but a brief survey of some of the major effects may be helpful to the uninitiated. More detailed discussions of the basic theory and practice will be found in references (8) and (12) of the Bibliography.

Capacity, usually expressed in pounds of air per minute, is governed primarily by impeller diameter, D, and revolutions per minute, N. For a series of "similar" machines, the volumetric flow Q (cfm) is proportional to ND^3, so that all sizes of such a series should have the same value of Q/ND^3. The basic capacity of the design, or "characteristic flow," which Q/ND^3 represents, can be increased by increasing the depth of the impeller passages or the "relative" area of the inlet. Any considerable departure from optimum proportions, however, will impair the efficiency.

As previously indicated, a supercharger must deliver 0.12 lb of air per min per engine hp. The volume flow at any altitude is obtained by dividing the mass flow by the density, to obtain the value of Q. The machine must then be selected or adjusted to bring the rated value of Q/N to the appropriate point near the peak of the characteristic curve, Fig. 3. In practice, the final adjustment of the capacity of the compressor is accomplished by changing the angle and the flow area of the diffusers suitably. (This is done by changing the entire diffuser, which is nonadjustable.) The volume flow required to maintain a given capacity increases rapidly with altitude, becoming 6.6 times as great at 50,000 ft as at sea level.

The maximum pressure ratio is an important criterion of the excellence of a given design, as it fixes the useful ceiling of the machine. The pressure-producing capacity of a centrifugal compressor is measured by the so-called "pressure coefficient"

$$\psi = \frac{6083 Y T_1}{V^2} \qquad [6]$$

where V is the impeller tip speed in feet per second. This coefficient compares the energy of isentropic compression of the air between the actual pressures involved in Y, with the energy theoretically imparted to the air by the impeller (which is proportional to V^2). From Equation [6], the necessary operating speed to deliver the required pressure ratio can be obtained as

$$V = \sqrt{\frac{6083 Y T_1}{\psi}} \qquad [7]$$

the value of YT_1 being taken from Fig. 4.

In general, pressure coefficients for impellers with straight radial blades vary with Q/N in about the same manner as the efficiency (e_i), as shown by the curves in Fig. 3. Although Equations [6] and [7] do not apply rigorously to impellers having curved blades, it may nevertheless be said that forwardly curved blades produce relatively high pressure coefficients, in that a lower tip speed is required for the same pressure ratio. This is secured, however, at the expense of a considerable reduction in stability and range of operation. Conversely, impellers with backwardly curved blades commonly show higher efficiencies but

lower pressure ratios for the same tip speed than the straight-bladed type.

Altitude performance depends upon the ability to develop pressure ratio with a minimum temperature rise over a wide range of stable operation, and therefore different types of superchargers should be compared on this basis, rather than at the same tip speed, as has sometimes been the practice in the past.

Substituting the value of Y in Equation [6], it can be shown that

$$p_2/p_1 = \left(1 + \frac{\eta V^2}{6083 T_1}\right)^{3.534} \quad \ldots\ldots\ldots\ldots [8]$$

The maximum pressure ratio which a given machine can develop is usually limited by the allowable stresses due to centrifugal force, which is proportional to the square of the speed. But, if this is not the limiting factor, there is a general tendency for the pressure coefficient and range to decrease at high speeds, as indicated by the change from curve A to curve B in Fig. 3. The ultimate ceiling may be reached at the point where the value of η collapses so that there is no further increase in pressure with speed.

The efficiency of a centrifugal compressor depends almost entirely upon how successfully the air is introduced into the impeller and conducted through the passages of the machine without shock, flow separation, or turbulence. This sounds much simpler than it actually is. The air entering the impeller is given a sudden terrific acceleration, sometimes reaching a figure of 6,000,000 fpsps, or 186,000 g. The internal air velocities are commonly of the order of 1000 to 1200 fps at the diffuser entrance. The latter figure would exceed the velocity of sound (about 1088 fps at 32 F) except for the fact that this velocity increases in proportion with the square root of the absolute temperature, which increases very considerably with the speed. At these speeds, the air particles tend to travel through the flow passages like rifle bullets, so that it is very difficult to make them turn corners and fill the varying flow sections without separation.

At the higher air velocities associated with relatively high-volume flow and tip speeds the performance of the compressor is usually limited by the occurrence of "shock waves" manifested by very sudden changes in pressure with high energy losses, as the velocity at the diffuser entrance approaches the sonic or acoustic value. The tendency of these shock losses to occur is measured by the so-called "Mach number," which is simply the ratio of the air velocity, u, to the velocity of sound, C, at the local temperature (or any convenient reference temperature). Since the critical value of u is determined by and is very nearly equal to the tip speed, V, and since $C = 49\sqrt{T}$ it is convenient to express the local Mach number as

$$M = \frac{V}{49\sqrt{T}} \quad \ldots\ldots\ldots\ldots [9]$$

Unfortunately, the local value of T at the diffuser inlet is usually not known, but for a given value of V it is determined by the inlet-air temperature, T_1, so that it is still more convenient to use a distorted Mach number

$$M_1 = \frac{V}{49\sqrt{T_1}} \quad \ldots\ldots\ldots\ldots [10]$$

in comparing the basic efficiencies of different compressors. This means that all of the values of efficiency versus Q/N should fall on the same curve, as A in Fig. 3, for a constant value of M_1 no matter how the speed and inlet temperature may be varied. A higher value of M_1 would tend to reduce the performance in the direction of curve B.

Since efficiency, pressure coefficient, and range are thus impaired by the high speeds and low temperatures required for high-altitude operation it is customary to employ two stages of compression when the total pressure ratio is greater than about 2 or 3 to 1. However, there is always a strong incentive to develop single-stage designs to yield the utmost in pressure ratio without too great sacrifices in performance, for reasons of mechanical simplicity, weight, and size.

The significance of the problem of operating range has already been indicated. The problem is becoming progressively more acute as the spread between maximum and minimum engine power increases, and as higher altitudes call for higher supercharger speeds. One expedient for increasing range is the use of a ring-type or vaneless diffuser, which gives the type of performance represented by curve C of Fig. 3. However, the penalty is usually a substantial increase in size (12), or else a loss in efficiency and pressure coefficient (13).

Speed, mechanical ruggedness, and weight are closely interrelated factors. The high speeds at which centrifugal superchargers operate not only set up high centrifugal stresses in the impeller but also generate vigorous vibrations in all parts of the machine, due to resonance effects and the impulses caused by the passage of impeller blades past the diffuser vanes. The energy and destructive power of these vibrations is sometimes surprising, and it requires very special care and experience to determine the necessary massiveness and structure to prevent premature fatigue failures.

For aerodynamic reasons, to preserve the proper proportions of the flow passages, the capacity of a given type of supercharger should not be increased faster than the square of the characteristic dimension, which is usually the diameter, i.e.

$$Q \propto D^2$$

In any series of similar machines, the weight increases with the cube of the characteristic dimension, or

$$W \propto D^3$$

Hence

$$W \propto Q^{3/2}$$

which indicates that the larger-capacity machines tend to become relatively heavy. This aspect of the problem becomes so serious that there is a strong incentive to cramp and compromise the design in order to maintain more nearly proportionate weights as the horsepower rating is increased. For this reason, the impression is sometimes given that the art is not progressing, since very real gains in basic merit are required to stand still with respect to efficiency while constantly progressing in capacity and altitude rating.

Types of Drives

The commonest type of supercharger, embodied in practically every major commercial and military aircraft engine today, is the radial centrifugal gear-driven from the rear end of the engine crankshaft. The speed is usually stepped up through two sets of gears to give impeller speeds of from 6 to 10 times the crankshaft speed.

For conservative performance at moderate altitudes, as in typical air-line service, a single-stage single-speed drive is adequate, but for high-performance military planes, it has been found expedient to employ some form of multispeed drive, for the following reasons:

If a centrifugal supercharger is operated at constant speed the pressure ratio and volumetric capacity are substantially independent of the initial pressure and density of the air. But the power is proportional to the weight flow, and hence to the density, and of course the final pressure increases in proportion with

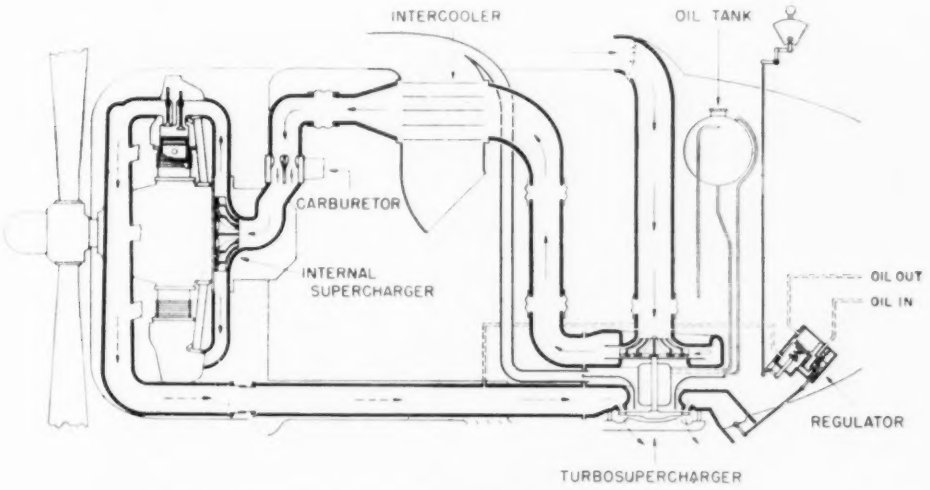

FIG. 8 SCHEMATIC DIAGRAM OF TURBOSUPERCHARGED POWER PLANT

the initial pressure. A supercharger designed to give a full-power manifold pressure of 45 in. Hg at 25,000 ft, where the pressure is 11.1 in. and the density is 0.0343 lb per cu ft, would therefore give a manifold pressure of 121 in. at sea level, and the power required to drive it would be 2.23 times normal. To avoid wrecking the engine immediately, the throttle would have to be closed to drop the manifold air pressure from 121 in. to 45 in. But the supercharger would still extract an unnecessarily large block of power from the engine, and the heat of compression, starting with a relatively high initial air temperature, would tend to cause heavy detonation unless the manifold air pressure and engine power were reduced still further. In order to maintain the maximum net engine power or economy at low altitudes it is therefore necessary to regulate the supercharger speed so that no more than the required pressure is generated at each level. In fact, it is one of the axioms of good flight engineering that the throttle should be kept open as far as practicable under all operating conditions.

Gear-driven superchargers, either single or two-stage, are now frequently provided with a two-speed drive having a mechanical clutch for shifting from low- to high-gear ratio. More recently, fluid couplings have been introduced, particularly in German engines, to provide continuously variable-speed control. An excellent description of the details of these drives is contained in a recent article by F. M. Kincaid of the Wright Aeronautical Corporation (14). All of them are characterized by a relatively high degree of mechanical complexity, especially when fully automatic control is provided to maintain the desired manifold air pressure independently of altitude. The variable-speed feature of the fluid couplings is achieved at the expense of considerable waste power, which must be dissipated in the form of heat in the oil coolers.

The exhaust-gas-driven turbosupercharger represents a very practical solution to the drive problem in terms of mechanical simplicity, flexibility, and power economy. As may be seen from the schematic diagram, Fig. 8, the impeller of the turbosupercharger is direct-connected to a single-stage turbine driven by the engine exhaust gas. The speed is controlled in a very simple manner by allowing excess gas, not required for turbine operation, to escape through the wastegate instead of through the turbine nozzles and wheel. This makes it possible to hold constant manifold pressure, with no throttling and no extraction of engine crankshaft power, from sea level to critical altitude. No more than the minimum required power is drawn from the turbine at any time, so that the excess back pressure which it imposes upon the engine is likewise never more than sufficient to supply the desired manifold air pressure. The significant fact here is that the reduction in engine power caused by this increased back-pressure is usually much less than the crankshaft power required to drive an equivalent geared supercharger (15).

As indicated in Fig. 8, it is common practice to employ an internal-geared supercharger in conjunction with the turbosupercharger, with an intermediate intercooler. With a relatively low pressure ratio, as in the system, Fig. 5, the internal stage has no speed control, since it will not generate excessive manifold pressures with open throttle at sea level if the turbo is cut out.

THE GENERAL ELECTRIC TURBOSUPERCHARGER

Figs. 9 to 12 show various views of the General Electric turbosupercharger of the type used in the Boeing Flying Fortress, Consolidated Liberator bomber, and the Lockheed Lightning and Republic Thunderbolt pursuits. Although military necessity prevents the disclosure of complete technical details, the major features may be indicated as follows:

Referring to the cutaway view, Fig. 9, the engine-exhaust stack connects to the nozzlebox *A*, which is directly above the turbine wheel *B*. The hot exhaust gases expand through the nozzles *C* and impinge upon the turbine buckets *D*. The pressure in the nozzlebox is regulated by means of the waste gage *E*, which vents excess gas to the atmosphere.

The power developed is transmitted through the shaft *F* to the impeller *G* (which is also shown in Fig. 6). The diffuser passages *H* discharge into a scroll-type collector in the outer portion of the compressor casing *J*, which has a radial outlet. The rotor assembly is carried in a ball bearing *K* at the impeller end to take the thrust load, and a roller bearing *L* at the turbine end to allow for expansion of the shaft.

The baffle ring *M* serves to shield the compressor casing from the heat of the nozzlebox, and its inner portion supports the nozzle ring.

The lubricating-oil pump *N* is driven by a worm gear from a worm sleeve keyed to the shaft. The pump is of the gear type, and actually consists of two separate pumps within a single casing. One element supplies oil under pressure to the gears and bearings. The other element is a scavenging pump which removes oil from the lower part of the bearing housing *P* and returns it to the supply tank.

The external appearance of the turbosupercharger is shown

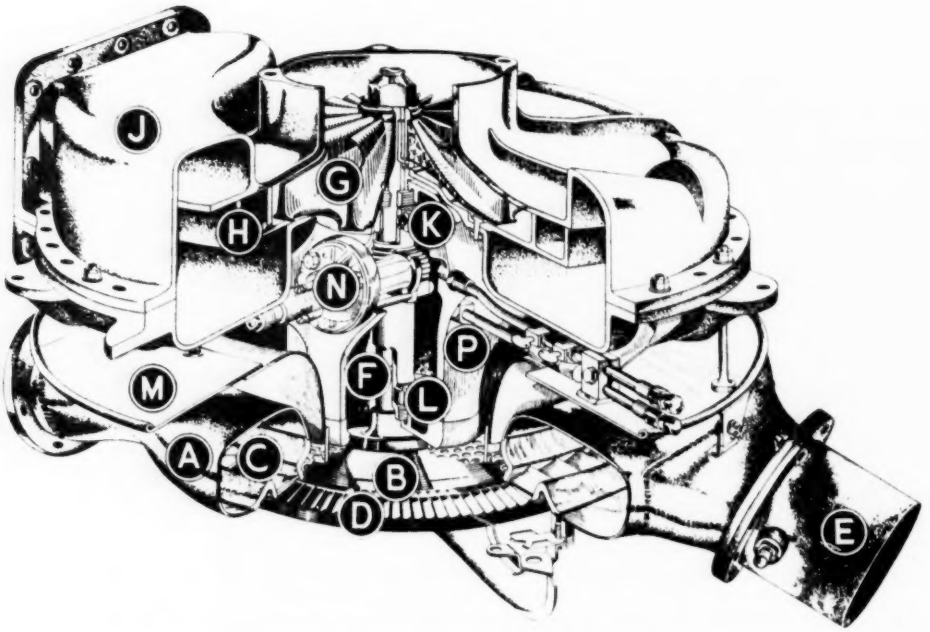

FIG. 9 CUTAWAY VIEW OF TURBOSUPERCHARGER

in Figs. 10, 11, and 12. In Fig. 10, the cooling cap has been removed to expose the turbine wheel.

The impeller is machined out of an aluminum-alloy forging. The compressor casing, diffuser, and bearing are aluminum-alloy castings. Turbine parts are made of alloy steels especially developed to withstand the high stresses, elevated temperatures, and corrosive action of the exhaust gases. Data on various materials of this latter class are given in reference (16).

As indicated in Fig. 8, regulation of the turbine waste gate is effected by means of a hydraulic servomotor containing a pressure-sensitive element connected to the engine exhaust stack ahead of the turbine. By adjusting the boost-control lever, the pilot sets the regulator to hold a constant nozzlebox pressure which will maintain the desired engine-intake-manifold pressure.

THERMODYNAMIC FEATURES OF TURBODRIVE

The development of the gas-turbine drive is described in references (16, 17, 18), and in a companion paper by Dr. Sanford A. Moss (19). The underlying thermodynamic principles are essentially the same as those applying to the conventional single-stage impulse-type steam turbine. The success of the turbosupercharger is based upon the development of an adequate mechanical design to enable the turbine to utilize the energy of the high-

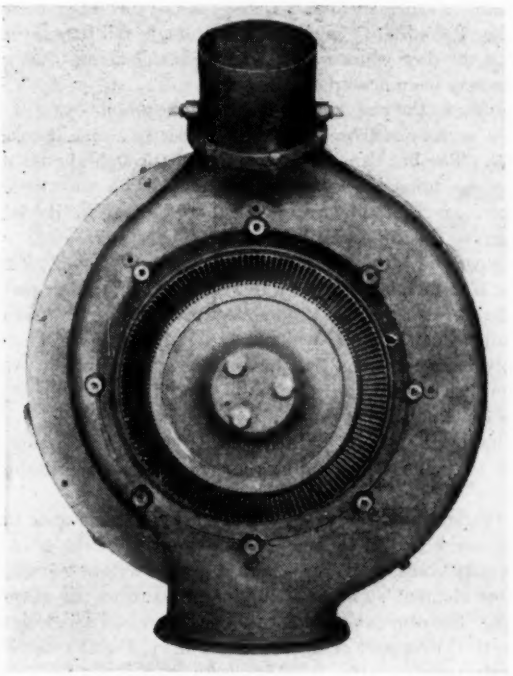

FIG. 10 WHEEL-END VIEW OF TURBOSUPERCHARGER

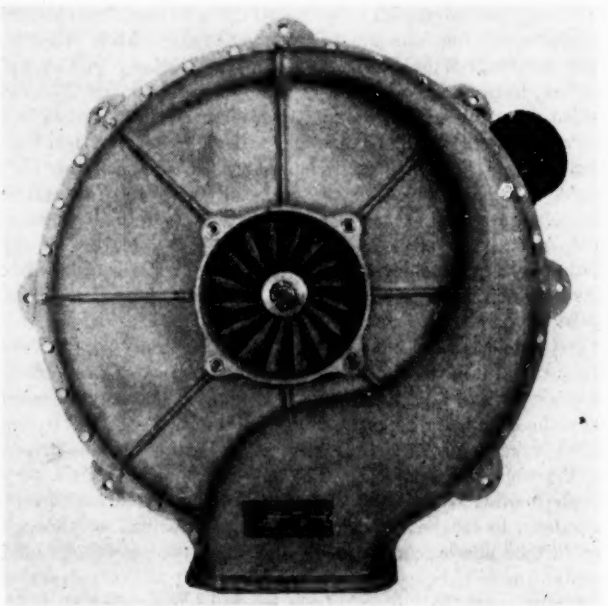

FIG. 11 COMPRESSOR-END VIEW OF TURBOSUPERCHARGER

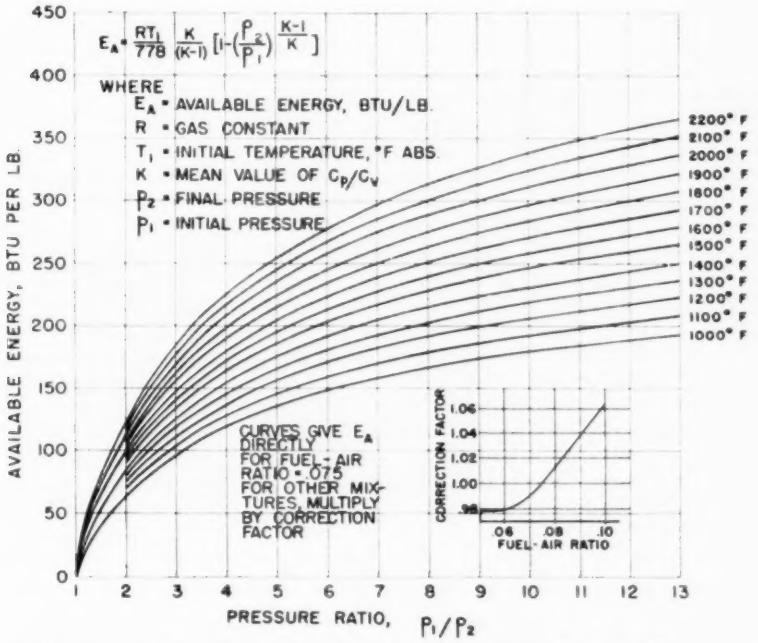

Fig. 13 Available Energy of Hot Exhaust Gas Versus Temperature, Pressure Ratio, and Fuel-Air Ratio
(Figures on curves are ordinary degrees F.)

temperature engine exhaust gases with satisfactory reliability and life and without undue penalties in weight or size.

Fig. 13 gives the available energy, in Btu per pound, of engine-exhaust gas for various temperatures, pressure ratios, and fuel-air ratios. The data are based upon recent information on the specific heat of gases reported by Heck (20), and Ellenwood, Kulik, and Gay (21), and are believed to be considerably more accurate for this purpose than the energy values based upon the properties of ordinary air. (To convert the available energy to hp per lb of gas per min, divide Btu per lb by 42.4.) It should be noted that this is primarily thermal energy, representing the waste heat of the exhaust gases and that the pressure ratio required to release a given amount of power decreases rapidly as the initial gas temperature increases.

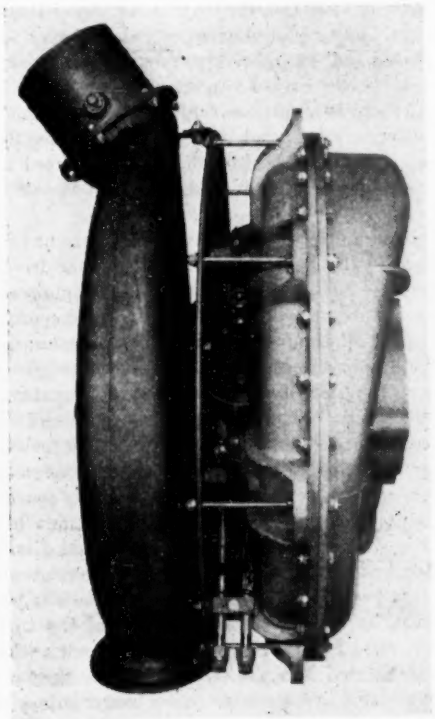

Fig. 12 Side View of Turbosupercharger

Actual exhaust-gas temperatures, in the case of high-powered military engines, vary from about 1200 to 1700 F, the higher figures being associated with higher outputs and leaner fuel-air ratios. Assuming a representative temperature of 1500 F, it is of interest to determine the available energy per pound of gas for a pressure ratio of 2.69, which corresponds to sea-level back pressure (p_1 = 29.92 in.) in the engine-exhaust stack at 25,000 ft (p_2 = 11.1 in.). The conservative "cruising lean" value of 0.075 will be used for the fuel-air ratio, although richer mixtures would be used for full power.

From Fig. 13, for p_1/p_2 = 2.69 and T_1 = 1500 F, the available energy is 122 Btu per lb, or 2.88 hp per lb per min. This figure must be multiplied by the turbine efficiency to obtain the actual shaft output.

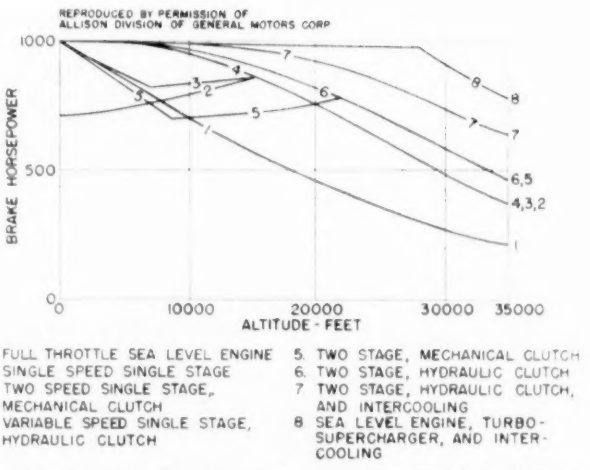
The engine requires slightly less than 1 lb of air per lb of exhaust gas. It will be assumed that the turbocompressor delivers this air at sea-level pressure at the carburetor under the conditions of Fig. 5 (p_2 = 31.67) with a compressor efficiency of 70 per cent. From Equation [3] and Fig. 4, the required power input to the compressor will be

$$0.00573 \times 148/0.7 = 1.21 \text{ hp per lb per min}$$

This means that the turbosupercharger can maintain sea-level pressures at both ends of the engine at 25,000 ft so long as the turbine efficiency is greater than 1.21/2.88 = 42 per cent. This is entirely practicable, even after allowing for losses due to gas leakage, etc., and is the basis of most turbosupercharger applications.

As the altitude increases, the compressor must develop a greater pressure ratio, which requires more power. But with constant engine inlet and exhaust pressures, the pressure ratio across the turbine also increases with altitude, so that the power available

continues to balance the power required. The ultimate level above which this balance can no longer be maintained is determined either by the attainment of the maximum allowable "turbo" speed, or else by loss of efficiency at excessively high pressure ratios. Beyond this critical altitude, the carburetor pressure and engine power begin to decline in the normal manner.



From the energy standpoint, it might be said that the turbo thrives on high exhaust-gas temperatures, as indicated by the curves in Fig. 13. However, at temperatures in the vicinity of 1700 F the cooling problem becomes very serious; to such an extent that it has been thought in many quarters, particularly abroad, that turbine operation at such temperatures was impracticable. The fact is that the ability of the turbine materials to withstand these high temperatures is due largely to the fact that no parts of the machine actually reach the full temperature of the gas. Practically all parts are cooled by intense radiation to the surroundings, and the nozzlebox is cooled about 400 deg below the gas temperature by the additional effect of a stream of "rammed" air. The effective temperature of the gas impinging upon the buckets is reduced several hundred degrees by virtue of the conversion of thermal energy into kinetic energy in the high-velocity jets (see reference 22). It appears, therefore, that present engine-exhaust temperatures are very nearly at the optimum level for turbo operation; if they were much higher the necessary reduction in turbine speed or life would be serious, and if they were much lower the performance would be impaired by the reduction in available power.

The problem of "afterburning" may be mentioned in this connection. Since aircraft engines are always operated with rich fuel-air mixtures at high powers, the exhaust gases contain considerable quantities of carbon monoxide and hydrogen; up to 14 per cent CO and 7 per cent H_2 (23). These highly inflammable gases will burst into flame if they come into contact with air before cooling below their ignition temperature (roughly 1100 to 1200 F). Because of their visibility at night, these flames must be suppressed in the case of bombers, many of which are provided with bulky quenching devices for this purpose. In turbosupercharger installations afterburning can cause local overheating if the gases come in contact with sufficient air, by entrainment or otherwise, before passing completely through and away from the turbine. But with suitable precautions to avoid this, the turbosupercharger has a salutary effect in helping to suppress visible flames by cooling the gas several hundred degrees, due to the conversion of heat into work.

Comparative Performance of Superchargers

The first criterion of supercharger performance is the ability to maintain full engine brake horsepower at all altitudes in the operating range of the airplane. The final measure is, of course, the actual performance of the plane, including rate of climb and maneuverability as well as speed in level flight.

The effect upon engine power can be determined or predicted a great deal more readily and accurately. Fig. 14 gives the results of a very interesting study of the performance of an engine equipped with various types of superchargers, recently published by the Allison Division of General Motors Corporation (24). Curve 1 represents a "sea-level engine" which has a small low-speed internal supercharger provided to produce full power by ground boosting the manifold pressure at sea level with full throttle. With a fixed impeller speed, the engine power is the same as that of the unsupercharged engine shown in Fig. 1. Curve 2 shows the result of speeding up the internal supercharger so as to produce maximum power at a rated critical altitude of 15,000 ft. This engine must be partly throttled at sea level to avoid excessive manifold pressure and detonation. The net output is reduced by the extra compressor power and temperature rise due to the higher impeller speed, as discussed in the section "Types of Drives." As the plane rises, the engine power increases, due to the reduced back pressure plus the favorable effects of the lower inlet-air temperatures, until the throttle is fully open at 15,000 ft.

Fig. 14 Altitude Performance of an Engine With Various Types of Superchargers

The remaining curves are determined by similar considerations of the shaft power required to drive the compressor, and the effects of manifold air temperature upon detonation and charge density. As just mentioned, the outstanding performance of the turbosupercharger (curve 8) is due to its ability to supply exactly the required pressure with no extraction of crankshaft power. The principal adverse effect of the turbosupercharger is to prevent the engine back pressure from following the normal decline of ambient pressure at altitude. Although curve 8 shows a slight loss of power with altitude, it has been demonstrated by flight tests that it is entirely practicable and convenient to hold 100 per cent sea-level power or more all the way up to the critical altitude with a conventional turbosupercharger installation.

On the other hand, the gear-driven supercharger, particularly the simpler single-speed types, are considerably lighter and more compact. If there is no intercooler, the drag will be less. If a turbosupercharger is not used it is possible to convert more of the exhaust energy into thrust by the use of rearwardly directed ejector-type exhaust manifolds (25), although the efficiency of this process is low.

It is extremely difficult to make valid comparisons of the relative performance of a given airplane with a gear-driven supercharger or with a turbosupercharger for the simple reason that, for optimum results, the plane must be designed specifically for the particular installation used. This is especially true in pursuit ships, where the supercharger has a marked effect upon fuselage shape and weight distribution. Moreover, the requirements of a light "hedge-hopping" plane are apt to be quite different from those of a heavy, high-altitude design. The performance of any supercharger, and particularly the turbo, depends so greatly upon the excellence of the installation that it is entirely possible to reverse the results of any such comparison by suitably butchering the job. It is significant, however, that the gear-driven superchargers have had the benefit of much more intensive work on the installation problem, so that some account should be taken of the potential as well as the actual merit of the turbo type. Even the latest and best turbo installations are not as closely and completely integrated into the power plant as they might be. But the fact remains that the turbosupercharger enjoys an initial and basic thermodynamic advantage, as indicated in Fig. 14, which becomes even more marked at higher altitudes. Finally,

it is still more significant that four of the outstanding planes that this country has contributed in the present war, the B-17, B-24, P-38, and P-47 are turboequipped.

Present Status of Turbosupercharger

The question is sometimes asked: Why is it that no foreign country has used the turbosupercharger in military airplanes during the present war? The answer is that, although a considerable amount of experimental work has been carried on abroad as described by von der Nüll (16), the practical difficulties of design and production have discouraged any large-scale application to high-performance Otto-cycle engines. The Germans have succeeded in applying a turbo to their Junkers Jumo 207 Diesel on a small scale, but since the exhaust-gas temperature entering the turbine is about 1000 F, the performance is correspondingly low. The outstanding success of the turbo development in this country has resulted from the sustained effort and continuous experience with the manufacture and application of this type of supercharger since 1917 which has been made possible by the support and cooperation of the United States Army Air Forces. Consequently, at the outbreak of the war this country alone had both the technical "know-how" and the facilities for producing these machines in the necessary quantity and quality. It was in recognition of this achievement that the Collier trophy was awarded jointly to the Army Air Corps and Dr. Sanford A. Moss, of the General Electric Company, by the National Aeronautic Association in 1941.

For several years the turbosupercharger has been in mass production, at a rapidly increasing rate. At the present time it is being produced at the rate of thousands a month in five large plants, two of them especially built for this purpose. The Ford Motor Company and the Allis-Chalmers Manufacturing Company are contributing in a substantial degree to the production of the General Electric design.

Since the start of the war large numbers of turboequipped planes have seen active service in the battle areas all over the world. All have given an excellent account of themselves. The turbo itself has achieved a remarkable record of reliability and outstanding performance under an extreme range of operating conditions. Many favorable reports have also been received in respect to the relative ease with which it has been serviced and maintained in the field. The most enthusiastic tributes, however, have come from pilots and crews who have repeatedly been able to outclimb and outdistance enemy planes whose engines weaken and falter in higher altitudes.

Future Prospects of Supercharging

As in many other branches of aviation, the war has given a tremendous impetus to the development of all forms and applications of supercharging. All known areas of theory and practice are being explored searchingly and extensively and new fields are being opened up under the incentive to improve the performance and extend the capacity of existing machines. Unfortunately, it is obviously impossible to discuss the results that are being accomplished. About all that can be said is that the general direction is up, and that "the sky's the limit." It might be added that superchargers are definitely ahead of engines, planes, and propellers in this direction, at the present time.

With reference to postwar supercharger applications, it is confidently anticipated that turbos will be applied to commercial transport planes, particularly for the longer, high-altitude runs with definite advantage in operating economy. Although there is a lack of adequate flight data to support this point there are a number of sound reasons, some of which have been cited herein, upon which to base the expectation. Von der Nüll (16) mentions some prewar German tests with "modern high-altitude engines," showing specific fuel consumptions of 0.441 lb per hphr with a turbosupercharger, as compared with 0.584 lb per hphr with a gear-driven supercharger, but the details are not given.

The advantages of high-altitude flight (3) which led to the development of the famous Boeing Stratoliners will doubtless encourage the development of pressure-cabin planes for operation in the higher levels of the stratosphere. Very much more adequate cabin-supercharging systems will then be available. Here again the basic economy and flexibility of the turbocompressor can be utilized effectively. Since it delivers pure air at about the desired pressure and temperature, the engine turboinstallation can be used to pressurize and ventilate the cabin by bleeding off a small fraction of the air leaving the intercooler. The internal-type supercharger cannot be so employed because it discharges a mixture of fuel and air.

But whatever the future may bring, it can be stated with assurance that the supercharger in its various forms will be ready and adequate for the demands of new advances in high-altitude flight, for without it such flight as we know it today would have been impossible.

Discussion

KENNETH CAMPBELL.[3] The paper constitutes a technical exposition of the basic principles, characteristics, and functioning of superchargers as applied to aircraft engines. It is clearly and comprehensively expressed, and the authors are to be congratulated on setting forth this condensed explanation of the subject as a whole. It is needed by the thousands of engineers in aeronautics whose assignments are nearly always concerned in some respect at least with the subject of supercharging and its many ramifications.

Without doubt, the authors would be the first to agree that the material of this paper is necessarily largely not new, measured by the very short time standards of aeronautical development, since everything in the field of aeronautics which is new, judged by these standards, is of use to the enemy and must therefore be left unsaid. The writer is privileged to be familiar, however, with the large amount of manpower and expenditure being devoted to physical research in the field of supercharging by the authors' organization, as well as with some of the results being obtained, and the reader can rest assured that the information given in the paper rightly comes from the oldest and one of the most active centers of supercharger development.

The paper is fundamentally sound, and we have little worthy comment to make taking issue with it technically. The authors recognize the existence of some exhaust energy from rearwardly ejected exhaust manifolds. It might be pointed out, however, that the thrust horsepower gain to the airplane from simple, rearwardly pointed exhaust stacks from each cylinder has for some years been calculated by many investigators to equal the mechanical power robbed from the crankshaft by the mechanically driven first stage, even in climbing flight. On the other hand, gain from directing the turboexhaust to the rear is necessarily slight. If these calculations be true, the comparison of curve 8 in Fig. 14 of the paper, representing the turbo performance, with the other performance curves of this figure will be very misleading to the uninitiated.

We enjoy and approve highly the statement made in the paper that the impression is sometimes given that the art of supercharging is not progressing, since very real gains in basic merit are required to stand still with respect to efficiency, while progress is constantly being made in altitude and capacity rating. During the period of supercharger knowledge covered by this paper, superchargers have increased from 500-engine-horsepower capacity to 5 or 6 times that capacity. As the authors indicate, in order to have maintained the efficiencies of the small superchargers in the larger models without further performance research, impeller diameters and other corresponding dimensions should have more than doubled; yet no such maintenance of dynamic similarity has had to take place. The fact that the efficiencies of superchargers of engines of 2000 hp are slightly better, and in some cases substantially better, today than the efficiencies obtained originally with superchargers for engines of 500 hp is the result of very extensive research work which has been going on in various localities in this country in supercharger development, without which the superchargers of large engines today would be failures. This is a point seldom appreciated in the past and one which the authors do well to express so clearly.

J. M. HELDACK.[4] It is extremely fortunate that the military authorities have allowed the presentation of such a timely subject, especially now when the nation's newspapers are full of the successes of our military airplanes, due especially to their superior high-altitude performance.

The authors have mentioned the problem of covering adequately the increased operating range of modern military-aircraft engines. Military operation requires both high-power and cruising-power operation at all altitudes up to and including the critical altitude of the installation. At present, the turbosupercharger is the only means of supercharging which allows this flexibility. It can be reasonably expected that postwar application on long-range transoceanic and transcontinental passenger and cargo airplanes will be predicated on turbosuperchargers designed to operate at their maximum efficiency while covering the cruising-power range of the engine. Such a combination allows the attainment of optimum conditions from the standpoint both of performance and weight saving.

It is not generally realized that the most economical engine revolutions (rpm) do not necessarily result in the most economical cruising speed for the airplane. The airfoil characteristics of the plane must also be considered. Normally, under given conditions of altitude and weight, there is a definite optimum point where increasing power slightly, even though it increases fuel consumption, results in a greater increase in aerodynamic efficiency to the extent that the over-all result is an increase in the ratio of miles per gallon.

Basically it becomes a problem of matching the plane speed, endurance, and economy to result in optimum performance. The flexibility of the turbo, and its resultant beneficial effect on economy, makes it an important factor to be considered in designing the aircraft power plant for postwar commercial airplanes.

AUTHORS' CLOSURE

The authors greatly appreciate Mr. Kenneth Campbell's generous comments, coming as they do from such a well-qualified source.

Mr. Campbell raises a controversial question of long standing as regards the extent to which the extra thrust from individual exhaust jets can be made to compensate for the extra power required from the crankshaft to drive the internal supercharger when a turbo is not used. The issue has remained controversial for so long chiefly because the actual result depends upon the conditions assumed in the comparison. The exhaust jets show up to best advantage in the case of high-speed pursuit planes at moderate altitudes, especially when fuel economy is of secondary importance, whereas the turbo is better adapted to heavy long-range bombers and transports or to any type of plane in the altitude levels above 30,000 ft. Even in the fighter class, the high-altitude performance of the P-38 and P-47 demonstrates

[3] Wright Aeronautical Corporation, Paterson, N. J.

[4] General Electric Company, San Diego, Calif. Jun. A.S.M.E.

the fact that the initial advantage of the turbo in respect to actual brake horsepower, as shown in Fig. 14, can be realized in practice, quite apart from calculations. It is freely conceded, however, that the excellent results lately obtained with two-stage gear-driven installations in pursuits will help to avoid any complacency in the turbo camp.

Mr. Heldack's comments are very pertinent and are especially welcomed in view of his close contact with the practical problems of aircraft design and performance. In reference to his remarks on the most economical engine speed, perhaps the matter might be stated this way: For a given airplane, total weight, and altitude there is an optimum "thrust horsepower," determined by the aerodynamics of the plane, which will give the best ratio of airplane speed to power. For a given thrust horsepower there is an optimum engine speed, determined by the characteristics of the engine and propeller, that will give the minimum fuel consumption. Optimum over-all economy, as measured by miles per gallon, can be obtained only by the proper selection of both power and engine revolutions (rpm).

The point is that the turbosupercharger makes it possible to realize this objective over a wide range of operating conditions, since the compressor speed, and hence the intake-manifold pressure, can be controlled independently of the engine speed without the loss due to throttling.

Test and Predicted Oil-Cooler Performance

By A. L. LONDON[1] and J. I. BREWSTER[2]

Air-side heat-transfer and pressure-drop laboratory test data are presented for a shell-and-tube-type oil cooler, employing steam as the shell-heating medium (1).[3] These data are compared with the information existing in the literature. The chief discrepancy observed is the surprisingly high Reynolds number obtained for transition between laminar and turbulent flow; the dip region being in the Reynolds number range 10,000 to 4000 instead of the usually expected range of 4000 to 2000. The test results, together with available oil-side conductance data, are employed to predict oil-cooling performance of the exchanger as a function of air-flow pressure drop.

Nomenclature

THE following nomenclature is used in the paper:

A_c = tube air-flow cross section for core
c, c_a = unit heat capacity of air stream, Btu/(lb °F)
c_0 = unit heat capacity of oil stream, Btu/(lb °F)
D = tube inside diameter (air side), $D = 4r_H$, ft
e = base of natural logarithms
f = over-all friction factor, including entrance and exit losses (dimensionless)
f' = tube skin-friction factor (dimensionless)
G = tube air-mass velocity, lb/(sec ft²), lb/(hr ft²)
g = 32.2 lb mass/slug mass (proportionality factor in Newton's second law, when employing both pound-force and pound-mass units)
h = unit conductance for thermal convection, air side, Btu/(hr ft² °F)
k = unit thermal conductivity of air, Btu/(hr ft² °F/ft)
K_f = constant relating β_f and β_q (Equation [1]) (dimensionless)
K_c = contraction-loss friction coefficient (dimensionless)
L = effective tube length, air side, ft
Δp = air-pressure drop, lb per sq ft, in. water
r_H = tube hydraulic radius, air side, equals flow cross section/wetted perimeter, $r_H = D/4$ (right circular cylinder), ft
t = temperature, F
t_{a1}, t_{a2} = air temperatures at tube entrance and exit, respectively, F
t_s = saturation temperature of core heating steam, °F
t_{o1}, t_{o2} = oil temperature at core entrance and exit, respectively, °F
T_{a1} = absolute temperature of entering air, $T_{a1} = t_{a1} + 460$, °R
Δt_1 = temperature difference, $(t_s - t_{a1})$, or average oil temperature to entering air, °F
U = over-all unit thermal conductance oil to air, Btu/(hr ft² °F)
V = air velocity, fps
w = oil flow rate, lb per hr
β = dimensionless moduli (see following group)
Δ = denotes pressure or temperature difference
ϵ = heat-transfer effectiveness (see following group)
σ = ratio of air-flow cross section to core cross section (dimensionless)
μ = air viscosity, lb/(hr ft), (centipoises)
ρ = air density, $\rho_0 = 0.075$ lb per cu ft, standard air density

Dimensionless Moduli:

$\beta_q = \frac{h}{Gc}\frac{L}{r_H}$ air-side number of transfer units
$\beta_a = \frac{U}{Gc}\frac{L}{r_H}$ over-all number of transfer units
$\beta_0 = \frac{\epsilon_a G c_a A_c}{w c_0}$ heat-transfer modulus employed in oil-cooling effectiveness expression, Equation [7]
$\beta_f = \frac{f}{2}\frac{L}{r_H}$ friction modulus analogous to β_q
ϵ_a = "air-heating effectiveness," $(1 - e^{-\beta_q})$, $(1 - e^{-\beta_a})$
ϵ_0 = "oil-cooling effectiveness," Equation [7]
f, f' = air-flow friction factors (see preceding group)
$\frac{L}{r_H}$ = modulus expressing air-side tube geometry
$N_{Nu} = hD/k$, Nusselt number, air side
$N_{Pr} = \mu c/k$, Prandtl number, air side
$N_{Re} = DG/\mu$, Reynolds number, air side

Description of Test Apparatus

The physical characteristics of the core tested are given in Table 1.

TABLE 1 PHYSICAL CHARACTERISTICS OF CORE

Tube material	Copper
Number of tubes	637
Tube pitch, in.	0.325
Tube layout, deg	60
Tube diameter, air side, ID, in.	0.256
Tube diameter, shell side, OD, in.	0.268
Effective heat-transfer length, air side, in.	9.0
Effective heat-transfer length, shell side, in.	8.0
Heat-transfer area, air side, sq ft	32.0
Frontal area (8.9 in. diam), sq in.	62.2
Tube-flow area, A_c, sq in.	32.8
Shell-side volume, cu in.	190
Number of shell-side passes along tubes	7
Length/hydraulic radius, air side, L/r_H	140
Tube-flow area/frontal area, σ	0.53
Tube-flow area/duct area	0.52

The core unit was installed in a 9-in-diam test duct connected to the suction side of a centrifugal blower. Air-flow control was provided by a variation of the blower speed afforded by the direct-current-motor drive. Details of the test duct-blower arrangement, together with the air-flow and pressure-drop-measuring instruments, are indicated in Fig. 1.

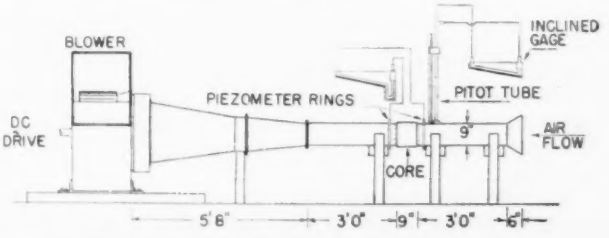

Fig. 1 Test Duct and Core Arrangement

Contributed by the Heat Transfer Division and presented at the Semi-Annual Meeting, Los Angeles, Calif., June 14–17, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

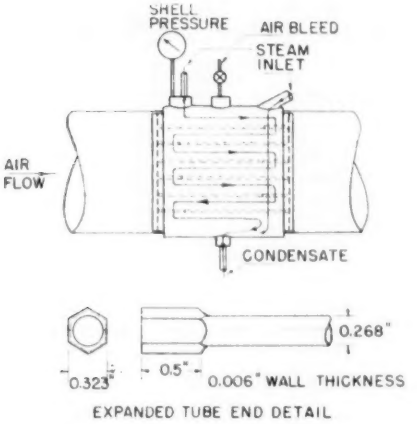

FIG. 2 SHELL-SIDE STEAM FLOW AND EXPANDED-TUBE-END DETAIL

The steam employed as the heating medium in the shell was delivered to a separator at about 30 psig pressure. After liquid separation, the steam was throttled to about 3 psig to provide some superheat at the entrance to the core. The condensate from the core drained to a standpipe and then to an aftercooler where some subcooling was provided to minimize flashing. The condensate was metered gravimetrically.

The energy state of the superheated steam entering the core was established by pressure-temperature measurements and the steam tables. The condensate state was determined by temperature measurement upstream from the standpipe. Steam and condensate temperatures were measured by mercury-in-glass thermometers with the bulbs extending 3 in. in the fluid streams through glands.

Air-state measurements were taken as follows: Air humidity, by wet- and dry-bulb readings in the room; air stream entering the core; by a mercury-in-glass thermometer located 2 ft upstream from the core; air heating, by a calibrated shielded difference thermocouple (copper-constantan). The upstream junction had a stationary location at the previously mentioned mercury-in-glass thermometer. The hot junction was located 8 in. downstream from the core and was arranged to provide an 8-point vertical traverse of the air stream, with the traverse points located at the centers of equal annular areas. The arithmetic average of the temperature readings served to approximate closely the bulk air temperature inasmuch as the velocity distribution was quite uniform.

Air flow was metered by a central location of the pitot tube after an 8-point traverse calibration established the relation between the center-line velocity and the average velocity with respect to flow area, Fig. 3(*a*).

Fig. 2 reveals schematically the 7-pass baffle arrangement and the steam-flow path in the shell. Also shown is a detail of the expanded hexagonal ends of the round tubes.

TEST RESULTS

Typical approach-velocity-head distributions are presented in Fig. 3 together with the calibration for average to center-line velocity. Also shown are typical temperature distributions downstream from the core as measured by the air-heating difference couple. The arithmetic average of the 8-point temperature traverse readings was used to evaluate the bulk air temperature rise.

Table 2 summarizes the cold-core pressure-drop data. In this table the Reynolds number is evaluated employing a viscosity of 0.018 centipoises (air at 80 °F)

TABLE 2 COLD-CORE PRESSURE-DROP DATA

Air density ρ, lb/ft³	Tube-air mass velocity, G lb/(sec ft²)	Δp, in. H_2O	Friction modulus, $(f/2)(L/r_H)$	Tube Reynolds number[a] $N_{Re} = DG/\mu$
0.0740	1.19	0.105	0.90	2060
0.0740	1.54	0.153	0.80	2710
0.0740	2.28	0.290	0.69	4020
0.0740	2.94	0.430	0.62	5090
0.0743	3.52	0.585	0.59	6210
0.0740	3.40	0.550	0.59	6000
0.0745	3.87	0.685	0.57	6830
0.0740	3.72	0.635	0.57	6580

0.0740	6.32	1.85	0.575	11200
0.0745	6.38	1.855	0.57	11300
0.0737	7.75	2.75	0.57	13700
0.0735	12.7	7.05	0.54	22400

[a] Based on viscosity $\mu = 0.018$ centipoises (80 F).

$$N_{Re} = \frac{DG}{\mu} \text{(dimensionless)}$$

which reduces to $N_{Re} = 1760G$ for G lb/(sec ft²). The friction-factor modulus is derived from the Fanning equation for the pressure drop

$$\frac{\Delta p}{\rho} = f \frac{L}{r_H} \cdot \frac{V^2}{2g} \text{ ft of air}$$

With G expressed in lb/(sec ft²) and p in in. of water this expression reduces to

$$\beta_f = \frac{f}{2} \cdot \frac{L}{r_H} = 167 \frac{\Delta p}{G^2} \cdot \rho$$

The foregoing calculation assumes negligible air-density change in passage through the tubes, which is a valid idealization providing the pressure drop does not exceed 4 per cent of the total pressure and the air is not heated in the core.

Mechanical-energy dissipation, as expressed by the modulus given, includes entrance-shock loss, skin friction in the tubes, and exit-shock loss.

Heat-transfer and pressure-drop data, obtained with steam heating of the core, are summarized in Table 3. Energy balances for the greater part of the runs are within 5 per cent, attesting to the general accuracy of the temperature and flow measurements.

[a] Based on $\frac{L}{r_H} = 140$, $c = 0.242$ Btu/(lb °F)

[b] Viscosity μ for average air temperature $\frac{t_{a1} + t_{a2}}{2} = 110$ F, $\mu = 0.019$ centipoises.

[c] Expresses per cent difference between heat transfer to the air and heat transfer from heating steam, based on steam-energy rate.

The number of heat-transfer units $\beta_q = (h/Gc)(L/r_H)$ were evaluated from the test data employing the relation

$$\epsilon_a = \frac{(t_{a2} - t_{a1})}{(t_s - t_{a1})} = 1 - e^{-\beta_q}$$

The unit conductance h was then determined as

$$h = (\beta_q Gc)/(L/r_H)$$

This procedure is equivalent to employing the log-mean rate equation with a heat-transfer rate evaluated from the air-heating data.

Examination of the air-temperature-traverse data shown in Fig. 3 indicates that the air from the lower half of the core was not heated as much as the air from the upper half. Conductances based on the upper-half temperature data were about 5 per cent ($N_{Re} > 7000$) higher than the average conductances listed in Table 3. This condition suggests the presence of a scale resistance on the shell side. An attempt to clean the core with commercial solvents and acid was not entirely successful. The data reported in Table 3 are for the core after cleaning was attempted. If the conductance, based on the upper-half temperature data are typical for the clean core, the magnitude of the scale resistance included in the h and β_q data of Table 3, amounts to about $^1/_{500}$ (hr ft² deg F)/Btu.

The friction modulus $\beta_f = \frac{f}{2}\frac{L}{r_H}$ (as obtained from the cold-core runs) and the number of heat-transfer units β_q are related by the Reynolds analogy (2). The similarity of these two moduli is revealed in Fig. 4, where β_f and β_q are plotted versus N_{Re}. A consideration of this graph indicates that

$$\beta_f \cong K_f \beta_q \text{ for } 8000 < N_{Re} < 20{,}500 \quad \ldots\ldots [1]$$

where

$$K_f = 1.2$$

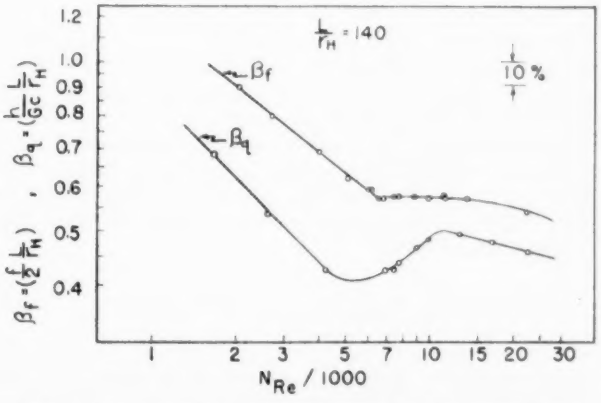

FIG. 4 EXPERIMENTAL HEAT-TRANSFER AND FRICTION DATA

The Reynolds analogy predicts a coefficient of 1 instead of 1.2 This increase can, in part, be attributed to shock at entrance and exit which contributes to the pressure drop, but is not associated with the skin-friction momentum and heat-transfer mechanism. Weise (3) reports a magnitude of 1.1 for the coefficient K_f.

An interesting revelation of these results (Fig. 4) is the definite dip in the characteristics starting at a Reynolds number of 10,000 for the β_q curve and 7000 for the friction-modulus characteristic. Normally, air flow with $N_{Re} > 4000$ is definitely turbulent in character, but for the core and test arrangement reported here fully turbulent flow obtained only for $N_{Re} > 10{,}000$. The reasons for this surprising result are not clear. Tentatively, it may be partially attributed to the following characteristics of the core- and test-duct arrangement:

1 Although the duct Reynolds number is 18 times that of the tubes (180,000 for a tube $N_{Re} = 10{,}000$), turbulence characteristic of this high Reynolds number was not established for the air entering the tubes because of the short approach section of the duct (4 diam), and the fact that the air was induced into the duct through a conical approach section from the relatively quiescent room conditions (Fig. 1).

2 The ends of the core tubes are expanded into hexagonals (Fig. 2) and thus provide a relatively smooth convergence from duct to tube flow. This minimization of shock at entrance may serve to perpetuate the duct-turbulence characteristic which is apparently considerably closer to laminar flow than the duct or even the tube Reynolds number alone would suggest, for the reasons first mentioned.

This rationalization is in part supported by the data of Washington and Marks (4) for flow through rectangular ducts having hydraulic radii of magnitudes comparable to that of the oil-cooler tubes. Their test arrangement provided for flow of compressed air into a relatively large inlet chamber, then through a rounded approach section into the duct of relatively small cross-sectional area. The turbulence of the air in the inlet chamber probably corresponded to quiescent air conditions and the smooth convergence approach section would tend to perpetuate this condition well into the duct. As a consequence the heat-transfer grouping h/Gc for the $^1/_8$-in. duct ($r_H = 0.0625$ in., as compared to the oil-cooler tube $r_H = 0.0640$ in.) departs markedly from the turbulent-flow characteristic in the neighborhood of Reynolds number = 10,000 (Bibliography reference 4, Fig. 8), which confirms the effect noted for the oil-cooler tubes.

This nonturbulent character of the flow at high Reynolds number is of more than academic interest in that turbulence conditions of the cold-air flow into an aircraft heat exchanger may correspond more closely to laminar conditions than to the turbulence characterized by the Reynolds number of the tubes. Therefore, predictions of heat transfer and pressure drop on the basis of turbulent flow may depart significantly from actuality.

For the core tested (ID = 0.256 in.) a $N_{Re} = 10{,}000$ corresponds to a 2 in. of water hot-core pressure drop, but for

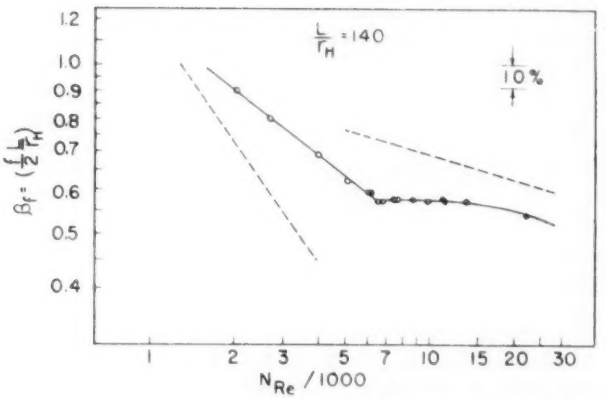

FIG. 5 COMPARISON OF PREDICTED AND EXPERIMENTAL FRICTION DATA

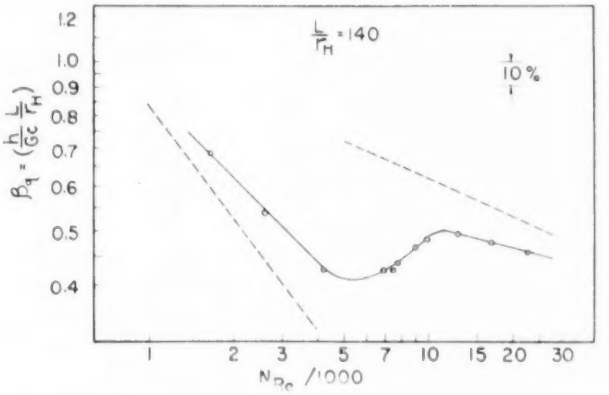

FIG. 6 COMPARISON OF PREDICTED AND EXPERIMENTAL HEAT-TRANSFER DATA

0.20-in-ID tubes of the same length at the same N_{Re} magnitude the pressure drop would be approximately 4 in. of water. Therefore this transition may occur in the design operating range of the oil cooler especially for the smaller tube sizes.

Fig. 5 compares the cold-core friction data with those predicted from available sources. The predicted curve is from the following equation given by McAdams (2)

$$\beta_f = \frac{f}{2}\cdot\frac{L}{r_H} = \frac{1}{2}\left[f'\frac{L}{r_H} + K_c + (1-\sigma)^2\right] \quad [2]$$

The first term in brackets $f'\dfrac{L}{r_H}$ is the contribution of tube skin friction; the second term K_c accounts for the contraction shock at entrance; while the third term $(1-\sigma)^2$ is the contribution of the sudden expansion at exit from the tubes.

For $5000 < N_{Re} < 25{,}000$ (ref. 2)

$$f' = 0.046\, N_{Re}^{-0.2} \quad [3]$$

and for purely viscous flow, $N_{Re} < 3000$

$$f' = 16/N_{Re} \quad [3a]$$

A sudden contraction at entrance would introduce a K_c magnitude of 0.27 for the area ratio $\sigma = 0.53$. However, the contraction is not sudden as the expanded hexagonal tube ends produce a converging section 1/2 in. long (Fig. 2). As a consequence $K_c \cong 0.27/2 \cong 0.135$ was assumed for this calculation.

These considerations introduced into Equation [1] result in the following relations used for the predicted curves in Fig. 5:

$$\beta_f = \frac{1}{2}\left(6.45\, N_{Re}^{-0.2} + 0.356\right) \quad [2a]$$

for

$$5000 < N_{Re} < 25{,}000$$

and

$$\beta_f = \frac{1}{2}\left(\frac{2240}{N_{Re}} + 0.356\right) \quad [2b]$$

for

$$N_{Re} < 3000$$

The exit and entrance losses contribute 20 to 30 per cent of the total friction.

Consideration of Fig. 5 reveals that the available friction-factor data adequately predict (within 15 per cent) the core behavior only for $10{,}000 < N_{Re} < 25{,}000$. For $N_{Re} < 3000$ the prediction based on viscous flow is not satisfactory since the entrance flow is not purely viscous and a parabolic velocity distribution does not obtain.

The comparison of experimental and predicted number of transfer-units data $\beta_q = (h/Gc)(L/r_H)$ is revealed in Fig. 6. The predicted characteristic for $N_{Re} > 5000$ was derived from the Dittus and Boelter correlation (2)

$$\frac{hD}{k} = 0.023\, N_{Re}^{0.8} N_{Pr}^{0.4} \quad [4]$$

which for air $N_{Pr} = 0.74$ reduces to

$$\frac{h}{Gc} = 0.0275\, N_{Re}^{-0.2} \quad [4a]$$

Tests by Brown and Barlow (5) performed on radiators having hexagonal tubes are in substantial agreement with Equation [4a], the magnitude of the conductances being only 4 per cent higher (coefficient of 0.0285 instead of 0.0275 in Equation [4a]).

For the laminar-flow region $N_{Re} < 4000$ the prediction of Norris and Stried (6) was employed

$$\frac{h}{Gc}\cdot\frac{L}{r_H} = 1.615\left(\frac{r_H}{L} N_{Pr} N_{Re}\right)^{-1/3} \quad [5]$$

or for $N_{Pr} = 0.74$

$$\frac{h}{Gc}\cdot\frac{L}{r_H} = 1.97\left(\frac{r_H}{L} N_{Re}\right)^{-1/3} \quad [5a]$$

Examination of Fig. 6 reveals that the predicted characteristic is within 20 per cent of the test performance for $10{,}000 < N_{Re} < 25{,}000$ and for $N_{Re} < 3000$. For the dip region, however ($3000 < N_{Re} < 10{,}000$) the agreement is poor.

Cold-core friction data together with the hot-core conductance data may be employed to predict accurately the hot-core pressure drop by use of the following approximate expression derived from Bernoulli's equation by assuming air density to be a function of temperature only.

$$\Delta p\,\frac{\rho}{\rho_0} = \frac{G^2}{g\rho_0}\left[\beta_f + \frac{\epsilon_a \Delta t_1}{2T_{a1}}(2 + \beta_f)\right] \quad [6]$$

In this expression $\Delta p\,\dfrac{\rho}{\rho_0}$ is the pressure drop (lb per sq ft) corrected to standard air-density conditions ($\rho_0 = 0.0750$ lb per cu

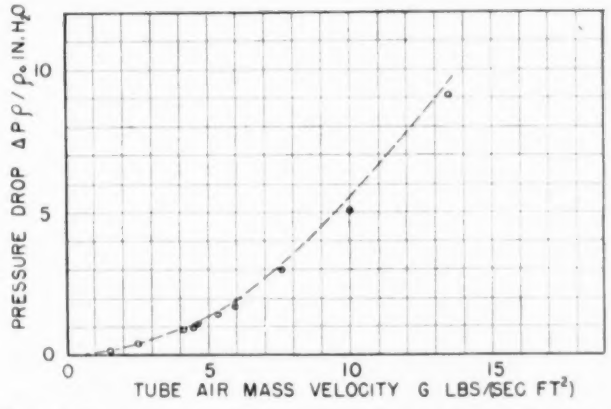

FIG. 7 COMPARISON OF PREDICTED AND EXPERIMENTAL HOT-CORE PRESSURE DROP

ft). To convert to $\Delta p \frac{\rho}{\rho_0}$ in inches of water, divide by 5.20 (lb per sq ft)/(in. H_2O).

Hot-core pressure drop exceeds that of the cold core, for a given mass rate of flow, for the two following reasons:

1 Increased skin friction and exit-shock loss as a result of higher air velocity.

2 A pressure drop necessary to produce the flow acceleration.

In Equation [6] the term $\left(\frac{G^2}{g\rho_0}\right) \beta_f$ is the "cold-core" pressure drop while the term $\left(\frac{G^2}{g\rho_0}\right) \frac{\epsilon_a \Delta t_1}{2T_{a1}} \cdot \beta_f$ is the additional skin friction and exit loss arising from the higher velocity flow. The remaining term $\left(\frac{G^2}{g\rho_0}\right) \epsilon_a \frac{\Delta t_1}{T_{a1}}$ is the pressure-drop requirement for the accelerated flow. The hot-core pressure drop will exceed that of the cold-core drop, by 14 to 18 per cent.

Comparison of predicted and experimental hot-core pressure drop is illustrative of the applicability of Equation [6]. For this calculation, the hot-core temperature difference Δt_1 is the temperature difference, saturated steam to entering air ($t_s - t_{a1}$). Magnitudes of β_f and β_q were obtained from Fig. 4. Term ϵ_a is evaluated as $\epsilon_a = 1 - e^{-\beta_q}$ The curve, Fig. 7, summarizes the results of these calculations and the data points of Table 3, corrected to standard density conditions, are superimposed for comparison. The agreement is within 5 per cent for most of the test points.

OIL-COOLER PERFORMANCE

The basic air-side thermal-conductance and friction data may be employed to predict oil-cooler performance provided oil-side conductance data are available. Oil-cooling performance can be conveniently related to core pressure drop by plotting "oil-cooling effectiveness," ϵ_0 versus core pressure drop, $\Delta p \frac{\rho}{\rho_0}$ for a given oil rate, as in Fig. 8.

In terms of temperature conditions

$$\epsilon_0 = \frac{(t_{01} - t_{02})}{(t_{01} - t_{a1})}$$

That is, ϵ_0 compares the actual oil cooling $(t_{01} - t_{02})$ to the maximum possible cooling $(t_{01} - t_{a1})$, which would obtain were the core cross section very large. "Oil-cooling effectiveness" may also be expressed in terms of the over-all conductance, air-flow rate, and oil-flow rate by integration of the basic heat-transfer-rate relations and energy-balance expressions, assuming constant U along the tube. The resulting equation is

$$\epsilon_0 = 1 - e^{-\beta_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [7]$$

where

$$\beta_0 = \frac{\epsilon_a G c_a A_c}{w c_0}, \quad \epsilon_a = 1 - e^{-\beta_a}, \quad \beta_a = \frac{U}{G c_a} \frac{L}{r_H}$$

Over-all unit resistance $1/U$ may be established from the resistance concept as consisting of the summation of air-side, tube-wall, scale, and oil-film unit resistances. For this illustrative calculation, the tube-wall unit resistance is neglected as being small. An estimated scale resistance of $^1/_{500}$ (hr ft² °F)/Btu is included in the test magnitude of h (Fig. 4). Oil-film resistance for an oil-flow rate of 4000 lb per hr (at an average temperature of 200°F) is estimated as $^1/_{130}$ (hr ft² °F)/Btu (7). Thus, $\frac{1}{U} = \frac{1}{h} + \frac{1}{130}$. From this expression and Fig. 4, U was evaluated as a function of G (for an average $\mu = 0.019$ centipoises). This information together with the assumed oil-capacity rate

$$w c_0 = 4000 \frac{\text{lb}}{\text{hr}} \times 0.49 \frac{\text{Btu}}{\text{lb °F}}$$

substituted into Equation [7] permitted the evaluation of "oil-cooling effectiveness" as a function of air-mass velocity G.

The prediction of pressure drop was accomplished employing Equation [6], together with an assumed inlet-air temperature $T_{a1} = 460 + 60 = 520$ °R, and an average oil temperature of 200° F. Thus $\Delta t_1 = 200 - 60 = 140$ °F. Departures of 20 °F from these assumed temperatures will not materially effect the evaluation of $\Delta p \frac{\rho}{\rho_0}$. Air-friction-factor modulus β_f, for the core was determined as a function of G from Fig. 4 (for an average μ

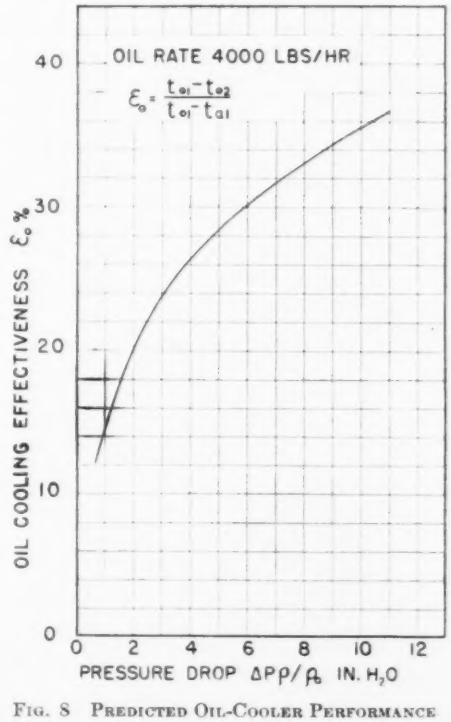

FIG. 8 PREDICTED OIL-COOLER PERFORMANCE

= 0.019 centipoises). The foregoing procedure allows the determination of $\Delta p \frac{\rho}{\rho_0}$ as a function of air-mass velocity G. The results of the prediction calculation for the particular 9-in. core employed in the test work, are revealed in Fig. 8. A family of similar curves could be plotted employing oil rate as a parameter. Such curves, together with oil-side pressure-drop data, would provide a complete expression of the performance of an oil cooler.

Summary and Conclusions

1 Air-side thermal conductance and friction-factor data are presented for a particular 9-in. shell-and-tube-type oil-cooler core.

2 The estimated magnitude of the scale resistance (shell side) which is included in the reported magnitudes of the air-side film conductance amounts to about 1 per cent at $N_{Re} = 1000$ and 8 per cent at $N_{Re} = 25{,}000$. This effect, in part, accounts for the discrepancy between the predicted and experimental conductance data. It also suggests the necessity for allowing for this significant scale resistance in design calculations.

3 An unexpectedly early transition from turbulent to semi-viscous flow is observed as starting at $N_{Re} = 10{,}000$ for both friction and heat transfer. This behavior may possibly be a characteristic of the core-duct test system, but data are lacking to confirm this suggestion.

4 Because of this early transition, predictions from published heat-transfer and friction data are not adequate for $N_{Re} < 10{,}000$.

5 The cold-core friction data may be employed to predict hot-core pressure drop with adequate accuracy.

6 Air-side thermal conductance and friction data, together with oil-side conductance and friction data may be employed to evaluate oil-cooler performance with respect to oil-cooling and pressure-drop requirements.

Acknowledgments

The authors express their appreciation to Prof. R. A. Seban of Stanford University and to Mr. R. H. Norris of the General Electric Company for their criticisms; to the Ethyl Gasoline Corporation for the graduate fellowship under which this work has been accomplished; and to Pratt and Whitney Aircraft for the loan of the oil cooler employed in the test work.

Boiler Embrittlement

By C. A. ZAPFFE,[1] BALTIMORE, MARYLAND

In the introductory section of this paper, boiler embrittlement as a field of study is traced back toward the very invention and genesis of steam boilers. The study is traced through the miscellaneous researches of several countries up to the establishment of unified research in three institutions: Britain's National Physical Laboratory in 1917, America's University of Illinois in 1917, and Germany's Vereinigung der Grosskesselbesitzern in 1920.

In the second part of the paper, the chronological study is extended to date, but with emphasis on a critical evaluation of all published work which can be found from America, England, Germany, France, Sweden, Italy, and Russia. The roles of stress, caustic, chemical attack, "aging," and hydrogen are given especial attention along with all other possible factors in boiler embrittlement. These factors are then shown to be identical with those observed in the attack of steel by hydrogen at elevated temperatures, a subject given peculiar neglect in the literature on boiler embrittlement.

In the concluding section, the various factors involved in boiler embrittlement are interpreted from the viewpoint that "boiler embrittlement" is nothing other than an intermediate stage in a naturally occurring hydrogen-purification process. The arguments which have revolved around intercrystalline and transcrystalline paths of the fracture, the behavior of inhibitors and accelerators, the prerequisition of stress and of caustic, and the role played by the steel are discussed to show how logically all observations resolve themselves in the light of this new conception. This interpretation for boiler embrittlement is then corroborated visually by simple experiments made directly upon specimens from boiler plate which exhibited "boiler embrittlement." Plans for future research along entirely new lines are suggested.

SINCE the imperial Russian yacht *Livadia*, built by the British for the Czar in 1879, suffered a mishap with the steam boilers employed in its radical design, the study of embrittlement in boiler plate has commanded international attention. Yet, subsequent decades of investigation have succeeded principally in defining the defect known as "boiler embrittlement," while its nature and underlying cause remain essentially unsolved.

Indeed a glance at even recent literature on boiler embrittlement reveals disagreement on nearly all points. The use of sodium sulphate, for example, was adopted many years ago into the A.S.M.E. Boiler Code (185)[2] as a prerequisite for preventing embrittlement; yet the Symposium on Boiler Embrittlement held by the Society just recently found most of the contributors refuting everything previously claimed for Na_2SO_4 (405, 406, 410). Parr and Straub patented the use of phosphate as an inhibitor of boiler embrittlement (266); but Schroeder and Partridge report a case in which commercial trisodium phosphate apparently caused cracking (319). Similarly, embrittlement from NaOH depends upon the presence of Na_2SiO_3, according to Schroeder and Berk (315), and Straub and Bradbury (320); whereas Desch refutes that claim by embrittling steel with pure NaOH (361); and Rice mentions that Na_2SiO_3 may even inhibit embrittlement (397). Within one publication, Schroeder and Berk prove that nitrates are excellent inhibitors of caustic attack, and then proceed to reproduce the phenomenon of boiler embrittlement, in their opinion, with nitrate attack (398). The steel itself plays no role in boiler embrittlement, according to Parr and Straub (211); yet the entire boilermaking industry in Germany has been based upon metallurgical studies of the steel. Even the descriptions of the defect are at variance, principally in regard to the path which the failure follows, until Perry has ventured to remark that transcrystalline or intercrystalline characteristics can be selected at the will of the operator (311).

Careful study of the mass of literature on the subject appears to reveal the basis for this disagreement. Indeed, half a dozen industries comparable to boilermaking long ago met and solved what undoubtedly is the identical problem, as will be shown.

At this late date, the annual cost of "boiler embrittlement" to the railroads alone is $500,000 according to a recent estimate (375). Besides that value in dollars and cents, one must reckon the loss in steel replacements, disruption of war production, and danger to lives and property—important factors in the present emergency.

1 EARLY HISTORICAL REVIEW OF INVESTIGATIONS LEADING TO STUDY OF BOILER EMBRITTLEMENT

Genesis of Boilers

Hero of Alexandria, in his book "Pneumatica," written about 130 B.C. (1), describes what were probably the world's first steam boilers. One, an "aeolipile," was a primitive steam-reaction turbine; the other was a hollow altar containing air which, when heated by a fire kindled underneath, allowed the expanding air to force water from a vessel below into a suspended bucket, which in turn then descended, opening the doors of a shrine. When the fire was extinguished, the air contracted, the bucket emptied, and the doors closed.

Except for such primitive nonsense, credit for the first commercial employment of steam as a medium of making heat do work belongs to Capt. Thomas Savery in England in 1698. His boiler was simply a hollow oval vessel made of metal (12). Among subsequent names of historic stature stands Newcomen in 1705, and Watt in the latter part of the same century. Of historical interest to many a locomotive engineer is the name "Rocket," which was the first successful steam locomotive, built in 1829.

Usually made of cast iron, early boilers often had flat surfaces and leaden, or even wooden, tops. Hoboken's great engineer, Stevens, who, in 1805, invented the water-tube boiler (12) which is essentially the progenitor of the modern boiler, constructed a boiler with its upper part shaped like a truncated cone and made of wooden staves held together with iron hoops. Copper was sometimes used, especially for parts in contact with the fire. About 1720, a boiler in Cornwall supplying steam for a Newcomen engine was actually constructed of large granite slabs

Note: Statements and opinions in papers are to be understood as individual expressions of their authors and not those of the Society.

(12). Little wonder that records from those days mention nothing of embrittlement!

Watt's "Wagon Boiler," so named because of its resemblance to the principal covered vehicle of that great era, introduced wrought iron as a structural material for steam boilers.

In 1857, steel was first used by the English Admiralty for the construction of marine boilers, but the results were far from satisfactory (7). To the *Bellerophon* goes the distinction of having the first inboard steel boiler. The commercial marine reported conflicting results, although land boilers made of Bessemer steel gave good service. Steelmakers were challenged to provide a more satisfactory material (3), which resulted in successful steam trials by the *Iris* and, in 1876, adoption of steel for steam boilers by the English Navy.

The use of steel then became generally adopted, although Parker (4), in 1878, stated that only two "of the modern form" were in existence in England at that time. Parker went on to give the first published comparison of advantages of steel over iron as a structural material for boilers, stressing the saving in thickness for any given pressure. In 1881, the same author noted that 1100 steel boilers were then in marine service (6).

Early Investigations of Explosions

In London, in 1815, a disastrous boiler explosion led to the appointment of a Parliamentary Committee, in 1817, to investigate the cause of that explosion and others which occurred about the same time. The recommendation of that learned body was that boilers thereafter should be made of wrought iron instead of cast iron or copper. Thereafter, boilers were periodically inspected by the Manchester Company, the pioneer inspection company of the world, from whom that practice subsequently spread to other countries (10).

Until 1830, boilers worked at about 7 psi, rarely over 10. The principle of high-pressure steam, then in its infancy, soon boosted the pressure to 30 or 40 psi, without bringing a simultaneous redesigning of the boilers. As a result, 288 explosions were reported in England between 1865 and 1870 (10).

In America, a parallel situation developed when the United States Treasury Department, in 1872, requested Thurston, President of this Society in 1881, to prepare a report on the causes and conditions of boiler explosions. Congress magnanimously appropriated $100,000 and the President was authorized to appoint a board to investigate "the singular mystery that has been supposed to surround their causes" (11). Thurston's comment then bridges the 60 years which have elapsed: "They (the Board) at once proceeded to spend money very freely—laid quite large plans; but for causes that need not be mentioned here, the expenditure of money was not as wisely made as it might have been!" His description of the futile efforts made to get various groups to co-operate in tracking down boiler failures casts a complimentary glow upon the contrasting success of the present Joint Research Committee on Boiler Feedwater Studies.

No report of that proposed investigation was ever published, though printing costs could hardly have exceeded the appropriation. Thurston discusses it, however (9, 11), and his hair-raising case histories of a dozen explosions, in which houses were demolished, locomotives turned into scrap, and bodies blown to hilltops a quarter mile away are quite sufficient to impress one that no effort made to solve and prevent boiler failures is unwarranted.

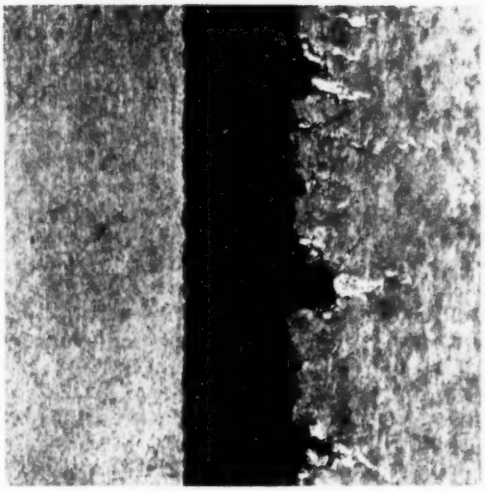
Thurston's conception, incidentally, was that a steam boiler is comparable to an explosive ordnance magazine, and he sought the answer to the explosion in the "expansive power common at the moment to the steam and to the water," which typified the general unawareness in that day of insidious processes within the steel, now called "boiler embrittlement." Most explosions, he concluded, were attributable to three causes; ignorance, carelessness, and utter recklessness.

Recognition of Brittleness in Boiler Steel During Fabrication

The Livadia. Prior to the *Livadia*, mentioned in the introduction, the study of boiler failures was primitive and largely nontechnical, resulting in conclusions to be compared with those of Thurston. Suspicions of the steel went no further than corrosion (6), and those failures wherein overheating, caused by local accumulation of dirt or sludge within the boiler, led to a craterlike eruption through the plastic metal (16).

The *Livadia* was an epochal event in yacht building, as well as in boiler making (5, 6, 8, 38, 59, 101). With a length of 230 ft, a beam of 150 ft, a double bottom, and triple sides forming two cell-layers each 6 ft through, this odd craft was to be fitted with ten boilers 14 ft 3 in. in diam; eight of them double-ended, 16 ft long, and two single-ended, $8\frac{1}{2}$ ft long. The boiler shells comprised three strakes of acid open-hearth $\frac{3}{4}$-in. steel plate with the lap joints treble-riveted, holes punched $\frac{11}{16}$ in. and reamed to $\frac{3}{4}$ in. The steel had passed Lloyd's tests, but one of the plates, after being punched, slipped out of the slings and developed cracks around the rivet holes (6, 101). It was assumed that punching had made the metal brittle, whereupon it was returned for annealing.

After completion of the boilers, they were tested hydrostatically. The first failed longitudinally at the joints of all three strakes. Another cracked before water ever entered it. Upon dismantling, the plates were found to be so brittle that pieces could be knocked off with a hammer.



This event, then, turned the eyes of metallurgists toward the study of the steel itself; but only toward the type of brittleness which manifests itself during fabrication. Regardless of the possible relationship between this early trouble and the modern problem of "boiler embrittlement," it is important, for the present, to distinguish the two by pointing out that the cracking which concerns us today develops only after the steel has been exposed to service conditions.

At this date, but little finality can be read into the many explanations advanced then for this fabricational brittleness. On the other hand, our improved position in the science of metallurgy permits two rather significant conclusions to be drawn: (*a*) The steel of half a century ago contained excesses of impurities now known to lead to "aging," or loss of notch-impact toughness after cold-working; (*b*) brittleness from hydrogen was likely.

Because hydrogen is to be discussed in relation to contemporary troubles, the second conclusion warrants some expansion. In his extensive discussion of the *Livadia's* boilers, Parker (6) concludes that (*a*) ordinary chemical analyses of the steel reveal nothing; (*b*) further working to 50 per cent reduction before punching eliminates the trouble; and (*c*) the steel is sound until punched, when cracks develop for some distance around the holes.

When "ordinary chemical analyses reveal nothing," in relation to brittleness in steel, hydrogen is a prime wager even today. The second point argues against a role of "aging," which is *aggravated* by cold-working, and points directly to hydrogen; for hydrogen, and no other element, can be removed in critical quantities by cold-work (384, 387). His last point, although applicable to other types of brittleness, certainly applies to hydrogen brittleness, as demonstrated in Fig. 1. Two specimens of ordinary boiler steel were annealed in a laboratory furnace $\frac{1}{2}$ hr at 950 C (1742 F), one in H_2, and the other in air. When these plates were cold-deformed in a manner analogous to punching, severe cracking developed all along the edge of the hydrogen-treated specimen.

Belief that the *Livadia's* steel was similarly steeped in hydrogen

(*a*) (*b*)

FIG. 1 EDGES OF TWO SPECIMENS OF ORDINARY BOILER STEEL, CUT FROM SAME SHEET, HEATED 1/2 HR AT 950 C, AND COLD-ROLLED TO 50 PER CENT REDUCTION; ×3
(*a*, Annealed in air; *b*, annealed in hydrogen.)

during annealing can be based upon the known effect of a hydrogen anneal in removing nonmetallic impurities from the steel. Parker reports P and S diminished by one half near the surface; and C, which is most readily removed, was reduced to a trace. As Siemens, a famous metallurgist of that day, remarked in the discussion, such a condition cannot possibly be traced back to segregation in the ingot, but must have resulted from some subsequent treatment. One need not assume the annealing treatment was quite as severe as that in the experiment just cited; for, as Barnaby points out in the discussion, the failure was only one out of 1100 cases, a second set of plates causing no trouble at all. Treatment that severe would have caused 1100 failures out of 1100. Parker's remark that "absorption of gases in the annealing furnace" may have caused the embrittlement suggests that even they regarded hydrogen embrittlement as a serious prospect, although the defect was unknown then. He "intended to pursue the question of the possible absorption of gases" as "a fruitful source of inquiry;" and his observation that the embrittlement reduced the ductility without affecting the tensile strength is typical of hydrogen.

Incidentally, these "preservice failures," typified in Fig 1, are transcrystalline, i.e., through the grain, which distinguishes them again from the "service failures," or "boiler embrittlement," which are predominantly intercrystalline.

RECOGNITION OF BRITTLENESS IN BOILER STEEL DURING SERVICE: "BOILER EMBRITTLEMENT"

In England. This transitional study of brittleness lasted for some years (37, 38, 39, 101), the discussion settling around brittleness observed during hydraulic-testing. Inconclusive comparisons of acid and basic open-hearth steels were made (38, 39). Annealing came under close scrutiny, because the opening of a crack indicated a role of internal stress (38). Steels which passed all tests of the British Board of Trade Surveyor and the Surveyor to Lloyd's Register would fail unexpectedly. Again, it is interesting to note that the fracture types discussed by Milton (38), and Arnold (37) are typical of those caused by hydrogen (404, 423).

According to Houghton (84), Milton wrote the first paper (38) on "boiler embrittlement" in 1905, wherein he noted that flanged steel plates in boiler service may crack, but that tensile and bend tests of the adjacent metal are entirely satisfactory. This fact stands as basic today (233, 398). The recognition of the fact that cracking might develop in service, rather than failure through the obvious means of corrosion or overheating, was the turning point in this field.

A growing pain of historic consequence in that regard was the famous case of the Dutch steamship, *Pahud*, an unclassed coasting vessel employed around Java, whose boiler exploded so violently that the boat sank (101). The boiler had been made in 1908, by a Dutch firm using basic open-hearth plates from a large German steelworks. German law required all plates to be annealed but, in this case, the plates were so large that the furnace equipment was not well suited. The boiler was of the triple-riveted, double-butt-strap type, and the rupture occurred along a row of rivets on a longitudinal joint. Butt straps were then removed from several similar boilers on other ships, and cracks between the rivets were found.

Wolff (97) blamed the failure upon fatigue, reporting an elaborate series of tests on the elastic movements of plates. He felt that short coastal service, i.e., "boiler-working," was responsible in developing intermittent and unequal expansions in the boiler shell, and cited the case of a Clyde-built vessel employed on the Yangtze. At the sudden approach of a typhoon, steam was raised rapidly; the shell plate split longitudinally, but was patched and thereafter served for 40 years.

Wolff also stated that the worst failures were from basic open-hearth steel, although acid steel fails, too. The fact that only in a few isolated cases did boilers fail, he felt, pointed to the steel as the source of the trouble. Houghton (101), however, thought the answer lay in the work of Ridsdale (24, 27), who had demonstrated that steel worked at blue heat develops cracks between the crystals near the surface. Service (108) remarked on the evident harmfulness of shearing; Bryden (100) blamed rolling, finishing at too low a temperature, and pointed out that the failures discussed by Houghton all occurred at the edges of the plates; Marquand (102) blamed overheating, or finishing at too high a temperature, as evidenced by the large grain size at the failure; McCance (103) showed that steel plate hardens to one half its thickness, during shearing whether sheared cold or at blue heat; Houghton (101) and Marquand (102) both hint at the bogy of "oxidized steel;" and Ridsdale (106) blames the weather, remarking that a cold floor on Monday morning, or snow and rain, if the plate is cooled outdoors, may lead to local brittleness. Houghton (101) quotes Colville as opining that the *Pahud's* boilers had been made from a "wild charge of steel dosed with silicon," which may be said to complete this shotgun pattern of logic.

Finally, Stead (109), who agreed with Wolff in his opinion on fatigue, obtained a "good" and a "bad" piece of steel, each passing specifications; but the "bad" steel, as a specimen 1 in. wide, would crack during one bend, whereas the "good" steel required numerous bends for breaking. The method of bending as a test for boiler plate was thereafter generally adopted.

In Germany. In Germany, these events were more or less paralleled, although the importance of annealing was recognized long before it was adopted elsewhere. Meunier, in his Report of the Chief Engineer to the Elsässischen Vereines von Dampfkesselbesitzern (28) for 1902, discussed the explosion of a boiler built in 1869, and proposed that the ductility loss occurs during service, in opposition to the general picture of that time. Meunier, therefore, antedates Milton in recognizing "boiler embrittlement." All boilers having 35 years of service should be replaced, in his opinion (35). Principally as a result of his work, the Reichs Chancellor issued a decree, known as the Würzburg and Hamburg Code (40) of 1905, which standardized boiler inspection both during fabrication and during service (41, 44).

Bach (33, 41, 42, 48, 49, 60, 65, 70) and Baumann (50, 70, 77, 157) were the authorities in Germany on boiler failures. It is an amusing commentary on the elusive nature of "boiler embrittlement" to find Baumann writing a monumental article 35 years ago on "The Present Status of the Question of Cracking in Boiler Plate" (50), in which he presumes to have the answer to boiler embrittlement. The same title was used almost verbatim only 3 years ago in Germany, and in substance composed recent papers in England (396) and America (297), as well as the present one, each one still claiming an answer.

From the start, German investigators suspected the steel. Sulzer (54) attempted to relate cracking to thermal strain by various physical tests. Bach (48) used specimens from a fractured boiler dome and tested them at various temperatures, emphasizing the necessity for designing boilers on the basis of the properties of the steel at the operating temperature (33). Bach (60, 70), Bauer (99), and Baumann (77) then showed that incipient cracks developed during riveting when too severe pressures were used, a line followed by recent investigators in this country (311). Boiler explosions (71) in Germany, in 1912, were blamed on improper heat-treatment of the steel (67, 167), and hot-working at too low temperatures (73). Bauer (99) and Baumann (77) also investigated segregations and inclusions as causes of cracking. Starck (184) blamed the brittle nature of ferrite crystals. Finally, the problem still unsolved, a disastrous boiler explosion in 1920, in Germany (283, 361), provoked the formation of the Vereinigung der Grosskesselbesitzern.

In America. Corresponding concerted study of boiler embrittlement began in England at the National Physical Laboratory (251, 265, 296, 361), in 1917, the first results of which were published by Rosenhain and Hanson (128), in 1920. In America, Parr pioneered present studies with a publication (94), also in 1917, which covered his work begun in 1912, as a result of boiler failures occurring around Urbana, Ill. (220, 233), and concluded with a research by Merica (92) on caustic embrittlement. Boilers had been installed in a building at the University of Illinois in 1874. Surface water was used until 1888, when a 160-ft well was dug. In 1898, operating pressures were increased and embrittlement began shortly, although the first official record occurred in 1910. First attempts, in 1912, to neutralize the alkalinity ended in 1915 with Parr's suggesting that sulphuric acid be added to the feedwater. Today, the work at the University of Illinois Engineering Experiment Station (92, 94, 181, 197, 200, 211, 223–226, 232–234, 243, 244, 254, 266, 320, 352, 353, 369, 416), at the United States Bureau of Mines (297, 300, 315–319, 331, 348–351, 380, 381, 398, 399, 411–413), and that of the Joint Research Committee on Boiler Feedwater Studies, represents America's principal contribution to the international problem of boiler embrittlement.

Everything prior to the authoritative investigations of these great international organizations for the study of boiler embrittlement, just named, may be considered as having historical interest only, although it serves well to orient the student of this subject. The following discussion, while also chronological and stepwise, will subordinate historical features to a critical examination of the manifold, and often divergent, data provided principally by those international organizations over the past 25 years.

2 CRITICAL STUDY OF PUBLISHED DATA ON BOILER EMBRITTLEMENT

Caustic Embrittlement

Today, the defect known as "boiler embrittlement," the subject of this paper, is still often called "caustic embrittlement" (326, 256, 259, 371, 378, 390), and perhaps correctly. In any event, the roots of present research certainly extend from the observation that caustic solutions develop a brittleness in steel which is characteristic of the defect which is now being considered.

Thomson (19), in 1894, and Stromeyer (59), in 1909, appear to be the first to discuss that action of caustic when they cited cases of boilers containing caustic in which embrittlement had proceeded to a degree where the rivet heads flew off. Stromeyer's explanation was that, in the presence of caustic, water reacts with the iron and forms iron oxide and hydrogen, "which leads to hydrogen embrittlement." In 1914, Andrew (81) enlarged upon the argument; but 1917 stands as the epochal year.

In that year, Desch, discussing Wolff's paper (97), described the embrittlement of caustic tanks and ventured the explanation that hydrogen entered the grain boundaries and "gradually opened up the metal until the crystals were distinct." To Desch, one of Britain's ablest scientists, therefore, goes the credit for anticipating by a quarter of a century the recent results of the National Physical Laboratory (396). Stromeyer (95, 96), in a classic experiment, proved that caustic embrittles steel only when stressed in tension. Two concentric, tapered rings were forced together, placing one under tension, the other under compression. Regardless of previous working or annealing, the compressed ring would not embrittle in caustic, whereas the ring in tension did. Stromeyer assumed that sodium carbonate in the boiler water breaks down to form NaOH under operating conditions of temperature and pressure, and that the NaOH caused the embrittlement (59, 95, 96, 150, 171). Furthermore, he noticed a "penetrating influence" of the caustic, which seemed to operate upon metal removed from the solution by $^1/_4$ in. of steel.

In the same year, Merica (92) and Parr (94) initiated the series of publications from the University of Illinois. Parr pointed out that normal feedwater has no NaOH and far too little carbonate to act on boiler plate, but that concentration is likely. Furthermore, depending upon temperature and the removal of CO_2, hydrolysis of the carbonate yields NaOH. Tests with steel, immersed in 13.6-normal NaOH at temperatures up to 280 C, clearly established the role of caustic in developing the hydrogen necessary for the hydrogen theory, whereupon Parr concluded, "the evidence seems to show that the embrittling effect of NaOH on steel is due to the evolution of hydrogen, and the absorption by the steel of the hydrogen in the nascent state." This statement, though similar to Desch's, missed similar fruitfulness for reasons soon to be disclosed. On the basis of the hydrogen theory, he suggested adding an oxidizing agent, such as $Na_2Cr_4O_7$, to depolarize the iron electrode. Sulphates, he added, might also be useful, at least as diluents. These ideas remain more or less secure today.

Certain basic facts regarding boiler embrittlement, recorded by these same investigators, are worthy of mention, namely, that embrittlement (*a*) always occurs below the water line; (*b*) is associated with waters having high alkalinity; (*c*) usually occurs in conjunction with a leak or seam where concentration of the soluble material to its saturation point is promoted; and (*d*) is accompanied by an exterior accumulation of a strongly alkaline incrustation.

In attempting to elucidate the role of hydrogen in causing boiler embrittlement, which is a phenomenon characterized by grain-boundary reactions at elevated temperatures, Parr and Merica drew an unfortunate comparison with the hydrogen-caused phenomenon of "pickling brittleness," widely discussed since the time of Ledebur (14, 15), and relating only to short-time tests and temperatures usually well below the boiling point of water. Discussion of that error will be reserved until its importance is established in succeeding paragraphs.

The Role of Stress

In the Intercrystalline Failure of Metals. As an alternative to the hydrogen theory, Parr (94) and Merica (92) had also suggested that the caustic ate out the "amorphous intercrystalline cement," a primitive metallurgical conception of grain-boundary material which is probably less stable than the body of the crystal. Andrew (81) had previously suggested such a thing, and Schroeder and Berk (398) base their entire argument upon essentially the same conception. Let us examine the broad aspects of intercrystalline failure from direct chemical attack to detect relevancy to boiler embrittlement, if any.

Since Roberts-Austen (13), in 1886, touched an Au-Cu-Ag alloy with $FeCl_3$ solution and found it breaking within a few seconds along several inches of the metal, many similar observations have been reported which may strongly influence one toward such an explanation for boiler embrittlement. Amagat (17), in 1893, forced mercury through 3 in. of cast steel at 3000 atm pressure, with indications of a selective and highly penetrative amalgamation. No previous flaw could be detected in the steel with a microscope. Cailletet, Colardeau, and Riviere (25) observed the same phenomenon at higher temperatures proceeding under relatively low pressures. Bridgman (66) finally discovered the role of stress, demonstrating that pressures exceeding the elastic limit would force mercury through the strongest steel.

Similarly, Desch found beta brass containing Al to granulate within a few seconds when placed in a solution containing a salt of mercury (82, 133); although cast Zn, Sn, and Pb corroded gradually without granulation (112). Copper cathodes in molten NaOH developed intercrystalline brittleness (127). Rawdon reports that mercury solutions for testing crack sensitivity of manganese bronze were adopted into the New York Board of Water Supply Specifications in 1915, and that the Aircraft Board adopted an immersion test of 15 min in mercurous-nitrate solution (105). Phosphor-bronze bars, immersed in mercurous-nitrate solution, cracked in 3 min, according to Arnott (131). LeChatelier complains of the disintegration of military canteens in the first world war (116). Made of an aluminum alloy, containing 3 per cent copper, the canteens disintegrated in service, showing oxidation around the grain boundaries. Again, copper develops intercrystalline brittleness when heated in Zn vapor (151); and Desch and White showed that electrolytic corrosion of beta brass is so pronounced at the grain boundaries that the zinc is removed, leaving an enrichment of copper, which may oxidize (79). Similarly, nickel steel has been reported to oxidize granularly, leaving an enrichment of nickel in the grain boundary (89).

Nitrate solutions are particularly effective, lead disintegrating into crystals when placed in dilute HNO_3 (119), or when used as an anode in nitric acid (86). Lead acetate has a similar effect on lead (129), although a single crystal is relatively immune. Porter reports $NaNO_3$ causing cracks within a few hours running the entire diameter of a 100-ft NaCl evaporating pan (146), an observation also made by Malcolm for smaller pans (141). Smialowski (288) and Andrews (335) have demonstrated the intercrystalline attack of steel by ammonium nitrate, Andrews proposing that grain-boundary carbide is the cause of the attack. The work on boiler embrittlement at the Bureau of Mines leans heavily upon this action of nitrates (398).

Among the first to discover the critical role of stress in these failures was Rogers, who claimed to have developed, in 1905, a mercuric-salt method for revealing internal stress in brasses (118). Smith (121) thought that Roberts-Austen's experiment with the gold alloy (13) confirmed the presence of a highly stressed surface film which led to fracture when fissured. Jones (140), in a paper much quoted in work from the Bureau of Mines, stated that service failures of steel from caustic clearly required stress. He proceeded to develop intercrystalline cracking in steel at temperatures up to 250 C, using $Ca(NO_3)_2$, NH_4NO_3, $NaNO_3$, $NaNO_3$ plus 5 and 10 per cent $NaHCO_3$, and KOH solutions, although neither $NaHCO_3$ alone, $(NH_3)_2SO_4$, $CaCl_2$, fused $NaNO_3$ + KNO_3 mixture, nor air would cause cracking. Around rivet holes, $Ca(NO_3)_2$ produced cracks in 28 days. In spite of the fact that some students of boiler embrittlement have attached great importance to this nitrate cracking, Jones admitted that the action of the KOH, which was the only nitrate-free solution with which he produced cracking, was unique; and he actually concluded that the caustic produces hydrogen which selectively weakens the grain boundaries. The nitrate, he thought, might supply an analogous agent, possibly nitrogen. Subsequent investigators, who have referred to Jones's work, never mention his own evaluation of his results, but emphasize the nitrate cracking, which is irrelevant to boiler embrittlement, as will soon appear.

In further proof of the importance of stress, Jonson found that brass immersed in ammonia and stressed in tension was unaffected until the elastic limit was reached, whereupon the metal fractured (85). Dickenson showed that molten tin and solder penetrate the grain boundaries of stressed brass (123); Merica found a difference in potential to exist between stressed and unstressed wires (87); Austin obtained intercrystalline embrittlement by stressing various metals in tension in solder (302); van Ewijk demonstrated the penetration of high-strength alloy steels by solders at 400 C (301), similar to Schuster's experiments with liquid brass on steel (269); Hodge and Miller showed intracrystalline penetration of austenitic "stainless" steel by the chlorides of iron and mercury (373). However, the most thorough research on the penetration of stressed steel by molten metals and alloys was reported by Schottky, Schichtel, and Stolle (242), who concluded that intercrystalline failure will result only if the stress is above some minimum, and only for those systems exhibiting solubility.

In "season cracking" of brass is found the widest discussion of intergranular cracking. "Season cracking" is one of those hapless terms which have no technical significance and simply pinch-hit until the phenomenon to which they refer is understood. In this case, the term comes from the resemblance of the defect to the cracks developing in timber upon seasoning.

With copper-zinc alloys, the defect is thought to be limited to metal having less than 80 per cent copper (98). Strain is essential, which lends a serious aspect to the problem because brass is principally valuable in the hard worked condition. Diegel, in 1906, appears to have been the first to discuss season cracking (43). Merica and Woodward reviewed the literature (93), up to 1917. Masterful papers on the subject include those of Hatfield and Thirkell (115), and Moore, Beckinsale, and Mallinson (144), both written more than 20 years ago. Both show the role of stress, the latter demonstrating the intercrystalline cracking produced by salts of Hg and NH_3 in brasses sufficiently stressed. Pure copper was not cracked by those salts, and only those brasses cracked in which Zn was greater than 6 per cent. Bassett (98), writing in an era not yet adapted to the automobile, cites instances of spun- or drawn-brass lamps on carriages breaking during winter storage in stables. Condensation of moisture during temperature changes plus absorption of ammonia from the stable atmosphere was indicated.

On the role of stress in causing cracking, Heyn's 1914 lecture before the Institute of Metals remains a classic (83). Heyn was the first to set forth clearly the underlying principles and to measure the stress. Incidentally, his method of measuring stress by cutting concentric rings from the specimen, although independently conceived, had been used 20 years previously by Howard at the Watertown Arsenal (18).

These examples have been cited because today there are those who attach great, but ambiguous, importance to the similarities with boiler embrittlement, probably following a suggestion made in 1919 by Rosenhain and Archbutt that boiler embrittlement was nothing other than the defect known as season cracking in brass, and as granular disintegration in lead (120). Such an opinion simply reverses the adage about the trees obscuring the forest, for the phenomenon of intercrystalline embrittlement in metal springs from a multitude of causes, none of the foregoing having any real resemblance to boiler embrittlement except that under the microscope the failure is intercrystalline in both cases. If comparison is valuable, and it certainly can be when correctly made, why not compare boiler embrittlement with the mass of untouched information on intercrystalline embrittlement and granular deterioration from hydrogen? Since the active presence of hydrogen in boiler embrittlement has been so amply proved, why not select for comparison the intergranular failure occurring in chambers for ammonia synthesis, hydrogenation autoclaves, in decarburizing steels with hydrogen, in general purification treatments using hydrogen, in the well-known "hydrogen sickness" of copper and its alloys; rather than with aqueous solutions containing chemicals having but little relationship to boiler feedwater? Why do investigators of boiler embrittlement continue to cite cases of intercrystalline-cracking from nitrates (398) when the NO_3^- ion is deliberately added because it is a good "inhibitor" of boiler embrittlement (319, 405)?

In "Boiler Embrittlement." Similarly, stress has been found to be essential to the intercrystalline-cracking known as boiler embrittlement (226), even to the extreme of Hatfield's suggestion (193) that the question of boiler-cracking was settled in 1898 when Stead showed fissures in the steel caused by machining and working (21, 22). Bauer early noticed that boiler-cracking was always preceded by cold-working, a condition difficult to avoid in processing boilers (90). Heyn and Bauer made an elaborate study of the stresses in boiler plate (68) and decided that tensile tests were poor indicators of suitability for boiler service (74). Impact tests were advised. A great deal of work in Germany followed that general line of thought as a result of Fry's development of an etching technique which brought out the strain lines in steel (149, 169, 179, 180, 183, 187, 196, 219). Hanson (136) and Rosenhain (148) noted that the outer plate and rivets of a 4-strake boiler embrittled worse than the inner plate and suggested that stress was consequently a more likely cause of boiler embrittlement than chemical attack. Sufficient reason for cracking could be found in internal stresses and cold-working, according to Whiteley (110, 204), Bolsover (216), Strauss and Fry (149), and Ness and MacCallum (210), although Houghton demurred (138). That corrosion only started at loci already initiated by excessive strain during cold-working was Fletcher's viewpoint (134). As a matter of fact, the argument at the 1921 session of the Faraday Society centered around the relative importance of stress and chemical attack in causing embrittlement, as did the 1925 meeting of the Vereinigung der Grosskesselbessitzern in Germany (183). McAdam concluded that boiler embrittlement was simply a pitting form of stress corrosion wherein hydrogen played no part and NaOH was unnecessary (240). Such a conclusion, of course, is ill-advised, for no traces of pitting are ever found (240, 319), NaOH is essential (181, 211, 233), and the defect depends upon hydrogen, as will be shown.

At the National Physical Laboratory, Rosenhain and Murphy (241) and Jenkins (280, 293) performed experiments in which specimens were stressed in various ways in various solutions at various temperatures, but no intercrystalline failure could be produced even in tests lasting 5 years. Tests in air at 300 C for 5 years also failed to reproduce boiler embrittlement (199), whereupon the safe assumption could then be made that stress alone is not the cause of that defect. Since that temperature lies in the range of "blue brittleness," the tests also eliminated the analogy originally proposed by Ridsdale (20).

To accentuate the specific nature of "boiler embrittlement," White and Schneidewind (245) outlined and illustrated the various types of cracking which follow from stress alone, stress in conjunction with corrosion, and from caustic attack. Of course, it must be recognized that all boiler failures are not caused by caustic embrittlement (23, 175, 261, 299). Surface cracks may even carry over from hot-working (239); and true corrosion and fatigue cracks are quite possible under boiler-operating conditions (181, 195, 220, 240, 312, 313). Nevertheless, the defect known as "boiler embrittlement" (135, 186, 213, 218, 255, 367, 368, 383, 397) is a specific phenomenon, whose cause clearly depends upon both stress and chemical attack.

Interestingly, research in Germany followed steadfastly the role of stress as it related to the properties of the steel (270, 272, 286, 354, 392), whereas Americans have emphasized the chemical aspect (198). In England, besides the researches already mentioned, some considered embrittlement to result simply from pre-existent intercrystalline spaces (124, 249), the so-called "Rose' Canals," which were proved to exist by the clever research of Tammann and Bredemeier (172), or from fissures developed during riveting (21, 22, 191, 193). Rosenhain and Hanson, noting carbonless bands and grain growth from critical amounts of cold-working, argued heatedly that they had at last found the answer to boiler embrittlement in large, brittle ferrite crystals (107).

Finally, Münzinger took a trip to America to examine our practice and wrote upon it at length in 1925, after returning to Germany. His message to the folks back home was that interesting results were being obtained in America from feedwater studies, the opinion being that the caustic concentrated in leaky seams (163, 165, 166). The fall meeting of the Vereinigung der Grosskesselbesitzern in that year concerned itself largely with Münzinger's report (183), whereupon that date may be said to mark the beginning of concerted international attention being paid to the combined effects of stress and chemical attack from NaOH.

The Role of Chemical Attack

Chemical attack, of course, must relate to chemicals in the feedwater. That is a principal weakness in the argument based upon nitrate-cracking when much more significant comparisons can be so readily found. In fact, Schroeder and his colleagues have frequently pointed out the well-known characteristics of boiler embrittlement which distinguish it from ordinary chemical attack, but provide, as their best answer, a theory based upon direct chemical attack. As mentioned by Parr and Straub (181), nitrates, chlorides, and sulphates may lead to corrosion because corrosion is associated with the H^+ ion; but the OH^- ion, which characterizes the feedwater of embrittled boilers, should inhibit such attack in boilers. That it does is borne out by fact, except for some extraordinary conditions in high-capacity boilers (365).

There is another well-established fact: namely, that boiler embrittlement is founded upon the reaction of iron with water to form hydrogen and black magnetic oxide

$$3\ Fe + 4\ H_2O = Fe_3O_4 + 8\ H$$

The oxide characteristically occurs as a smooth, adherent, black scale to be distinguished sharply from the highly localized accumulations one must expect from selective corrosion, as required by the theory of Schroeder and his colleagues. The rusting of iron in general, which they admit is the basis of the phenomenon, is notoriously undiscriminating in its attack; that is, it is non-

selective (137). Other objections to their argument will be treated as they develop in the discussion.

Because the role of feedwater and chemical attack has been so frequently discussed in this country, only a skeletonized review of essential points will be made here. In the monumental publication by Hall and his colleagues (192), and in the papers of Straub (223, 225), Chapman (236), and others (207, 231), the subject is considered in detail.

Briefly, caustic is kept in the water as a necessary prevention of dissolution of metal at any anodes which may develop, 100 ppm effectively inhibiting corrosion. If carbon dioxide escapes, the caustic may concentrate

$$Na_2CO_3 + H_2O = CO_2 + 2\ \underline{NaOH}$$

Even with this increase in NaOH, however, the solution is still harmless to steel. Further concentration is necessary, as early pointed out by Parr (94). In 1910, Stromeyer had reported iron tubes cracking in caustic evaporators when NaOH exceeded 40 per cent (63). In 1917, Parr had shown that iron did not react with NaOH solutions from $^1/_2$ to 2 normal, but that, at higher concentrations, 5 to 10 normal, the passivity vanished and the anodic reaction proceeded (94)

$$Fe + x\ OH = FeO_x + x\ H$$

At 150 to 200 C, however, H was generated in a 1-normal solution, a fact shown by Krassa (58) in 1909. Still, such concentrations never occur in boiler water; whereupon the assumption was made that the solution concentrated around rivets and in leaky seams to a point where the steel was attacked (181). That was the viewpoint taken back to Germany by Münzinger and discussed by Thiel, Kriegsheim, Ries, Rösing, and Baumann at the meeting of the Vereinigung der Grosskesselbesitzern (183), and elsewhere by Baumann (188), and by Splittgerber (170).

Demonstration of such concentration soon followed. Berl (189), in 1927, used glass capillaries to show that evaporation and the slow diffusibility of substances in such confined spaces quite readily led to concentration. His observation (190) is today generally accepted as factual (233), especially because the alkaline incrustation always noted around failed parts is virtual proof of the mechanism (233).

For the prevention of embrittlement, Parr's early ideas were based upon the hydrogen theory and concerned adding salts that would react with the NaOH or with the H to make it harmless. Such an argument is still valid today, although the studies have been advanced to include many other additions. Endless argument over the results which have been obtained are principally due to causes that will be considered after the discussion of another phase of the problem has provided a basis for an understanding.

The Role of "Aging"

No adequate discussion of boiler embrittlement can fail to mention the energetic figure of Stromeyer who, as early as 1905, made bending tests after successive intervals of time and found that the ductility of boiler steel decreased upon standing at room temperature (39). Although admitting that the brittleness may begin at sheared edges, Stromeyer nevertheless felt that the defect was more generally located and proposed that P was to blame when its content exceeded 0.05 per cent. The same thing is observed today (200). In 1907, Stromeyer (52, 53) proposed his famous "aging" theory for boiler embrittlement, which threw steelmakers into consternation because he effectively showed them that steel may be harmed by boiling in water. Tests made at temperatures from a wintry —16 F to that of boiling water and for periods up to 16 years showed that steel became brittle with age, and that increasing the temperature accelerated the process. In 1909, Stromeyer introduced N into the question of aging (59), along with impurities in general, although he was never able to provide an explanation for the effect that was either logical or decisive.

About 20 years later, Fry (178, 209) brought the "aging" argument to practical fruition with the development of a "nonaging" steel, "Izett" steel, so named from the initials of the German words "*immer zäh*," meaning "always tough." Fry believed, as did Stromeyer, that boiler steel aged into brittleness upon heating at 200 C. Subsequent to the time of Stromeyer, oxygen was identified as a likely cause of aging; consequently, Izett was a steel to which sufficient Al had been added so that the oxygen was stabilized as Al_2O_3.

Because oxygen may not be the only element responsible for aging, Izett steel need not be the final answer. Pfeil (212), for example, blames C; and N was considered along with P by Stromeyer (59). However, it is possible to coalesce these seemingly contradictory opinions and to show that each nonmetallic impurity may play a part.

Unfortunately, the valuable lesson to be learned from these investigations on aging was obscured by the research of Parr and Straub (211), in 1928. Although Parr and Straub themselves state that cracking will not occur if the steel is not stressed above the range of the yield point (181), a fact widely recognized, they tested a group of steels without regard to load/strength ratios, and concluded by comparing a flange steel, tested at its yield point, with a specimen of Izett having a 25 per cent overload. Even under these conditions, the Izett specimen was 200 to 300 per cent more durable than most of the fifteen specimens tested, and had a life exceeded only by two S.A.E. 1112 steels and the flange steel just mentioned. Neuendorff (252) also remarks that Parr and Straub's results are valueless because, "for reasons unknown to the reviewer," the flange steel had less load than the Izett. Those tests were made exceedingly critical to the problem of boiler embrittlement by the authors emphasizing the erroneous conclusion (211): "The embrittling effect occurs without regard to impurities or composition of the plate and that any defense of the embrittling distress attempting to charge it against the faulty iron is without basis in fact" (181), and "any ideas that embrittling distress may be due to faulty iron is without basis in fact" (200). Again, Straub remarks (200), "Pure iron was embrittled in the same manner as boiler plate." Obtaining "pure" iron is an accomplishment but few metallurgists yet dare boast; none would in 1927. In the same article, on the other hand, he observes that S and P accelerate embrittlement.

Along the same line, Parr and Straub (181) tested 3.5 per cent Ni steels, again without regard for load/strength ratios, and concluded that Ni exerts "no effect other than raising the yield point and, consequently, the initial stress necessary to cause embrittlement." On the contrary, examination of their data shows that the 3.5 Ni steel had 1000 per cent longer life than the best plain-carbon steel; that the best Ni steel had a yield point of only 40,000 psi and lasted $8^1/_2$ days, whereas six of the eight carbon steels had yield points above 40,000 psi and failed before 1 day had elapsed, one with a yield point of 49,000 psi failing in $3^1/_2$ hr. In the same vein, these investigators later (211) discounted the effect of sorbitic heat-treatment because it doesn't "stop" embrittlement, thereby losing for the science the fact that the finer dispersion of the carbide is definitely favorable.

Such work has been aptly categorized by Gillett (395) as "metallurgical naïveness," who with numerous instances reminds investigators of boiler embrittlement that they err when assuming that "steel is steel." Perry (311) is essentially in agreement with Gillett, and with metallurgists in general, when he states that the railroads find it "impossible to accept the prevailing ideas

regarding the relation of . . . boiler water to the failures," and that "factors other than boiler-water conditions contribute to boiler failures, and until such factors are corrected, failures are bound to occur regardless of the water used."

Izett steel, in spite of this, has been amply defended, though American investigators of boiler embrittlement seem poorly informed of it. Ulrich (227, 235) deliberately repeated Parr and Straub's tests, but with careful arrangement of the ratio of load-to-tensile strength so that an acceptable basis for comparison resulted. In addition, his values were corrected for the variation of the tensile strength between room temperature and 250 C (154, 201), which apparently was overlooked in the work of Parr and Straub. The Izett showed a marked superiority over flange steel in respect to embrittlement in caustic solution, a result also reached by the German Official Testing Laboratory (194). Finally, American investigators likewise reported recently that aluminum-killed steels are more resistant to cracking (398).

Comparing Bessemer, open-hearth Duplex, and Izett steel with respect to embrittlement from cold-working and from heating, Epstein (248) found that Izett suffered no increase in tensile strength and but little decrease in ductility upon heating to the blue-brittle range, so that it was considerably more ductile than boiler steel; and that aging around rivet holes was so shallow that the notch toughness was unaffected. Fry (238) pointed out that boiler steels, if nonaging, would promote welding practice for boilers. Studying boiler plate at room temperature after cold-working, Bauer found a progressive decrease from 6.3 to 2 in notch-impact values over a period of 1 year, with no end point indicated (132, 252). In a similar study, Goerens reported a great improvement from an addition of 3 per cent Ni (160). Lastly, Herzog and Portevin (342) demonstrated that nitrate solutions, generally so destructive to steels, do not readily fissure killed steels, which shows the necessity of considering the metallurgical quality of the steel in such problems.

The Role of Hydrogen

The Fe-H_2O Reaction as a Source of Hydrogen. Since Ledebur (15), in 1889, discussed rusting brittleness in iron along with pickling brittleness, the hydrogen produced by the reaction of Fe and H_2O has received universal attention. In 1903, Whitney (32) originated the electrochemical theory for the corrosion of iron by water, wherein H^+ ions are replaced by metal ions, according to the theory of Nernst

$$Fe + 2\,H^+ = Fe^{++} + \underline{2\,H}$$

Walker and his colleagues (55, 56) extended the theory in 1907, and 2 years later Friend (57) measured the hydrogen produced by steam acting on iron foils and powders at temperatures up to 350 C. Friend showed that magnetic iron oxide resulted from the action, an observation substantiated by every case of boiler embrittlement (181), and presented curves showing that at the lower temperatures the reaction undoubtedly still proceeded, but more slowly.

In 1919, Fuller (114) published a research proving that tap water reacts with iron to produce hydrogen which diffuses through the iron, and that steam greatly aggravates the action. His observations are notable, because some have raised the question whether the nascent condition of the hydrogen in rusting really compares with the hydrogen developed during pickling, which is known to penetrate iron. It does, though the reaction is considerably slower.

Schikorr (221, 222) developed 18 atm pressure of hydrogen by reacting iron turnings with deaerated water without any limit being indicated. The evolution was doubled between 25 and 35 C, which is consistent with the logarithmic nature of chemical reactions. When an iron plate was used, a coating of Fe_3O_4 developed in 2 hr, but no measurable hydrogen was produced. This suggests that the gas may have been absorbed by the steel, as shown by Fuller (114). Powder has such a large ratio of surface to volume that reaction, rather than occlusion, would be favored. Baylis (176), and Berl and his co-workers (190, 206, 215, 229, 246), made similar observations, the latter reporting that NaOH added to the water in quantities above a certain minimum greatly increased the evolution of hydrogen.

In actual tests on boilers, Fellows found hydrogen both in saturated and in superheated steam, and in the water both as it entered and as it left the economizers (217). Fellows made the significant remark that a commercial process for producing H_2 is the steam-iron reaction. His attention, however, was centered upon the oxidizing phase of the reaction, and he did not note that his curve, showing increasing oxidation of the steel with increasing temperature, likewise represents increasing hydrogenizing, by virtue of the decomposition of H_2O, and the standard reaction

$$3\,Fe + 4\,H_2O = Fe_3O_4 + \underline{8\,H}$$

That H_2 may be a predominating noncondensable gas in steam was demonstrated by Hall and his co-workers (192) with a laboratory boiler. Straub and Nelson (369) collected great amounts of H_2 from water and caustic solutions allowed to react with steel. In the same line come the researches of Potter, Solberg, and Hawkins (330, 414, 415), which were prompted by the fact that modern boiler installations are using temperatures as high as 1200 F, and pressures of the order of 1400 psi, truly simulating in severity the commerical process for making hydrogen, mentioned by Fellows. Again, however, those investigators began with their attention turned to the oxygen rather than the hydrogen, principally because they were studying scaling. That gas finally forced their attention by diffusing through the steel and vitiating their results, and again by unexpected quantities suddenly evolving from the steel. Their method of measuring oxidation was to employ measurement of the hydrogen which was produced, since it would be a chemical equivalent. As a result, those investigators provide some interesting facts attesting the prominence of hydrogen in steam boilers.

In another field, Dällenbach (277) reports that the penetration of hydrogen through the steel walls of mercury-arc rectifiers from the cooling water upsets their service (298).

Finally, Norton (377) reports a research establishing further the penetration of iron by hydrogen from tap water. What is of special significance to investigators of boiler embrittlement is the fact that sodium chromate, an inhibitor known since the days of Parr (94), stopped the diffusion of H; and that a sand-blasted steel tube coated with Na_2SiO_3, a great accelerator of embrittlement, developed so much hydrogen on the opposite surface during 15 min of heating at 200 C that the experiment had to be discontinued.

These researches can leave no doubt that in steam boilers an unlimited supply of hydrogen is available; furthermore, that that hydrogen develops under conditions favoring its diffusion into the steel.

Action of Hydrogen on Steel at Ordinary Temperatures—Transcrystalline Brittleness. One of the prolonged arguments in the literature on boiler embrittlement is that concerning the path taken by the fracture, i.e., is it around grains or through grains?

When steel is exposed to nascent hydrogen at ordinary temperatures, as in acid-pickling, cathodic electrolysis, and the rusting reaction, the hydrogen atoms enter the iron lattice and diffuse through the body of the grain; not through the grain boundaries

(321). Consequently, the deleterious effect of the gas at ordinary temperatures is *intra*granular (186), rather than intergranular. The gas may enter grain boundaries, of course, but its pressure there cannot exceed the pressure within the grain unless secondary reactions with impurities set in. Although Pfeil (182) and Williams and Homerberg (162) appear to have recorded such an instance at ordinary temperatures, such reactions are unlikely over a short period of time.

In previous publications from Battelle Memorial Institute, the action of hydrogen within the grain at ordinary temperatures has been sufficiently discussed (384, 386–389, 404, 418–420),[3] so that anything more than a summary statement here is unwarranted. Briefly, each grain of the steel is intrapenetrated with a vast, geometric system of ultramicroscopic imperfections. These are commonly observed when the metal is cold-deformed or etched. They may also be observed when the metal is stressed internally by precipitations such as the Widmannstätten action, or during nitriding, or carburizing, when the supersaturated phase may be seen to collect along the crystallographic planes that once contained minute voids. Those same imperfections collect hydrogen when it is a supersaturated phase; and it always is, practically speaking.

Now, hydrogen can only enter the iron lattice when H_2 is dissociated into atomic H. That is why pickling, cathodic electrolysis, and rusting are prolific sources of absorbable H, for the H atom actually meets the iron lattice before it meets another H atom with which to combine to form stable, insoluble H_2. In a gaseous-hydrogen atmosphere, only one out of approximately 10^{30} of the gas particles is an atom. Consequently, gaseous hydrogen can be stored in steel containers without measurable loss. Conversely, no one has yet conducted a pickling experiment under such great pressures of H_2 that the pickling action was reversed. Nor has any investigator of boiler embrittlement ever carried the bomb test to a point where the pressure of H_2 was sufficient to reverse the oxide-forming reaction.

By the same token, it must be conceded that the hydrogen atoms within the steel, when encountering the crystal imperfections just discussed, or any other discontinuity, will recombine in the direction of equilibrium, which, at room temperature lies far toward the side of tremendous pressures of the insoluble, molecular gas. Actual measurement of the pressures which may develop in that manner is not difficult. Bardenheuer and Thanheiser (205) obtained nearly 5000 psi, using a dilute NaOH solution and found no more indication of an end point than in a similar test at Battelle Memorial Institute wherein hydrogen penetrated 1/4 in. of solid steel and became trapped under a pressure which ruptured the gasket at 500 psi (387). Secondary observations of blistering and swelling of heavy plate confirm the theory in indicating that that gas can rupture the strongest steel (387, 404).

[3] References (287, 340, 358, 384–389, 400–404, 417–427) constitute a complete bibliography of published work from Battelle Memorial Institute on hydrogen in iron and steel.

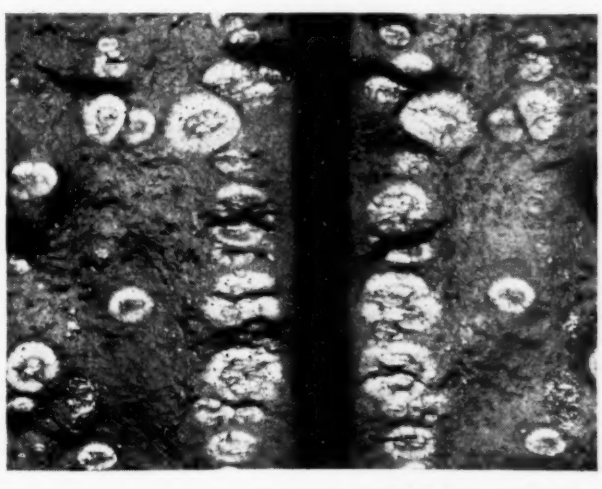


FIG. 2 LOCALIZED TRANSCRYSTALLINE HYDROGEN EMBRITTLEMENT CALLED "FISH EYES," OBSERVED ON FRACTURE OF A TENSILE SPECIMEN OF WELD METAL; ×3

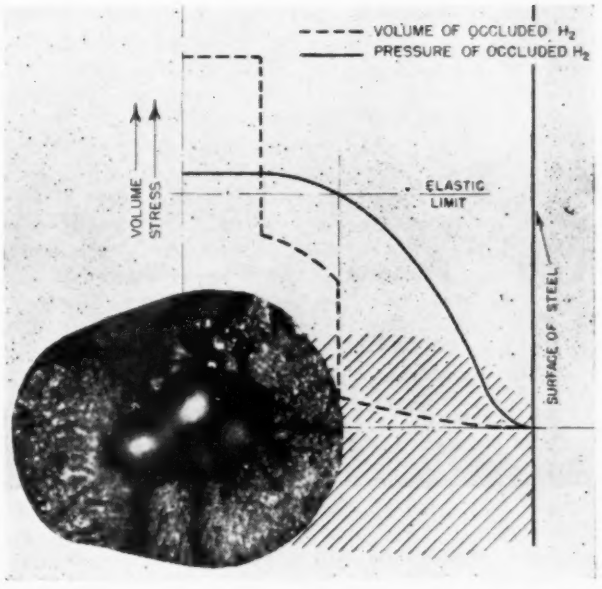

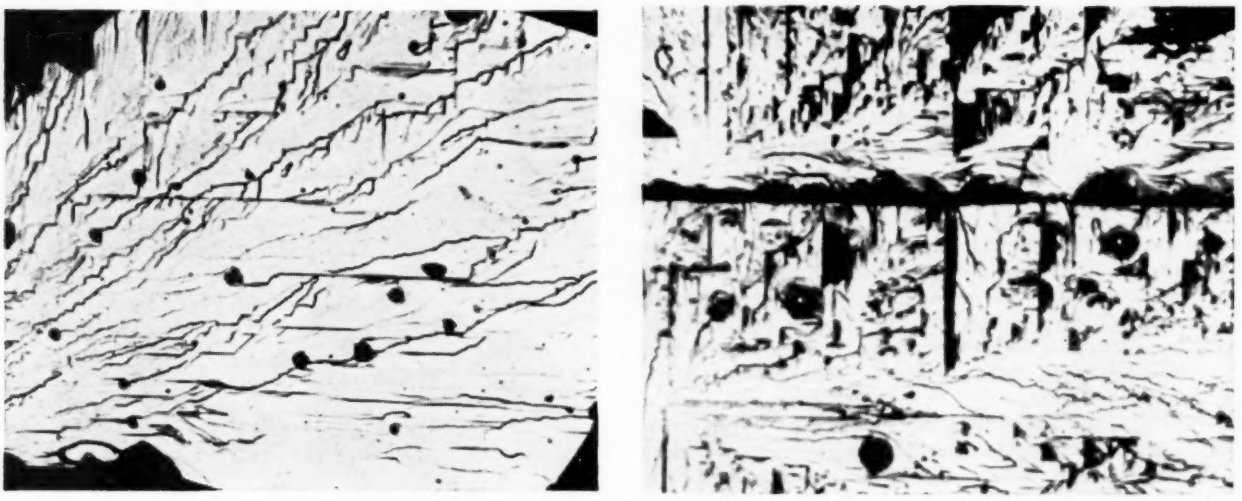

FIG. 3 ENLARGEMENT OF "FISH EYE," SUPERIMPOSED ON SKETCH DESIGNATING PROBABLE PRESSURE-VOLUME RELATIONSHIPS OF OCCLUDED HYDROGEN

(Note shiny interior suggesting presence of reducing gas such as hydrogen.)

When steel absorbs sufficient hydrogen to congest those slip discontinuities, "*intra*granular embrittlement" results.

In the following illustrations, this type of embrittlement, which is caused by hydrogen alone, is clearly illustrated. "Fish eyes," a welder's nuisance, appear in Fig. 2. In this case, the hydrogen has been obtained through dissociation of the gas at high temperatures, rather than through the energy of an aqueous reaction, as in pickling or rusting (26, 388). The shiny appearance of the embrittled zones is characteristic of hydrogen embrittlement and expresses the fact that the fracture in these zones lies along flat, transgranular imperfection planes which have been distended and extended by the trapped gas. Reflection of light from those flat, extensive facets is the cause of the brightness. One of the "fish eyes" is enlarged and superimposed upon a sketch in Fig. 3, which designates the probable pressure-volume relationships of the occluded gas. Note that, throughout the brittle zone, the gas is under pressure which exceeds the elastic, or cohesive, strength of the steel.

The two views in Fig. 4 were made possible by the fact that the fracture is transgranular across flat, crystallographic planes. Single facets under high magnification were observed by a technique recently developed at Battelle Memorial Institute (423). Note the system of "imperfection planes" which intersect the main cleavage plane being examined and reveal the crystallography of the metal. Certainly these illustrations give striking proof that the temporary brittleness from hydrogen at ordinary temperatures, variously called "pickling britteness," "acid brittleness," "hydrogen embrittlement," and so forth, is definitely and in-

(*a*) (*b*)

FIG. 4 DIRECT VIEW AT HIGH MAGNIFICATION OF SINGLE CLEAVAGE FACETS OF HYDROGEN-EMBRITTLED IRON BROKEN IN IMPACT

herently transcrystalline. Incidentally, specimen (*b*) in Fig. 4, though identical with "fish-eye" brittleness, is a steel embrittled cathodically, and therefore applies directly to the present argument.

Curiously enough, White and Schneidewind (245), and later Schroeder and Straub and their colleagues, used a research by Pfeil (182), in 1926, as illustrative of the type of fracture caused by hydrogen during pickling or cathodic electrolysis (385); yet Pfeil stands almost alone in reporting intercrystalline failure from pickling brittleness. This selection, it is interesting to note, actually counteracted their own unfortunate choice of pickling brittleness as a parallel case of boiler embrittlement, and probably sustained interest in hydrogen for a few years. Closer examination of Pfeil's work, however, shows that he actually obtained transcrystalline fracture, just as everyone else has, when ordinary specimens are used, and he discusses it at some length. However, when he went to the great trouble of growing crystals 1 in. or so in diam, the specimen broke through the grain boundaries, which is hardly surprising and is too far-fetched a case to be used excusably for comparison with boiler steel. Unhappily, Pfeil elected to display this unusual specimen upon the first page of his work, whereupon a great deal of misapprehension has resulted.

What investigators of boiler embrittlement have done, then, is to compare boiler embrittlement, which is predominantly intercrystalline, with ordinary pickling brittleness, which is distinctly transcrystalline; but they selected a misleading example purporting to show that pickling brittleness was intercrystalline, while the fact that, *under the conditions of boiler service, hydrogen attacks steel in a manner differing distinctly from pickling brittleness and which is truly intercrystalline is scarcely mentioned in the entire literature on boiler embrittlement.*

Action of Hydrogen on Steel at Elevated Temperatures—Intercrystalline Brittleness and "Boiler Embrittlement." Knowledge of intercrystalline attack of steels by hydrogen at elevated temperatures has stood in the literature at least since the invention of the Haber-Bosch process for ammonia synthesis (257, 267, 268) in 1908. In his Nobel Prize lecture in Stockholm (257), Bosch points out that one of the first problems which had to be faced was intercrystalline hydrogen embrittlement.

True, ammonia synthesis, such as the Haber-Bosch (257), or the Claude (289) process, utilizes pressures up to 1000 atm and temperatures from 400 to 600 C (752 to 1112 F); and hydrogenation processes, such as the Fischer-Tropsch, have conditions of temperature and pressure but little less severe at about 700 atm and 450 to 550 C (842 to 1022 F)(329); whereas only extraordinary steam units attain that temperature range, and never those pressures. Nevertheless, the difference is only of degree, for all processes supply H to the steel, although the rate varies. Boilers, accordingly, require months or years to fail in most cases, whereas the attack of boiler-type steel under the conditions of ammonia synthesis is so severe that its use is positively precluded. For example, Barber and Taylor (275) report steel actually pulverizing in 1000 hr from grain-boundary hydrogen attack in the hydrogenation of heavy liquid hydrocarbons. Investigators in that field have so little occasion to observe ordinary pickling brittleness that the following type of statement (275) abounds in their literature: "In all cases of hydrogen brittleness, the fracture takes place along the crystal boundaries." Compare this with the conclusion of Schroeder and Berk in their recent publication (398) on boiler embrittlement: "No intercrystalline cracking was found in any of the specimens," the "specimens" being steels loaded cathodically with hydrogen at room temperature, or for only short periods of time at elevated temperatures, in an attempt to reproduce boiler embrittlement under conditions which could not possibly result in anything but the irrelevant "pickling brittleness," if they became embrittled at all.

Among the major contributions in the literature on intercrystalline hydrogen attack are the researches of Vanick in America (156, 158, 161, 202, 203); Inglis and Andrews (262), and Sarjant and Middleham (314) in England; Naumann (329, 346) in Germany; Jacqué (334, 344, 345) in France; Giacomo (362) in Italy. Vanick began in 1922 with a steam-boiler failure which he associated with gases in the steel (156), but unfortunately did not blend that research with his subsequent conclusive studies on the behavior of steel under conditions of ammonia synthesis.

In 1923, Vanick (158) tested plain-carbon steel and wrought iron in NH_3. Below 300 C, reactions were slow, but at higher temperatures intergranular disintegration set in rapidly. De-

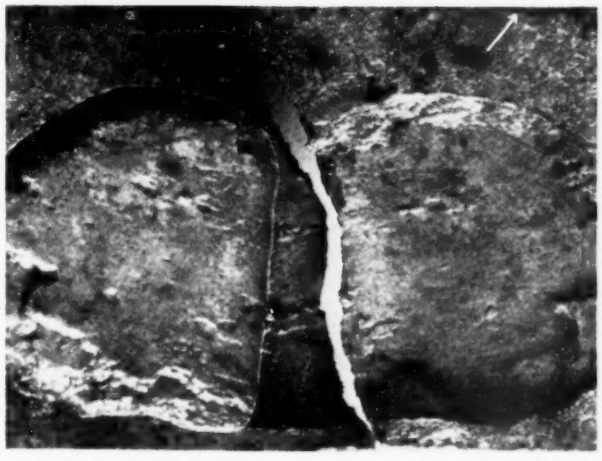

FIG. 5 PLAIN-CARBON-STEEL PLATE AFTER EXPOSURE TO NH_3 AT 500 C AND 12,000 PSI; ×3

(Note large, deep-seated blister which is peeled back, and smaller blister showing as a fissure, indicated by white arrow. The fracture through this zone illustrates a second hydrogen activity, i.e., intergranular embrittlement.)

carburization leading to fissuring was the principal reaction he observed, in exact agreement with the latest English research on boiler embrittlement (396). The deterioration, i.e., "internal decay," he so aptly called it, progressed evenly from the cool to the hot end of the tube, which is a significant demonstration that the intergranular hydrogen attack of steam boilers and ammonia chambers would differ in degree, or rate, as would be expected from the difference in operating temperatures. The fact that boiler embrittlement seems restricted to temperatures below 250 C should not confuse the present argument, since boiler embrittlement depends rather precariously in its fulfillment upon such factors as seam concentration and boiler-water impurities. How such factors change at temperatures above 250 C is but little known.

Vanick also observed that inclusions were definitely reduced in these tests, some being completely removed, by the infiltering H. When situated suitably with regard to the surface of the plate, these inclusions led to blisters from the accumulation of gaseous reaction products (275).

An example appears in Fig. 5. The specimen is carbon steel after exposure to NH_3 at 500 C and 12,000 psi. Note the large deep-seated blister which is folded back, and the smaller one showing as a fissure. The fracture through that zone reveals the simultaneous hydrogen embrittlement. In the micrograph, Fig. 6, may be seen the only remaining islands of pearlite which could be found in the entire section, and those appear nearly completely decomposed. The straight crystallographic lines are "needles" of iron nitride. In other words, the equilibrium with the external gas has demanded that both nitrogen and hydrogen penetrate the steel. At any discontinuity within the steel, those gases will tend, of course, to re-establish their relationships at 12,000 psi. Secondary reactions with carbon and other nonmetallics to form products such as insoluble CH_4 are likewise driven toward their respective equilibria, which lie sufficiently far to the right to cause effective removal of a visible precipitate such as iron carbide.

Williams and Homerberg (162), in 1924, likewise stated that hydrogen reduced inclusions in their tests on the role of hydrogen in boiler embrittlement (168). They recognized the two distinct forms of hydrogen embrittlement being discussed in this paper and concluded that water as a reaction product distends the grain boundaries and leads to subsequent failure of boiler plate. Unfortunately, they had used electrolytic methods and did not defend themselves when subsequent confusion over hydrogen embrittlement obscured the importance of their results. Their tests lasted about 30 days, which was apparently just long enough for sufficient reaction products to accumulate to cause some grain-boundary weakness. Many years before, Law (45, 51) discovered that hydrogen caused "pickling blisters" on steel sheet (31), but insisted they were formed from H_2O produced by H reacting with the oxide inclusion usually found there. Neither Law nor Williams and Homerberg modified that statement; whereupon Law lost the value of his argument, because water is not found in blisters, nor is oxide always present (46); and Homerberg and Williams became discredited by similar observations. At the ordinary temperatures of pickling and electrolysis, H reacts but slowly with impurities in the steel (153), and blisters, as well as the brittleness, are simply caused by molecular hydrogen. Higher temperature favors those reactions.

By the subsequent work of Vanick (161, 202); Vanick, de Sveshnikoff, and Thompson (203); Barber and Taylor (275); Maxwell (294, 310); Giacomo (362); Puchner (379); Jacqué (334, 344, 345); Wright and Habart (355); Kosting (281); Bosch (257, 267, 268); Naumann (329, 346); Sarjant and Middleham (314); Nowitt (376); and others (328, 336, 343, 363, 382, 391); the following general facts for hydrogen attack at elevated temperatures became clearly established:

1 H from the gas phase dissolves atomically within the lattice of the steel, leading to temporary brittleness.

2 H inside the steel then reacts with nonmetallic impurities, especially C, next with O, but depending entirely upon the stability of the oxide. S, N, and P may be attacked to varying extent, depending upon the stability of their respective phases. The insoluble gaseous products congest in grain boundaries, since they are insoluble in the grain.

3 When the pressure of these insoluble products exceeds the cohesive strength of the grains, the gas forces intercommunication and separation which manifests itself in loss of mechanical properties, cracking, swelling, blistering, or subsequent penetration of a corroding chemical.

4 The attack is favored by increasing temperature, pressure, and stress, is strongly influenced by the constitution of the steel and possibly by its heat-treatment.

Discussion of these facts has been available in textbooks for years (289, 372); yet, scarcely mention of it can be found in the entire literature of this country on boiler embrittlement.

Perhaps some actual cases of intercrystalline hydrogen at-

tack under conditions differing from steam boilers only in degree will be of value. In Fig. 7 is a macrograph of the surface of a carbon-molybdenum steel which served as a catalyst basket in an ammonia-synthesizing unit. Note the blisters in surface layers and the fracture occurring through embrittled metal, both defects being caused by hydrogen reacting with impurities in the steel. In Fig. 8, a section through that specimen shows the savage deterioration caused by the hydrogen. The micrograph, Fig. 9, shows intercrystalline attack with much greater definiteness than is obtained in cases of boiler embrittlement, if a distinction is to be drawn. Note the complete decarburization. The general absence of visible decarburization in boiler embrittlement in no way reduces the significance of these observations, as will appear later.

After 1 year of service in hydrogen at 400 C and 400 psi, a carbon-steel tube showed the deterioration evident in Fig. 10, where a section of the tube has been bent outward. In Fig. 11, micrograph (*a*) shows the condition of outer layers of that steel—carbide in the grain boundaries, but still largely unattacked; and micrograph (*b*) shows complete decarburization and marked intercrystalline fissuring in the inner layers.

The next two illustrations demonstrate a point that is vital to an understanding of boiler embrittlement, for it largely bridges the gulf that seems to stand between the operating conditions of steam boilers and the hydrogen-attacked units under discussion. Fig. 12 shows a section of a carbon-steel tube from service in high-purity hydrogen at 400 psi similar to that in Fig. 10. But, in this case, the temperature was 100 deg lower, i.e., 300 C, whereas the time of service was doubled to 2 years. Correspondingly, deterioration is practically identical for each case. A macro-etch shows the depth of the decarburized zone. In Fig. 13, micrograph (*a*) again shows pearlite between the grains, attacked but not destroyed; while micrograph (*b*), taken in the decarburized zone, again shows the complete removal of carbide and the marked intergranular fissuring. Though it cannot be stated with certainty, the accumulation of pearlite toward the grain boundaries of the ferrite seems to be a preliminary action in the removal of carbon from steel by hydrogen.

Correspondingly, K. G. Jones[4] points out: "At pressures above 400 psi, with temperatures above 200 C, we know that hydrogen will cause decarburization over a long period of time. Carbon steel would not be satisfactory in ammonia over 200 C at

(Note (*a*) complete decarburization, marked intercrystalline fissuring, and, in micrograph (*b*) the adjoining corrosion which is obviously secondary to the hydrogen attack.)

our plant pressure of 12,000 psi." Compare this with the recent monumental report from the National Physical Laboratory on boiler embrittlement (396), wherein it is reported that boiler plate, embrittled in caustic solutions at temperatures slightly above 400 C, analyzed up to 10 volumes of gas per volume of metal, that the gas was predominantly methane, and that, upon reheating the steel to 625 C, internal fissures actually became recarburized on their surfaces.

Hydrogen attack in high-pressure plants is influenced markedly by pressure (289, 372). For example, Tongue (289) reports that H_2 at 1 atm pressure caused no decarburization of a high-carbon steel in 1 week at 500 C, but at 200 atm the carbon content of the surface layers decreased from 1.4 to 0.1 per cent in 16 hr. Autoclaves in hydrogenation processes never reach even the lowest H_2 equilibrium pressure shown in Fig. 17, which will be described shortly. At those lower pressures, Newitt (376) reports that H attack can be observed at temperatures as low as 200 C, even in their comparatively short-time tests. Inglis and Andrews report slight attack at 150 C, over a period of 2 years (262).

In Fig. 14 are shown two micrographs from a specimen similar to that in Fig. 6. No nitrides are evident, but decarburization is complete. In micrograph (*a*), intergranular failure is outstanding; in (*b*), the same type of intergranular failure is shown near a locus of outright corrosion. Is it not obvious that the corrosion is subsequent to the actual deterioration of the steel by hydrogen? "Selective corrosion" in this case is quite evident, but it has been *enabled* by the embrittling factor; it did not *cause* the embrittlement.

Plainly, the principal difference between the two fields of investigation, boiler embrittlement and hydrogen attack of reaction chambers, is that with boilers a longer period of time is required to complete reactions which are rapid at higher temperatures. The fact that in one case ammonia produces the soluble H, in another case hydrocarbons, or pure H_2, and in another case steam or NaOH, is quite irrelevant, since the ability of steam to cause steel to absorb H requires no further demonstration. Other distinctions, such as the lack of visible decarbonation in most cases of boiler embrittlement, are superficial and will be resolved during later discussion.

Consequently, a glance at the cures that have been provided for H attack in reaction chambers should be well repaid. Briefly, the industry developed both mechanical and metallurgical devices. Double-walled units were used with the nitrogen passing through the interspace to prevent hydrogen from penetrating the outer mantle (267). Another double-walled unit used an outer mantle built to withstand stress and drilled with holes to permit the escape of hydrogen that penetrated the inner wall, which was "gastight" and grooved on the outside to aid the gas in reaching the holes in the outer plate (267). Vanick (161), and later Lewkonja and Baukloh (263), tested an Al coat on iron and found good resistance, except that such a coating is impracticable because of its imperfections. Pier (284) patented a shell of 1–6 per cent Cr steel with a lining of Zn or Zn alloy. A British patent concerns a lining of Ta or Ta alloy (314).

Liquid steel was treated with H to remove O, C, S, P, and other impurities which might later react with H during service. Such steel, it is reported, actually did withstand H attack (289). An English patent suggested similar treatment of the plant parts with H while red-hot before the final forging or rolling. In test, such steel remained unchanged after 300 hr, whereas ordinary steel embrittled in 24 hr (289).

Most of the research, however, has had to do with the composition of the steel. Plain-carbon steel, which takes months or years to fail under the milder conditions of steam-boiler service, fails in a few hours in the more severe service of ammonia synthesis (274, 307). Consequently, alloy steels must be used. Research soon showed that the principal attack was on carbon in the steel, and that the attack could be lessened by stabilizing that element with alloy elements forming more stable carbides than does iron, much as oxygen is "killed" in steels by adding Al. Chromium received the most and the earliest attention, and, thereafter, numerous other carbide formers, such as Ti, V, Zr, Cb, Ta, and W.

On these additions, Krupp steelworks in Germany holds the most interesting patents (282). Their subject matter is well covered by Naumann (329, 346), whose paper (346), in 1938, is easily the outstanding contribution on the subject of H attack of steel and its prevention. His findings are largely contained in the diagram, Fig. 15, in which the effect of various alloy additions upon the resistance to H attack is illustrated. Si, Ni, and Cu had no effect. Mn, Cr, W, and Mo increased the resistance in the order named; and Ti, V, Zr, and Cb showed no special effect until a limit was reached, beyond which a sudden and astonishing resistance to the highest temperatures studied showed itself. This phenomenal action clearly depends upon carbide

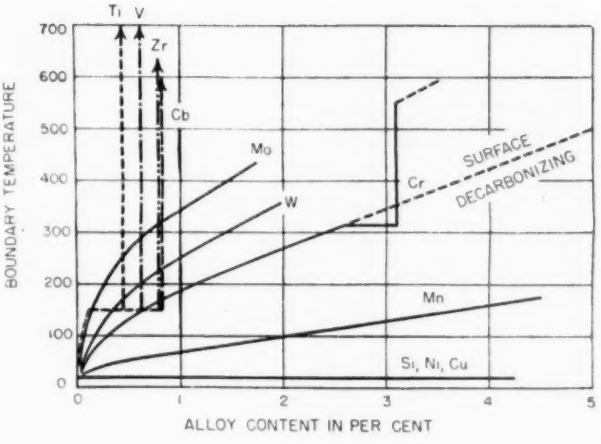

FIG. 15 EFFECT OF ALLOYING ELEMENTS ON RESISTANCE OF STEEL TO HYDROGEN ATTACK AT ELEVATED TEMPERATURES; NAUMANN

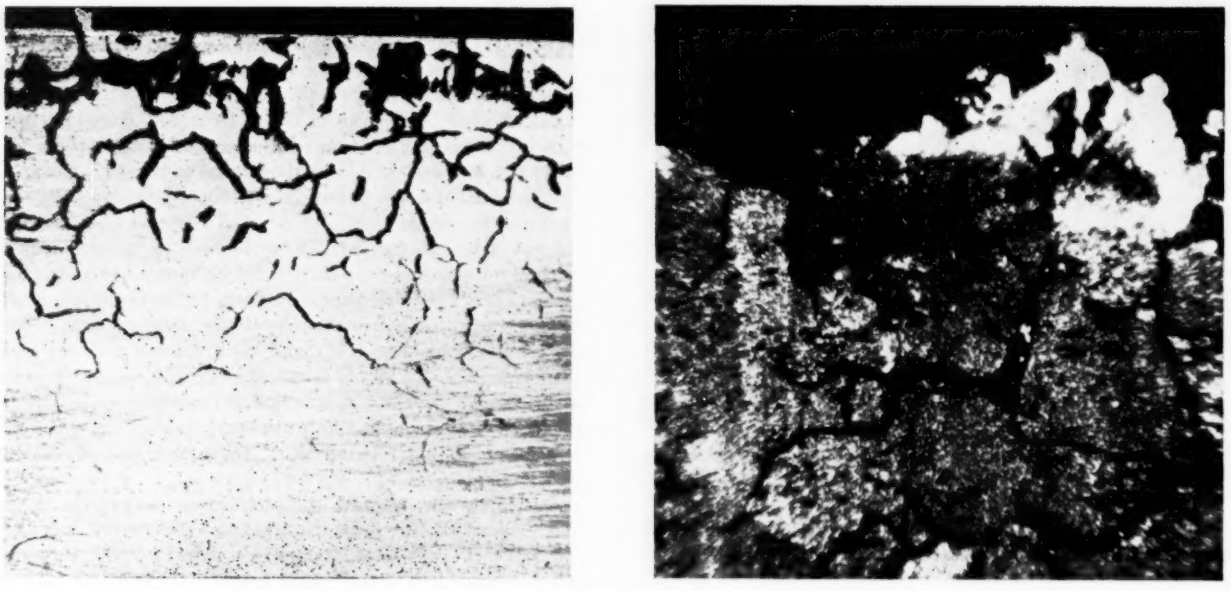
formation, and hence upon carbon content; but for ordinary mild steels, such as boiler plate, less than 1 per cent of any one of these elements is all that is required. The maximum effect occurs when the vanadium content, for example, is greater than 5.6 times the C content, the formation of V_4C_3 then being assured. In any event, the patents state, C should be kept below 0.30 to 0.35 per cent.

Again, it is interesting to compare a statement from the recent publication on boiler embrittlement by Schroeder and Berk (398), who finally demonstrate for the first time in this country that killed steels show "distinctly better resistance" to embrittlement, but who conclude that that effect cannot be due to deoxidation because vanadium "which is also considered an efficient deoxidizer" doesn't show that improvement. They refer to tests of their own on steels having a vanadium content of only 0.25 to 0.30 per cent; and, referring to the curves in Fig. 15, one can readily understand why such steels would not reveal the stellar role of that element. Also, metallurgists now regard vanadium as a weaker deoxidizer than aluminum.

In another field, intercrystalline attack by hydrogen is also sufficiently prominent to warrant some attention, i.e., the so-called hydrogen embrittlement of copper, or "copper sickness." Vanick had tested copper in an ammonia-cracking unit in 1924, and found, after 4 months at 400 C, that it had expanded by 30 per cent of its diameter and fissured to its core (161). In the catalyst well, where the hydrogen is expectedly more nascent, a copper tube fissured in 6 days along a temperature gradient from 200 C to 600 C. If the copper had been deoxidized with boron, only slight fissuring resulted; and an oxygen analysis of that copper showed a content only 10 per cent of the ordinary. Bosch also points out that the failure of Fe and Cu in H_2 is identical (257).

Forty years ago, Heyn showed that copper heated in hydrogen at temperatures above 600 C increased in volume and developed fine fissures from H reducing cuprous oxide to form steam which became trapped within the metal (34). Also, tin oxide in bronze led to the same result. Archbutt, about the same time, removed the oxygen from copper by heating it in hydrogen, and found similar fissuring and bloating (36). Bengough and Hill found that CO, as well as H, diffused into the copper and formed insoluble compound gases (61); although Sieverts and Krumbhaar, studying the solubility of N_2, CO_2, H_2, and CO in copper found only the hydrogen soluble (62).

Embrittlement from H_2, CO, and steam was established by Ruder, who showed that temperature controlled the reactions to a large extent (88), and that hydrogen at elevated temperatures causes intercrystalline attack (91). Dry H_2 incepted embrittlement at 400 C, moist H_2 at 600, steam at 700, and CO above 800 C. Copper, deoxidized with boron, was not affected at all. Similarly, Johnson found that copper, deoxidized with ferrosilicon, was not affected by H even at 780 C (80); and Bengough and Hill had reported an analogous role for arsenic (61), on the argument that the arsenic stabilizes the oxygen in copper. Because carbon does not dissolve appreciably in copper, H attack principally concerns oxygen. Al, P, Mg, and numerous other oxide stabilizers came into use (80), all on the basis of the assumption that the hydrogen-oxygen reaction led to intergranular failure just as in boiler embrittlement. Redding noticed embrittlement of copper sheets simply from remanent machining oil left on the surface during annealing (147), and Ellis reported a 70 per cent loss in strength and a 90 per cent loss in ductility when vaseline was smeared on copper plates before annealing in a closed furnace (143). Pilling noticed embrittlement during brazing copper in a gas flame (145). In all cases, the source of hydrogen is evident.



Determining the relative diffusion rates of various gases through copper, Pilling (104) lists H_2O at 65, CO at 17, and CO_2 at 0.6, when H is taken at 1000. If Cu is treated with H_2 while liquid, corresponding to the patent recently discussed for steel, a sound ingot results and embrittlement is prevented. However, if oxygen is absorbed, even during casting, the hydrogen-oxygen reaction is enabled (125). Sulphur in the grain boundaries also leads to intercrystalline failure (125); so oxygen is not alone, just as it is probably not alone in permitting boiler embrittlement, as evidenced by the incompleteness of "killed" steel. Moore and Beckinsale, in an outstanding paper (143), determined that as the oxygen content of copper became less, H attack began at higher temperatures. Bamford and Ballard (122) likewise discussed similar behaviorisms of hydrogen in brasses.

Finally, in purifying steel, especially in decarburizing, a hydrogen treatment at elevated temperatures is not only well known, but stands almost as the only means by which nonmetallics may be removed from solid steel. And, again, the grain boundaries are the path for occlusion and migration of the gaseous phase. The same Andrew whose work on caustic embrittlement (81) is quoted so widely in the literature, several years earlier had written on decarburizing steel with hydrogen (64, 69). Other investigators soon showed that H diffusing through the steel is attracted to impurity atoms, such as C, N, O, etc. (325, 347), and that insoluble reaction products develop whose removal constitutes the purification treatment (78, 111, 116, 117, 130, 152, 250, 253, 256, 263, 264, 279, 290–292, 303–305, 322–325, 338, 339, 347). The H removes not only C and O, for practicable desulphurization with H has been demonstrated (303, 304), at temperatures above that of boiler service, of course.

Other metals than steel and copper suffer similarly from these deleterious equilibria of hydrogen and nonmetallic impurities (237); and the scope of those reactions even extends into welding (337, 370).

During the hydrogen purification treatment, intergranular weakness is exhibited (263), as would be expected, because the seat of the reaction with the nonmetallics is in the grain boundary. In Fig. 16 are shown two typical examples of intergranular weakness in steels treated in hydrogen, but removed before the reaction products have escaped. Consequently, the grain boundaries are congested with the expansive gases, and the steel suffers from intergranular hydrogen embrittlement. If the treatment is allowed to go to completion, those insoluble gases escape, the grains weld together again, and the steel becomes ductile iron.

By now it should be firmly established that steel, when ex-

(*a*) (*b*)

FIG. 16 MICROGRAPHS OF FREE-MACHINING STEEL INTERRUPTED DURING A PURIFYING TREATMENT IN HYDROGEN AT ELEVATED TEMPERATURES

(*a*, Unetched, lightly polished; ×10; *b*, etched; ×30. Note distinctly intergranular fissuring.)

posed to hydrogen at sufficient temperature and for a sufficient period of time, suffers the following action:

1 Hydrogen enters the steel atomically.
2 Hydrogen reacts with the nonmetallic impurities.
3 Gaseous reaction products congest the grain boundaries to disruption, which is embrittlement.
4 Disruption permits escape of the gaseous products to the atmosphere.
5 Ductility returns.
6 The steel has become purified iron.

Because it is universally agreed that hydrogen does enter boiler plate, this progressive action positively must be an entity in "boiler embrittlement," whatever its degree of importance. Obviously, the action never even approaches completion; but only the first three steps are necessary for embrittlement.

Beginning with this firmly established background, let us now attempt to determine the ranking of hydrogen attack as the cause of "boiler embrittlement."

3 THE STATUS OF "BOILER EMBRITTLEMENT"

STEAM-IRON EQUILIBRIA: THE CASE OF THE CLOSED BOILER

In view of the consideration just paid intercrystalline hydrogen attack, an interesting comparison is afforded with recent statements of Schroeder and Berk (398), regarding the possible role of hydrogen in causing intercrystalline embrittlement in boilers. Those investigators succinctly dismiss hydrogen from all consideration by subjecting the hydrogen "theory" to two peculiar tests. They state that the theory "may be tested, first, by determining whether or not hydrogen will produce intercrystalline cracks," whereupon they conduct room-temperature and short-time tests at 250 C, which of course produce only transcrystalline brittleness, or none at all. Not a word of recognition is given in their report to any of the references just reviewed, in which intercrystalline failure from hydrogen attack is the only consideration.

Upon drawing the astonishing conclusion that hydrogen does not cause intergranular weakening, Schroeder and Berk proceed with a second and, in their opinion, a decisive test. They state: "The action of hydrogen might also be tested in a second way, namely, by determining whether or not intercrystalline cracks can be produced in its absence;" whereupon they resort to an "anodic" treatment, whose complete irrelevancy can be established in numerous ways. The simplest is probably to point out that boiler embrittlement has none of the visual evidence necessary for a selective anodic attack. There is the common observation that "embrittled specimens are not corroded but are covered with a thin shiny . . . layer of black iron oxide" (181); as well as Schroeder's own observation that boiler embrittlement is not corrosion or corrosion pitting (240). What can anodic attack, which almost by definition is direct attack beginning at the surface and working inward, possibly have to do with such a phenomenon? To a metallurgist, who is aware that the intercrystalline failure of metals covers a vast field of individual conditions and causes, it is inadequate to test a specific case like boiler embrittlement with a nonspecific test.

The hydrogen mechanism, on the other hand, is an indirect attack, and therefore provides an immediate and a simple answer, since the gas does not deteriorate the metal until after it has passed through a finite surface layer of solid metal, so that its reaction products may become trapped. Once inside the iron in atomic solution, the gas then may react with impurities to produce retained gases with resultant deterioration of the plate. Or, the deterioration may later breach the surface, of course, as demonstrated in Fig. 14.

From their inadequate tests, Schroeder and Berk draw a conclusion which threatens to suspend an understanding of boiler embrittlement for many more years. They state: "At present there seems little reason to believe that hydrogen causes boiler cracking or that it plays an essential part in such failures" (398). Similarly, the University of Illinois Engineering Experiment Station states: ". . . we should divorce the idea of hydrogen embrittlement from the phenomenon of caustic embrittlement . . . that type of embrittlement due to hydrogen . . . is not the effect that we get in the so-called embrittlement caused by caustic"

(181). Rech regards Parr and Straub's work, in which they compare boiler embrittlement with pickling brittleness, as "eliminating the hydrogen theory" (220).

On the other hand, the 1941 Report on "Intercrystalline Cracking in Boiler Plate" by the National Physical Laboratory in England, names hydrogen as the fundamental cause of boiler embrittlement. The English investigators studied the defect by analyzing the gases in boiler plate after laboratory tests under somewhat exaggerated conditions. They do refer to Naumann's research on hydrogen attack, just discussed, and conclude that ". . . cracking produced by the action of sodium hydroxide was almost identical with that produced by gaseous hydrogen under high pressure."

Reversibility of the Steam-Iron Equilibrium. Besides the reasons already given for the present misunderstanding of the role of hydrogen in boiler embrittlement, there is another which is almost more surprising because it concerns elementary chemical principles, and the work on embrittlement in this country has been dominated by chemists. For example, Partridge and Schroeder state: "That oxides would be reduced by hydrogen passing through the steel, as postulated by Williams and Homerberg, seems unlikely . . . in view of the evidence . . . that the reaction proceeds rapidly in the opposite direction, iron removing oxygen from water and forming a coating of oxide with the simultaneous liberation of hydrogen."

Surely the error in such a statement is evident. In the chemical reaction

$$A + B = C + D$$

one side of the equation represents reactants, the other products, and the direction of the reaction depends only upon the concentration of the various components in respect to their concentrations when at equilibrium. Consequently, the most avid reaction going from left to right that one can conceive can be made to go in the opposite direction by reducing the concentration of the reactants sufficiently. Thus hydrogen and oxygen explode to form water, but the water in turn can be broken down into hydrogen and oxygen again if means are available for removing the tiny amount of dissociation product which must always be in equilibrium with the compound. Electrolysis, for example, is an accelerated means for removing the 10^{-7} mols of hydrogen ion present in 1 liter of water, which shifts that strong reaction into reverse and the water disappears.

Within a steam boiler the reaction[5]

$$3\ Fe + 4\ H_2O = Fe_3O_4 + 4(2H = H_2)$$

visibly always goes to the right because one of the products escapes as a gas. The equilibrium concentration of H_2 never becomes realized, and the entities on the right are continuously generated so long as free iron remains in contact with steam. Researches already discussed have amply demonstrated the continuous presence of hydrogen in the steam coming from steel boilers. The *rate* of generation, of course, depends upon the many factors which influence that contact, and must not be confused with the *equilibrium* now to be considered.

On the other hand, the reduction of Fe_3O_4 by hydrogen to produce water vapor and metallic iron is well known in metallurgy. That is the reverse of the action in the steam boiler and gives practical proof of the well-established fact that the equation just given is truly reversible. In fact, the chemical relationships for that equilibrium over a great temperature range have been so well developed both in this country (260) and abroad (253) that it is difficult to reconcile the complete lack of recognition paid it in literature on boiler embrittlement.

Briefly, when both Fe and Fe_3O_4 are present in excess, as they are in the steam boiler, their chemical activities remain constant for any given temperature and may be conveniently placed at unity. The equilibrium constant for the reaction

$$K = \frac{(Fe_3O_4)(H_2)^4}{(Fe)^3(H_2O)^4}$$

may then be greatly simplified

$$K' = H_2/H_2O$$

in which the two gases may be expressed in terms of their partial pressures

$$K' = P_{H_2}/P_{H_2O}$$

This expression reveals the highly significant fact that, at any fixed temperature, the ratio of hydrogen to steam is fixed whenever iron and its oxide are present together. In terms of the "phase rule"

$$F = C - P + 2$$

there are three components and four phases when water and steam are both present; then

$$F = 3 - 4 + 2 = 1$$

and the system is seen to be univariant, having but one degree of freedom. That is, when temperature, for example, is specified, all other entities become fixed. Thus, for a boiler operating at 200 C, the steam-gage pressure automically becomes established at 211 psi, as is well known. What is not so well known, were one to judge from the published researches on boiler embrittlement, is that the potential pressure of hydrogen becomes fixed for exactly the same reason.

Notice the following interesting features of this system:

1 The *ratio* of H_2 to steam for any given temperature is fixed at some constant value by the thermodynamics of the Fe–Fe_3O_4–H_2–H_2O system.

2 The actual steam pressure, P_{H_2O}, for any given temperature is fixed at some constant value according to a similar thermodynamic law for saturated steam, as every boiler operator knows.

3 Consequently, the hydrogen pressure, P_{H_2}, becomes fixed at some constant value easily determined from the equilibrium constant $K' = P_{H_2}/P_{H_2O}$

In other words, the operator fixes the temperature of his boiler, which in turn fixes the pressure of the steam, which in turn fixes the potential pressure of hydrogen—a pressure which the boiler will always strive to attain, but in vain, unless the boiler is sealed to permit that gaseous product to accumulate.

That immediately suggests the question: *What maximum pressure of hydrogen could theoretically develop in a closed boiler?*

As already mentioned, the data for $K' = P_{H_2}/P_{H_2O}$ are readily available in the literature (253, 260). Because Fe_3O_4 is the stable form of iron oxide below 560 C (394), the system is unique, and its data are therefore applicable to the steam-iron equilibria wherever they occur. The universal agreement on the form of the Fe-H_2O equation underlying boiler embrittlement is especially fortunate, and should remove the last doubt about the validity and applicability of the values which are plotted in Fig. 17.

The lower curve represents the variation of steam pressure with temperature, and is more or less familiar to all boiler operators.

[5] In the reaction, the double designation of the hydrogen (2 H = H_2) is used to avoid a common, futile argument over the form the hydrogen actually takes, and to remind one that both the atomic and molecular forms do exist in keeping with their own equilibrium and that of the whole chemical system.

The upper curve represents the equilibrium pressures of hydrogen, P_{H_2}, corresponding to the saturated steam pressure for each temperature.

Those curves are undoubtedly surprising to many. Observe that the ordinate is logarithmic to allow encompassing the tremendous span of pressure involved. Even at 350 C, where the ratio nears a minimum, 10 lb of hydrogen pressure are required for every pound of steam; at 250 C, the ratio has risen to 100 to 1; and at 100 C, nearly 1,000,000 psi of H_2 must dilute the mere 15 psi of steam if equilibrium is to be reached.

The bewildering magnitude of such figures should not be allowed to confuse their significance. They simply show that the steam-iron equilibrium in a steam boiler at 100 C lies so far toward the right that for all practical purposes it is irreversible. Hydrogen could never accumulate under sufficient pressure to reduce the iron-oxide scale as rapidly as it was being formed, since the boiler obviously would explode before 1,000,000 psi could be reached.

The Grain Boundary as a Tiny, Theoretical Boiler. Within the body of the steel there is no steam, of course, but there may be hydrogen and nonmetallic impurities, such as the same iron oxide found within the boiler. The equation

$$3\,Fe + 4\,H_2O = Fe_3O_4 + 4(2H = H_2)$$

then must proceed *toward the left*, which is the reverse of the over-all boiler reaction.

In other words, hydrogen diffusing through the steel *must* tend to reduce each particle of iron oxide it encounters, just as iron ore is reduced by hydrogen in metallurgical practice. The reduction, of course, is governed by the same thermochemistry which governs the boiler reaction. Consequently, we can determine the potential, or limiting, pressures of H_2 and H_2O within the steel just as they were determined for the boiler. In fact, the locus of the oxide constitutes a tiny, theoretical boiler itself, wherein steam must be formed as a product of the hydrogen-oxide reaction. Because this is simply the reverse of the boiler reaction, the ultimate equilibrium is shown by the curves in Fig. 17, with an exception soon to be noted.

As a result, it now appears that cumulative gases within the steel could lead to congestion and disruption of the grain structure just as the cumulative gases could explode a sealed boiler if the steam-iron reaction were able to go to completion.

This, then, would seem to be the fundamental nature of the phenomenon of boiler embrittlement.

The same action is demonstrated in the hydrogen attack of catalyst chambers and hydrogenation units, as previously discussed. There, however, products besides H_2O are plainly involved, just as they undoubtedly are involved in boiler embrittlement (396). Parr and Straub (211), for example, found that high S and P led to more rapid failure, whereas, the general conclusion of work already reviewed is that O, C, and possibly S, N, and P are affected by the hydrogen (262). Straub, discussing White and Schneidewind's paper (245), mentions an instance of cracking being associated with nitrogen.

All nonmetallics with which hydrogen reacts, such as C, S, P, and N, must be expected to contribute to the total accumulation of gaseous products. Because P_{H_2} is fixed, these simultaneous equilibria are obviously similarly fixed. No calculations will be made here other than to point out that, for the equilibrium involving iron carbide and methane (253)

$$Fe_3C + 2\,H_2 = 3\,Fe + CH_4$$

$$K = (P_{H_2})^2/P_{CH_4}$$

$$\log K = -7990/T + 8.75$$

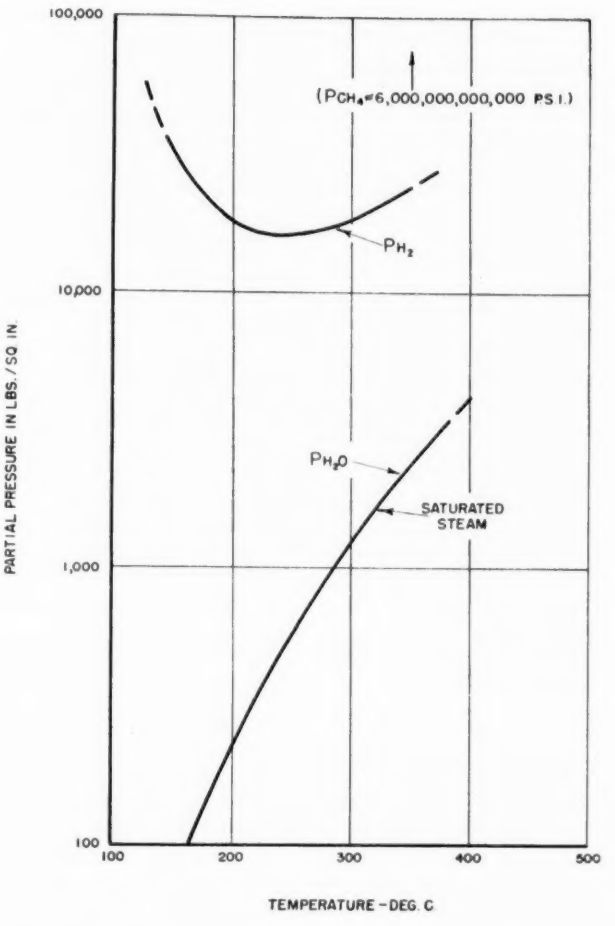


FIG. 17 CURVES SHOWING EQUILIBRIUM PRESSURES OF STEAM AND HYDROGEN OVER IRON AND ITS OXIDE FOR BOILERS OPERATING WITH SATURATED STEAM

whereupon, even at 350 C, the partial pressure of methane necessary for equilibrium with the steam and hydrogen prescribed for that temperature is approximately 5,760,000,000,000 psi! And at lower temperatures that figure rapidly increases! An arrow in Fig. 17, indicates that the methane pressures lie far off the graph.

Here again, the fantastic magnitude of these figures must not be allowed to contribute an impression of unreality. That monstrous value for P_{CH_4}, within its admittedly wide limits of accuracy, contributes the thoroughly sound information that iron, under the prescribed hydrogen pressure (see Fig. 17) of approximately 20,000 psi, could never be *carburized* by methane superimposed under any pressure available to us mortals. Or, from a more practical standpoint, the reaction to form methane under those conditions is irreversible. So long as carbon and hydrogen encounter one another within the steel, they will tend to add to the accumulation of insoluble gases. The concept is borne out by the fact that carbon may be removed from steel by hydrogen even at temperatures so high that methane is largely decomposed.

In this preliminary study, no conclusions will be drawn regarding the relative importance of the gaseous products in causing the grain disruption recognized as boiler embrittlement. Obviously, that is an important consideration, since it would indicate which nonmetallics in steel should be avoided. The beneficiation provided by deoxidizing steel with Al is undoubtedly

significant, as is the fact that such steel still ultimately fails in Schroeder's embrittlement detector. The literature on hydrogen attack concerns itself largely with carbon and methane, whereas decarburization is rarely noticed in boiler embrittlement. High-pressure boilers nowadays approach the service of hydrogenation units (365, 393); then decarburization is clearly indicated (365). Similarly, the English report marked decarburization from caustic embrittlement in tests on boiler plate at supernormal temperatures (396). Each of the gas reactions, of course, has its own equilibria and distribution of products and reactants over a temperature range. The same reaction need not be expected to predominate in these different services. The matter is best left temporarily simply as granular disruption by gases whose pressure can be expressed as

$$\Sigma P = P_{H_2} + P_{H_2O} + P_{CH_4} + P_{H_2S} + P_{NH_3} + \ldots\ldots\ldots$$

Equilibrium Versus Actual Boiler Conditions. Let it be understood that the foregoing calculations are based upon the ideal conditions of chemical equilibrium, but that they cannot be classed as being "only theoretical," since those equilibria have been determined and redetermined from actual experiment and have been made practicable. Of course, the values at high pressures are extrapolations and are subject to a consequent inaccuracy whose consideration is irrelevant at this time.

However, the question very naturally arises: *How closely are these calculated gas pressures likely to be approached in actual boiler service?*

Consider a unit, such as a boiler, separated into two compartments by a diaphragm of steel. In compartment *A*, the diaphragm has a clean fresh surface. In compartment *B*, the surface has such a heavy layer of Fe_3O_4 that for the present experiment it is inexhaustible. Compartment *B* is evacuated, leaving nothing but the Fe_3O_4, which is a product of the boiler reaction. Into compartment *A* saturated steam at 200 C is introduced, which is a reactant in the boiler reaction.

Immediately the steam reacts with the fresh iron surface of the diaphragm in the typical boiler reaction

$$3\ Fe + 4\ H_2O \longrightarrow Fe_3O_4 + 4(2H = H_2)$$

Now, regardless of the actual amount of the hydrogen which enters the steel, some quantity enters which is *that particular quantity injected by steam at 211 psi.*

In due time, some of the hydrogen will reach the Fe_3O_4 layer on the opposite surface of the diaphragm. There the well-established reaction for the reduction of iron oxide by hydrogen will occur

$$Fe_3O_4 + 4(2H = H_2) \longrightarrow 3\ Fe + 4\ H_2O$$

which is the reverse of the boiler reaction and has already been amply discussed, as have the pressures of the gases which must result.

Nevertheless, to recapitulate: H_2O will be produced in compartment *B* until enough steam is generated to reoxidize the iron and send H back into compartment *A* just as rapidly as the H_2O in that compartment is doing the same thing in the opposite direction. Obviously, the steam pressure in compartment *B* must then become 211 psi, since that is the steam pressure in compartment *A*.

At the same time that P_{H_2O} is increasing in compartment *B* enough H must precipitate from the iron without reacting with the oxide, of course, so that P_{H_2} is allowed to increase with P_{H_2O} n accordance with the curves in Fig. 17. Likewise, in compartment *A*, the portion of hydrogen which does not enter the steel will form molecular hydrogen until the steam is diluted with that same P_{H_2} that is ultimately attained in both compartments. The unit is then at equilibrium.

This fictitious experiment, of course, is simply a convenient means for representing the relationship between the steam boiler and the grain boundaries and inclusions within the steel which contain impurities reducible by hydrogen.

Reconsidering the "phase rule," an interesting thing will be noticed; within the grain boundary, or compartment *B*, there are only three phases, since water cannot exist at 200 C, until P_{H_2O} becomes 211 psi; then

$$F = 3 - 3 + 2 = 2$$

and the system is bivariant; whereas within the boiler, or compartment *A*, the system remains monovariant.

Thus the system is not completely described when the temperature alone is fixed. One more variable must also be stabilized. Ultimately, P_{H_2O} is that second variable which becomes fixed in the ideal unit when the steam therein reaches saturation and the fourth phase forms. But until the pressure of one of these gases is fixed, only the ratio of P_{H_2}/P_{H_2O} can be known, without any restriction as to the actual pressures of either gas. The total pressure may then be a matter of thousands of atmospheres, or only a few millimeters, so far as the chemical laws are concerned.

Without doubt, that brings us to the critical point in the phenomenon of boiler embrittlement, since the injection of hydrogen by the steam in the boiler cannot continue at the same rapid rate it had at that first instant when the surface of the iron was fresh and exposed. A covering of oxide immediately develops, which retards subsequent oxidation.

Without fear of confusion, we should now shift our attention from thermodynamics to kinetics; from ideal computations of equilibrium to actual rates of reaction, and how those rates may interfere with and upset the equilibrium. Plainly, the rate at which H is injected into the steel determines the concentration of the H within the steel, and that concentration in turn determines P_{H_2} within the grain boundary, or compartment *B*. This linking of rate with concentration is entirely valid, since the steel represents a reservoir for hydrogen through which the gas must obey the law of diffusion, in which rate and concentration are interdependent.

In other words, the gas ratio, and then the total pressure of $P_{H_2} + P_{H_2O}$ within the grain boundary, can become established by the fixing of P_{H_2}. Thus if H were supplied to the diaphragm in compartment *A* by some device, permitting a much greater rate of infusion than from steam at 211 psi, a superficial equilibrium could be imposed. The concentration of H within the metal would become abnormally high and the pressures of H_2 and H_2O in compartment *B* would adjust themselves to some supernormal values.

In the same way, if Fe_3O_4 in effect covers a part of the surface of the diaphragm in compartment *A* so that less H per unit time is injected into the steel, the gases in compartment *B* will adjust themselves to an equilibrium corresponding to steam in compartment *A* at something less than the actual pressure.

This, then, seems to be the explanation for the fact that boiler embrittlement depends upon agents like caustic and stress which will counteract the natural protection against hydrogen injection afforded by Fe_3O_4. Similarly, "accelerators," such as sodium silicate, counteract the depression of hydrogen absorption. Without these counteracting agents, all agree, boiler embrittlement will not occur; conversely, it is possible that every steam unit would suffer embrittlement if it were not for the retarding and protecting effect of this cumulative reaction product, Fe_3O_4.

Is Failure Intercrystalline or Transcrystalline?

Since time immemorial for this subject, an argument has raged over the path followed by cracking in embrittled boiler

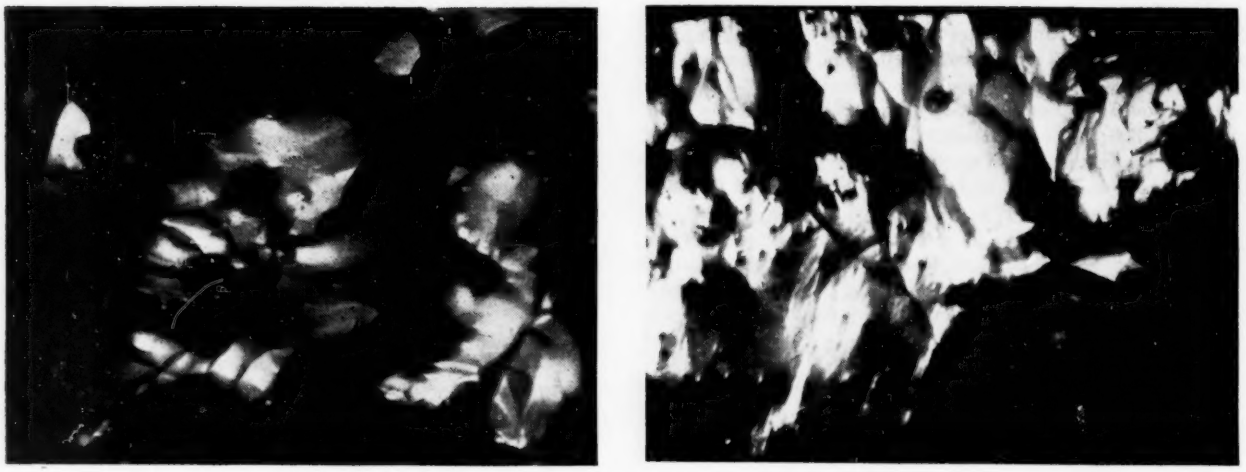

FIG. 18 DIRECT MICROGRAPHIC STUDY OF GRAIN BOUNDARIES ON A FRACTURED FACE OF INGOT IRON, EMBRITTLED INTERCRYSTALLINELY BY HYDROGEN

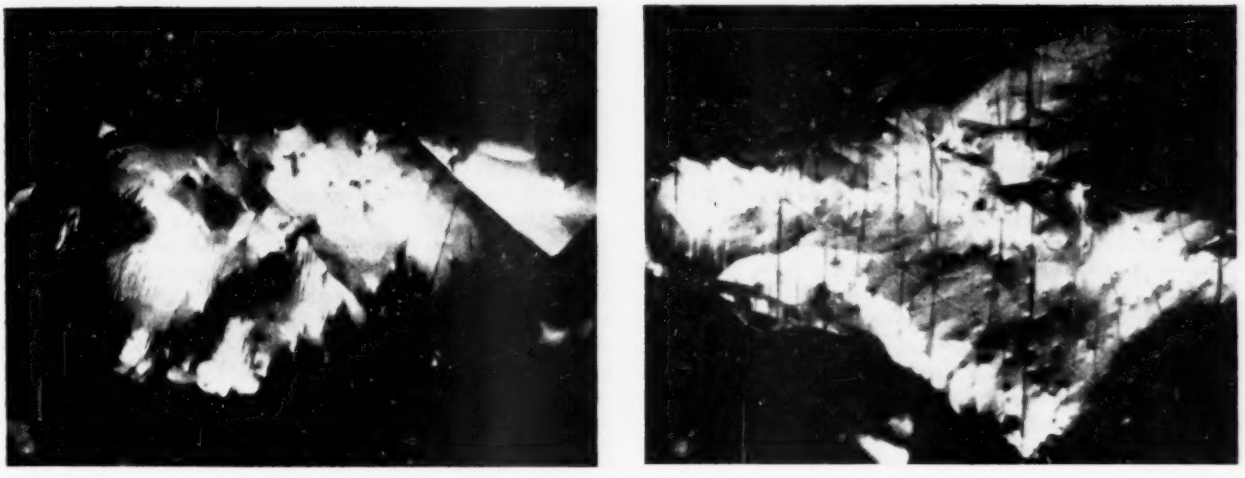
(Specimens fractured after interrupting a purification treatment in hydrogen; ×200.)

steel (97, 139). Many have given positive assertion to the fact that the cracks are exclusively intercrystalline (181, 220, 232); but others have noted that the cracks sometimes pass directly through the grain (137, 183, 406, 410), Perry (311) mentioning that either type may be shown "at the will of the operator." One case is even reported of cracking along twinning planes (133)! Numerous reasons have been advanced (128, 136), most of them superficial, none satisfying.

Now it should be clear why the cracks do exactly what they are observed to do. Let us refer again to Fig. 17. Only steam and hydrogen are shown there; but it is evident that at lower temperatures, the ratio of H_2/H_2O acquires such a predominance of H_2 that hydrogen must rely upon itself to embrittle steel. Its habitat is within the grain; consequently failure, when it occurs, is through the grain—transcrystalline. At higher temperatures, the ratio decreases until the sum of $P_{H_2} + P_{H_2O}$ is measurably greater than P_{H_2} alone; consequently failure, when it occurs, selects the habitat of the mixed gases, which is the grain boundary, since the gaseous product, H_2O, is insoluble in the grain.

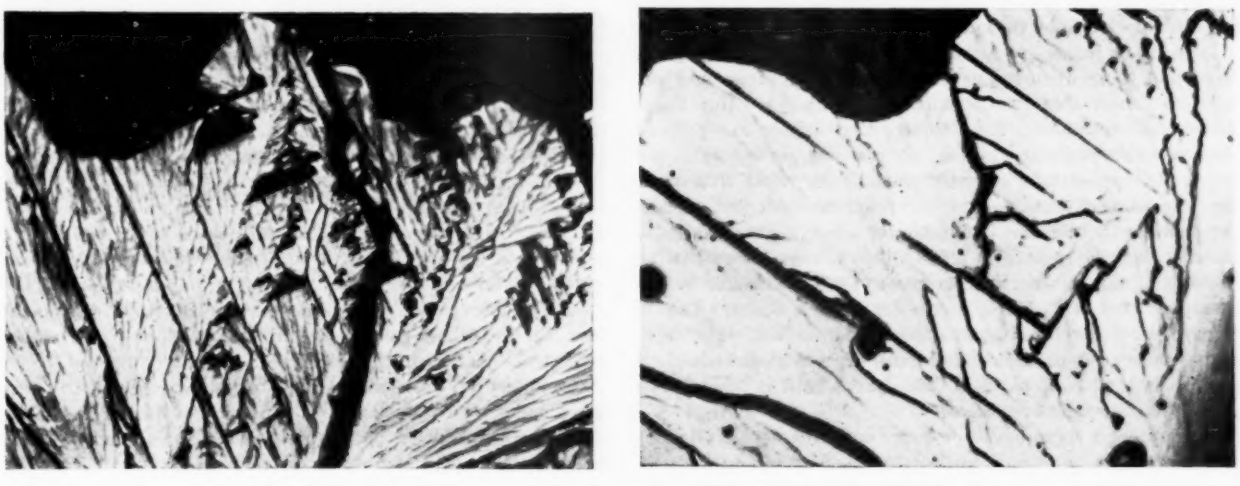


The gaseous products which are not shown, viz., CH_4, H_2S, NH_3, etc., have a role similar to that of steam with but one important distinction. That is, at lower temperatures some of their equilibria lie far toward the gaseous product, as is the case with methane, but without effect because the rate of reaction is so slow at ordinary temperatures. Consequently, grain-boundary failure, which depends upon an accumulation of those gaseous reaction products, tends to be suppressed at lower temperatures. Williams and Homerberg (162) found some reduction of oxide inclusions during cathodic electrolysis, as did Law years before (51). In fact, Pfeil's case of intergranular failure which has caused so much misunderstanding was unquestionably real.

In ammonia synthesis, then, intergranular attack is the rule; in acid-pickling and cathodic electrolysis, including short tests in caustic solutions at temperatures up to 250 C, or so, reaction products are seldom allowed to accumulate, and simple transcrystalline hydrogen brittleness is the rule. In boiler service, the tendency is definitely toward intergranular attack, because the extended period of service compensates for the low temperature; but the condition is sometimes intermediate. Some grains then break transgranularly, expressing the fact that the total gas pressure in the boundary may not always exceed that of pure hydrogen alone within the grain. The fact that sudden shock in the cracking process may also drive a fracture through a grain should not confuse this explanation, which applies to run-of-mill embrittlement.

Fortunately, this explanation need not rest upon theory alone, for the action can be directly followed through a micrographic technique recently developed at Battelle Memorial Institute (423). Samples of iron and steel showing various types of embrittlement by hydrogen have been fractured and studied at high magnification directly upon the untouched fractured face, as in Fig. 4. Micrographs showing both end stages and intermediate stages of embrittlement are presented in Figs. 18 to 20, inclusive. Fig. 18 is a view of a grain boundary as a surface instead of the customary line in sectioned specimens. Ingot iron, containing oxygen as its principal impurity, was heated in hydrogen at 1000 C for some days and was then withdrawn and fractured in impact. The specimen corresponds to those in Fig. 16, which were embrittled by accumulation of hydrogen reaction products in the grain boundary. Note the rough surface in the second view, suggesting that some impurities were still in place.

Fig. 19 represents the intermediate stage, wherein the pressure of grain-boundary gases is but little greater than the pressure of elemental hydrogen within the grain. The fracture, consequently, is intergranular, but transgranular planes of weakness have opened to accept the path of the fracture should a grain boundary hesitate. The first micrograph shows just a few crystallographic traces, and represents the specimen as it was removed from the hydrogen treatment. The second micrograph shows another specimen subsequently charged with hydrogen electrolytically, whereupon transcrystalline weakness was greatly developed. Nevertheless, that piece still chose to fracture predominantly through the grain boundaries in spite of the cathodic treatment. Evidently the pressure of residual gases in the grain boundary remained predominating—which may explain Pfeil's test, incidentally, since he may have occluded such products during his treatment for grain growth.



In any event, Fig. 19 verifies the discussion concerning the curves in Fig. 17, and explains why in certain cases the fracture of embrittled boiler plate occasionally chooses to pass through a grain. Fig. 20 is comparable to Fig. 4, and shows the other extreme. These specimens were purified in hydrogen, too, but the treatment was carried to completion. The grain boundaries were relieved of their burden during a subsequent treatment in vacuo, the metal healed, and cathodic electrolysis developed a strictly transgranular weakness.

(*a*) (*b*)

FIG. 19 MICROGRAPHIC STUDY SIMILAR TO FIG. 18, BUT SHOWING CRYSTALLOGRAPHIC MARKINGS DEVELOPED BY ELEMENTAL HYDROGEN WITHIN GRAIN

(Micrograph *a*, ×350; micrograph *b*, ×1000.)

Fig. 18 therefore may be said to represent hydrogen attack under conditions of ammonia synthesis; Fig. 20 pickling-brittleness; and Fig. 19 boiler embrittlement.

The key to another puzzling observation in boiler embrittlement may be contained in this same explanation. The fact that the metal adjoining a crack is not brittle (38 has been held by some to disprove the hydrogen theory (233). On the contrary, that observation is in exact accord with the present argument, since escape of the gas through the surface of the fracture will permit ductility to return in the surrounding metal, just as it is known that boiler steel will recover its ductility if allowed to lie around awhile at temperatures well below those for annealing (155, 177). Although the compound gases are highly insoluble, they do ultimately lose at least their high compression, just as hydrogen does in a shorter period of time in the case of pickling brittleness. How could a theory of selective corrosion possibly fit these facts?

On the other hand, Straub's broad statement (233) that the adjacent metal retains its original properties may be going too far. In spite of the tendency to recover upon standing, more careful examination would very likely show deterioration of the proportional limit, if not the tensile strength and ductility, in agreement with well-established characteristics of intercrystalline H attack (262, 314).

EFFECT OF STRESS

Stress is doubtless important to cracking in boilers, for it plays a similar role in all other forms of hydrogen activity. Certainly the crack itself is caused by superimposed stress since hydrogen itself only embrittles—never cracks—sound steel (404, 418–420, 423). There is, however, an outstanding paradox in existing conceptions on boiler embrittlement which has received no attention and yet is critical to the entire subject.

Long ago there was established as a fundamental in metallurgy that, at temperatures where steel is elastic, the grain boundaries appear to be stronger than the grain itself (47, 113, 137). As Humfrey, an English metallurgist examining a boiler failure 30 years ago (75), observed: "It is a well-marked fact that the joints

between . . . the individual crystals . . . are considerably stronger than the gliding or cleavage planes within them." A moment's reflection recalls the fact that "cold-work," almost by definition, causes plastic deformation of the metal along slip planes within the crystal. In other words, stresses "beyond the yield point," which are so necessary to attaining boiler embrittlement, can scarcely be conceived to weaken the grain boundary, because those stresses are relieved by the imperfections called slip planes operating within the grain. As a matter of fact, even at the ultimate breaking load, after the stress necessary to start slip has been greatly exceeded and failure finally takes place, that failure is still through the grain, taking place along major planes of imperfection within the crystal commonly called cleavage planes. If the grain boundary is weakened at all, stress must disrupt the grain itself even more. How, then, can one adopt a theory of selective corrosion, a theory which depends upon the preferential weakening of grain boundaries by strain, and find it at all congruous with the facts? Furthermore, cold-working increases the solubility of steel in aqueous solutions, it is well known; but the increased rate of solution involves the grain itself in most cases, because cold-working makes the metal anodic, and because the effect of the cold-work is upon the grain itself. The selective-corrosion theory would seem to require the grain boundary to become electropositive from cold-working, when the exact opposite appears to be the case.

True, other forms of cracking, such as "season-cracking" in brass, and those discussed earlier, depend upon stress and yet have no conceivable relationship with hydrogen. But those cases remain unsolved. Even though they appear to represent selective grain-boundary attack, no one has yet provided an acceptable explanation for the phenomena. And if anyone wishes to take advantage of this exception, he must first explain why boiler embrittlement is notable for occurring underneath a smooth, black layer of iron oxide which always attests its inception and source; whereas every case of intercrystalline failure from plain chemical attack, to the best of the author's knowledge, shows the expected granulation on the surface. The present gas theory is tenable in that regard, since hydrogen dissolves into the iron without physical disturbance until it reaches the scene of its subsequent reactions.

In the present specific case of boiler embrittlement, hydrogen affords a simple and ready answer to this seeming paradox of stress. Any stress which exceeds the yield point likewise opens the imperfection or slip planes which house hydrogen in the elastic range (refer to Figs. 4, 20). Two factors then come into play: (*a*) More hydrogen is produced by the steam-iron reaction, because the iron is made more active chemically and because infiltration of the liquid into those imperfection planes permits a greater reactive area; (*b*) more hydrogen is absorbed because of the greater chemical activity and because the opened rifts afford sites for occlusion. In other words, in cold-worked steel, a greater movement or flow of reactive hydrogen gas occurs through the metallic membrane of surface grains, permitting a sufficient supply to reach inner grain boundaries where resultant gaseous products accumulate until they disrupt the grain-to-grain contacts, and the matrix is brittle.

Although stress is admittedly vitally important to embrittlement of steam boilers, it must not be classed as a truly fundamental factor, except in actual cracking. The fundamental factor in the destruction of ductility is the equilibrium between infusing hydrogen and the impurities within the steel. Stress aids in the attainment of, or the approach to, that equilibrium. Whether it simply breaks off the protective Fe_3O_4 layer, or whether its action is more subtle, cannot now be determined. It is plainly an accelerating factor which increases the rate of hydrogen infusion beyond some value that is probably critical for boiler conditions, below which the gases either diffuse from the steel faster than they can develop embrittling pressures, or embrittling pressures are not attained in the lifetime of ordinary boilers. The actual cracking does depend upon superimposed stress, and should not be confused with embrittlement, which is simply a condition of the metal wherein it is unable to respond to stress except by rupturing.

Such a conception of stress can be strengthened by numerous observations. Even in "pickling-brittleness," Langdon and Grossman long ago observed that cold-working accelerated embrittlement (126); and that cold-worked steel occludes inordinate quantities of hydrogen is common knowledge (384–389). At temperatures of the hydrogenation plant, where stresses are likely to fade rather quickly, previous cold-working greatly increases the intercrystalline failure caused by hydrogen (332), as it does in ammonia synthesis (372). Körber noted a similar effect with regard to decarburization in hydrogen (327); and, at Battelle Memorial Institute, specimens of carbon steel heated in hydrogen showed a tremendous increase in decarburization when the steel was simultaneously deformed in tension. In conditions of ammonia synthesis, stress is exceedingly important in accelerating deterioration; but with longer periods of time quite the same results are obtained without stress.

Effect of Caustic

Similarly, the effect of caustic, as important as it is, must be regarded simply as an accelerating, or catalyzing factor. A great many reasons have been advanced to explain the admitted fact that boiler embrittlement, as it is observed, depends upon NaOH; and there is no reason to doubt that that chemical concentrating in seams and crevices leads directly to the trouble. But again, the ultimate gas pressure obtainable in the grain boundaries, which is the basis for embrittlement, is the same whether Fe_3O_4 is produced by caustic or by pure distilled water. The gases which can form are dependent only upon impurities within the steel, and their partial pressures are controlled only by temperature, for the whole gaseous system is proscribed by involving saturated steam, as already explained.

Consequently, caustic must be placed in a category with stress as an agent which accelerates the infusion of hydrogen so that the gases will occlude more rapidly than they disperse, leading to embrittlement in an observable period of time. Whether the caustic itself reacts with the iron (229), whether it increases the electromotive force of the solution with respect to the iron (211), or whether its function is to dissolve the oxide reaction product, which would otherwise seal off the steel for further attack by H_2O (360, 365), is at present immaterial. Tajc even suggests that NaOH is "neither an active ingredient of the corrosion process, nor a factor in determining the stability of the resulting iron oxide" (333). He concludes that NaOH peptizes the oxide to form a colloid, which befits the third suggestion just listed.

Be that as it may, the important feature is that caustic is the agent in boilers which provides hydrogen infusion at a rate sufficiently rapid to surpass that critical value above which embrittling pressures of gas develop and below which the gases dissipate rapidly enough to make harmless the reactions which have been discussed.

There can be little doubt that gaseous hydrogen under 20,000 psi, the pressure corresponding to the potential pressure of the hydrogen produced on the boiler wall, would produce embrittlement in boiler steel at 250 C in the absence of the steam-iron reaction, since intercrystalline H attack from less pressures and at lower temperatures has already received discussion.

Of course, the attack would depend upon the impurities in the boiler steel, for that pressure of hydrogen alone is insufficient to

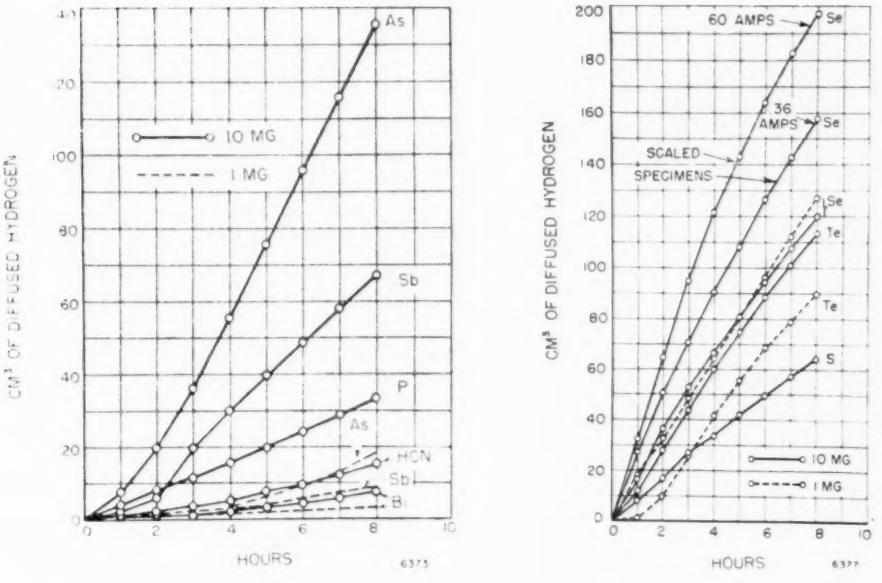

FIG. 21 HYDROGEN ABSORPTION FROM 10 PER CENT H_2SO_4 ELECTROLYTE
(*a*, Traces of elements from Group V of the Periodic Table added to the electrolyte. *b*, Same for Group VI. Steel surface = 10 sq in., T = 25 C. Baukloh and Zimmermann.)

cause embrittlement (refer back to Fig. 3). That, then, leads to conclusions regarding the role of the steel.

EFFECT OF COMPOSITION AND HEAT-TREATMENT OF THE STEEL

The foregoing suggests an important point, that boiler embrittlement is a metallurgical study as well as a chemical one. In fact, the work of Schroeder and of Straub, and their respective collaborators, has advanced the chemical aspects of the problem so far beyond the metallurgical aspects that the rest of the problem is now almost purely metallurgical. Their tests, however, also demonstrate that "killed" steel, i.e., steel whose oxygen is stabilized or removed, is superior in its resistance (398), a fact discovered 15 years earlier by the German investigator who invented Izett steel. Aluminum oxide, of course, is much more resistant to chemical attack than is iron oxide; and the ultimate equilibrium pressure of H_2O over Al and Al_2O_3 is so negligible that that oxide effectively precludes grain-boundary congestion from steam. In other words, iron containing no impurities other than Al and oxygen probably would never show hydrogen embrittlement until the pressure of the hydrogen itself became great enough to cause the transcrystalline type of brittleness.

Likewise, the general role of "aging," first mentioned by Stromeyer many years ago, should now be clear, since "aging" is nothing other than the precipitation of certain impurities from the mother lattice. As separate, precipitated phases, most of those impurities are amenable to H attack. A truly "non-aging" steel, such as is approached by Izett, would simply have no important quantities of nonmetallics with which the hydrogen could react.

In tests reported by Solberg, et al (414, 415), steel alloyed with Cr showed increased resistance to attack by steam, which now assumes significance in the light of the analogous results already discussed on H attack. Boilermen often decry the use of alloy steels because of expense; but in industries where the effects of hydrogen are recognized, nothing but alloy steels receive consideration. Pilling and Straub (409), it is interesting to note, just last year obtained a patent for alloy steels containing Ni, Cu, Al, Be, and Ti in amounts up to 3 and 5 per cent to resist caustic-cracking. Even the ammonia-synthesis industry seldom resorts to such alloys. According to Krupp's experience, a low-carbon steel with 1 per cent or less of vanadium may do the job. That would certainly bear investigating.

The problem is to obtain steel as low in nonmetallics as possible, while retaining necessary mechanical properties, and rendering those impurities which are present as harmless as possible both by alloying and by heat-treatment. No improvement need result from removing oxygen, if C, S, or N, for example, are left in harmful quantities. Stromeyer many years ago, discussing Houghton's paper (84), blamed embrittlement principally on N and P, and stated that when $P + 5\,N > 0.08$ per cent, failure results.

By heat-treatment, some nonmetallics can be put in solution. Rapid cooling from the anneal then tends to prevent their precipitation. At least, their migration to grain boundaries can be prevented, which acts to prevent accumulation of gaseous products in the grain boundary. Obviously, heat-treatment can only be a palliative. In carbon steels, a "sorbitic" heat-treatment is advised, because a finely disseminated pearlite results. Grain-boundary carbides seem especially harmful.

INHIBITORS AND ACCELERATORS

When hydrogen is accepted as the underlying cause of boiler embrittlement, an understanding of several hotly argued points on the action of so-called inhibitors and accelerators is possible. At the outset, Parr (94) concluded that oxidizing agents should inhibit embrittlement if hydrogen were its cause. In 1926, Parr and Straub stated that "NaOH is the only salt in the boiler which will embrittle steel" (181), and showed that Na_2SO_4 stops embrittlement when present in amounts approximately 3 times the total alkalinity as Na_2CO_3 (197). Then, in 1936, Straub and Bradbury (320) and Schroeder and Berk (315) simultaneously revealed a powerful role played by minute impurities in the caustic solutions that had been used in test (364). Principal among these was Na_2SiO_3, although the presence of Ca, Mg, and Al (320) and TiO_2, GeO_2, Sb_2O_3, and $SbCl_3$ (331) exerted an effect, too. Phosphates, chromates, tannates, acetates, besides

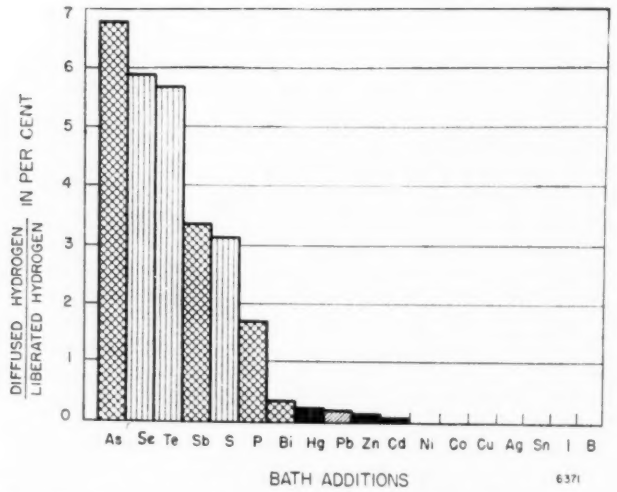

FIG. 22 DIAGRAM OF RATIO ABSORBED/LIBERATED HYDROGEN AS AFFECTED BY ACCELERATING ELEMENTS ADDED TO THE 10 PER CENT H_2SO_4 ELECTROLYTE IN 10-MG ADDITIONS PER LITER
(Current density 10 amp per sq ft, T = 25 C. Baukloh and Zimmermann.)

sulphates, were found to retard embrittlement by Parr and Straub (211), though a paper by Schroeder and Partridge (319) raises some question about Na_3PO_4. Schroeder, Berk, and O'Brien then state that dilute HNO_3 can be substituted for NaOH (331), although the year before Schroeder, Berk, and Partridge (317) found that sufficient quantities of oxidizing agents inhibit embrittlement; whereas in the recent A.S.M.E. Symposium on Boiler Embrittlement (405–408, 410, 412, 416) Bardwell and Laudemann (405) claim that their dilute addition of $NaNO_3$ has eliminated embrittlement in detector specimens on the whole Chesapeake and Ohio Railroad to date.

Finally, Na_2SO_4, the old stand-by written into the Boiler Code (185), itself failed to stop embrittlement (206, 311, 341, 397, 405, 406, 410), although Straub pointed out that the sulphate is ineffective unless a certain minimum of NaCl is also present (416). In the meantime, the National Physical Laboratory in England refuted Schroeder's silicate theory by obtaining embrittlement in pure NaOH, thereby proving that silicate can only be an accelerator. Rice even points out that the silicate may hinder embrittlement (397).

Desch undoubtedly comes closest to providing rhyme and reason when he observes that an inhibitor often acts as an accelerator under different conditions of temperature and pressure (361), similar to Straub and Bradbury's observation that sulphate protection disappears as the steam pressure increases, but that then another type of inhibitor fortunately becomes effective (352, 353).

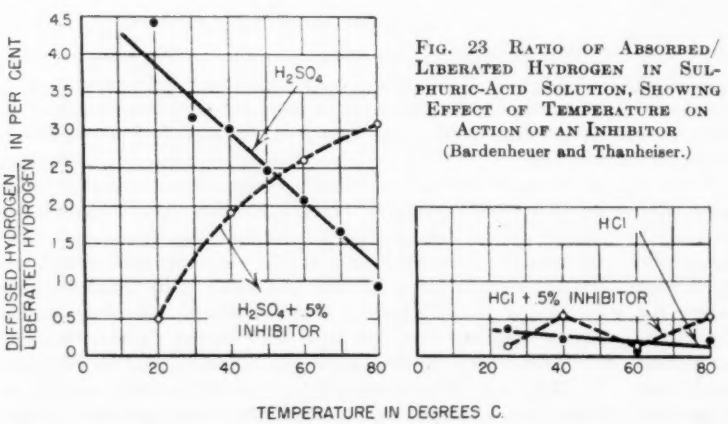
In 1926, two Russian investigators, Alekseev and Polukarov (173, 174), discovered that a trace of As or Hg in an aqueous electrolyte led to rapid embrittlement of the steel cathode. Later, other elements were added to the list (250, 273), until Baukloh and Zimmermann (306), in 1936, provided the astonishing results shown in Figs. 21 and 22. The curves, in Fig. 21, show the tremendous increase in hydrogen absorption during cathodic electrolysis caused by seemingly negligible amounts of elements from groups V and VI of the Periodic Table. Arsenic present almost as a trace, for example, may increase the hydrogen absorption 100 times over that from a "pure" solution. As a matter of fact, in greater quantities these elements may act as inhibitors, which is significant in view of the analogous observations just recounted for boiler embrittlement (211, 361, 397). Körber and Ploum (250) even go so far as to suggest that iron containing none of these impurities will not dissolve in acid which contains none of them. In any event, these results offer significant comparison with the seemingly discordant findings of investigators on boiler embrittlement, for inhibitors and accelerators in hydrogen-caused boiler embrittlement would very reasonably be those inhibitors and accelerators here discussed. A diagrammatic illustration of the effect of these accelerators in aiding infusion at the expense of liberated portions of the gas stands in Fig. 22.

In the canning industry, the presence of sulphur and such elements has also been found to increase hydrogen evolution so greatly that the cans may swell and burst (247, 309).

In regard to inhibitors,[6] there is another interesting factor in boiler embrittlement which warrants study. Bardenheuer and Thanheiser (205), for instance, show very clearly that any inhibitor has its optimum range of temperature, and perhaps other conditions. When that range is exceeded, its inhibiting nature may disappear. One such instance is illustrated in Fig. 23, in which a plot of the ratio of absorbed to liberated hydrogen indicates that the absorbed fraction, which is the important fraction, of course, may increase without any evidence of a change in the visible evolution of gas.

The point to be made is that this type of action could operate at the steel-steam interface to promote or to inhibit the absorption of hydrogen, giving rise to the terms "inhibitors" and "accelerators." The suggestion simply amounts to an elaboration of Parr's original ideas. Christmann (258), for example, found that H from the steam-iron reaction reduces Na_2SO_4 in boiler water to form H_2S. Perhaps the inhibiting action of the sulphate is such a chemical one, removing a portion of the H before it can penetrate the iron. On the other hand, the argument over sulphate, i.e., whether its effect depends upon precipitation of a solid phase (181, 197, 297), may be explained by assuming that its precipitation on the steel would be a better barrier to hydrogen in spite of the fact that its chemical activity is then identical with that of the saturated solution (297). Na_2SO_4 is anhydrous above 33 C, whereupon a precipitated coating would protect the steel from steam attack. Na_2SiO_3, an accelerator, is strongly hydrated. Thus, Norton (377) observed a tremendous diffusion of hydrogen through an iron tube when it was coated with Na_2SiO_3, the accelerator, and heated to the boiler temperature of 200 C.

In further agreement, Norton found that sodium chromate, an inhibitor, completely stopped the diffusion through steel of hydrogen from tap water.



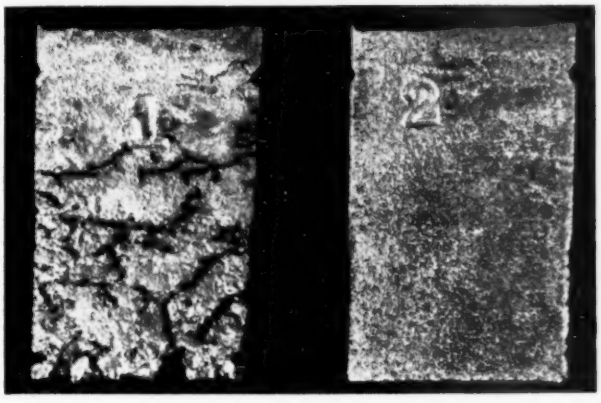


FIG. 23 RATIO OF ABSORBED/LIBERATED HYDROGEN IN SULPHURIC-ACID SOLUTION, SHOWING EFFECT OF TEMPERATURE ON ACTION OF AN INHIBITOR
(Bardenheuer and Thanheiser.)

(*a*, Tensile fracture showing synthetic "fish eyes." *b*, Side view of half the specimen after deep-etching in HCl.)

Also, Langdon and Grossman long ago observed that Na_2SO_4 inhibited cathodic embrittlement from hydrogen (126). And Hill points out that Na_2SiO_3 is widely used in flotation, possibly because it has an interfacial effect on gas absorption (308).

Such observations suggest returning to the original opinions of Parr (94) on adding agents from the standpoint of frustrating hydrogen absorption. Simple tests at proper temperatures, using boiler steel as a diaphragm, with the various solutions on one side and a means of collecting transfusing hydrogen on the other side, might soon provide an empirical basis, at least, for selecting inhibitors suitable for any particular operating condition. Though Schroeder's embrittlement detector is a clever qualitative test, these diffusion experiments would provide quantitative information, and rapidly. Furthermore, that information would be so fundamental that running individual destructive experiments upon new boiler installations might become unnecessary, since the results could be predicted.

Why these substances affect hydrogen absorption as they do is

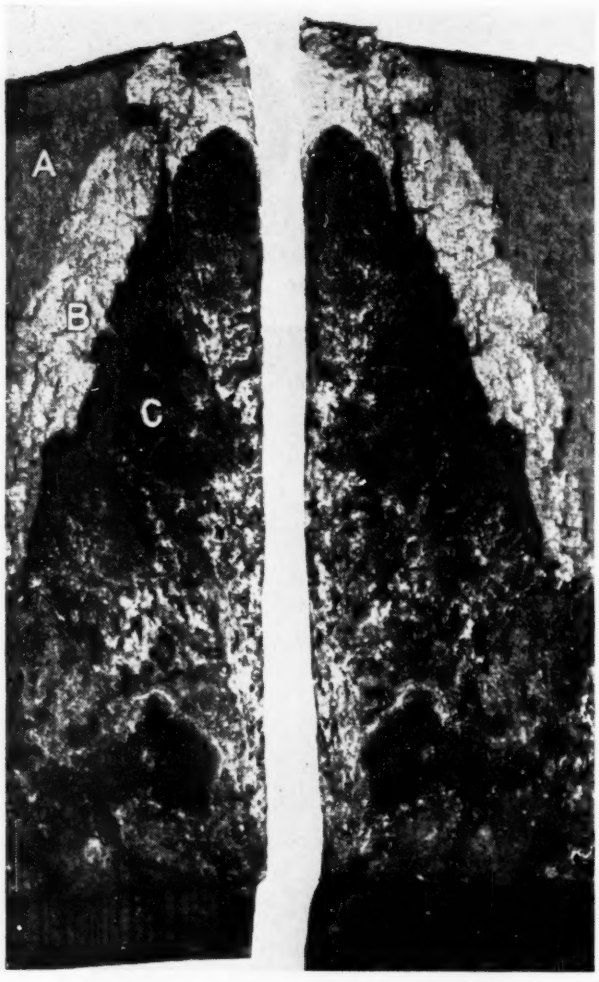

FIG. 27 FRACTURED FACES OF A PARTLY CRACKED BOILER PLATE
(*A* shows a zone of seemingly normal, ductile metal farthest removed from the source of attack; *B* is a zone of hydrogen-embrittled metal preceding *C*, which is a zone of direct chemical attack, progressing into the original crack and into the intergranular voids opened by the hydrogen attack. ×2.)

as yet unknown. That they do is sufficient basis for prosecuting such an investigation.

VISUAL PROOF OF THE HYDROGEN THEORY

In earlier sections of the paper, transcrystalline brittleness from elemental hydrogen was described as a function of pressure within crystallographic planes of the grain; and micrographs actually showed these planes opened by the gas during embrittlement. That they truly are opened, and with some permanent set, is shown in the illustrations which follow. In Fig. 24 are two clippings from the respective edges of the two sheets shown in Fig. 1. It will be recalled that one was embrittled by hydrogen and the other was not. Deep-etching in HCl developed severe fissuring in the embrittled specimen, as may be seen. In other words, the solution was able to penetrate more rapidly into metal that had been embrittled by hydrogen.

In Fig. 25, a similar instance is shown in regard to the "fish eyes" discussed earlier. The fractured faces of a tensile specimen of weld metal are shown as (*a*) and (*b*), the former being an original face; the latter the corresponding face after deep-etching in HCl; (*c*) is a side view of specimen (*b*). Note the savage attack of hydrogen-embrittled portions, attesting the distending and weakening forces of that trapped gas. In Fig. 26 the explanation is put to a more severe test. A tensile specimen of ordinary steel akin to boiler plate was coated with Glyptal except along four longitudinal stripes at quadrant positions. Cathodic electrolysis developed four synthetic "fish eyes," as may be seen in the fractures at (*a*). After 1 year of standing at room temperature, during which time all brittleness must have vanished, the specimen developed the marked preferential chemical attack shown in Fig. 26 (*b*). Thus hydrogen embrittlement truly distends and weakens the body of the grain. It must be remembered that these three figures pertain to transcrystalline brittleness, but also that they illustrate how hydrogen paves the way for subsequent chemical attack, a question which may have some significance in boiler embrittlement.

In intercrystalline H attack, such as boiler embrittlement, the compressed gas in the grain boundaries must have a similar effect, the only difference being that it opens the grain boundaries to subsequent chemical attack instead of the planes within the grain.

Accordingly, the whole story of boiler embrittlement seems to

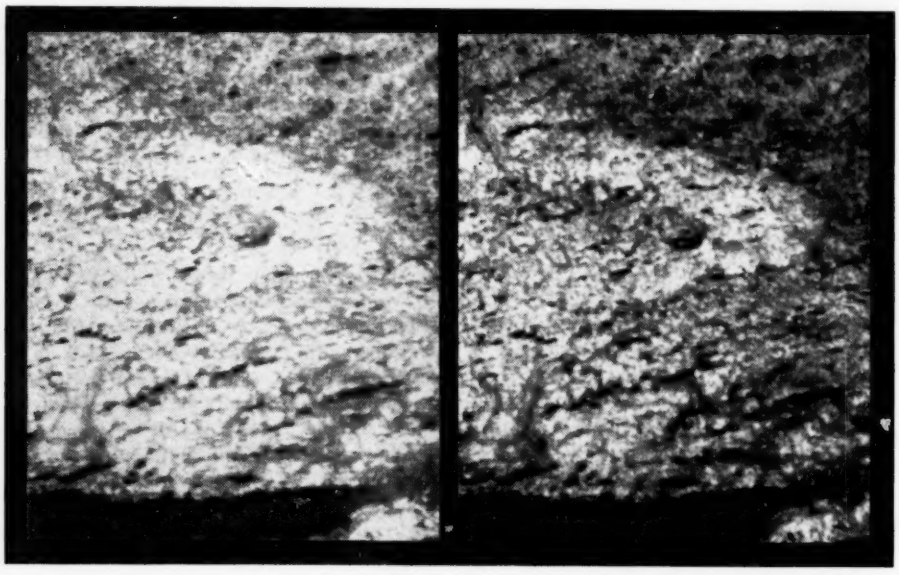

FIG. 28 STEREOMACROGRAPH OF ZONE *B* IN FIG. 27, SHOWING POROSITY FROM HYDROGEN ATTACK AND PROGRESSION OF BOILER EMBRITTLEMENT; ×10

lie within the single illustration, Fig. 27. Several samples of embrittled boiler plate were kindly furnished by Dr. Schroeder and Mr. Berk. Among other tests, these plates were broken open along visible cracks. A typical fracture through a crack beginning at a rivet hole in the outer plate of a double-plate boiler shell is shown in Fig. 27.

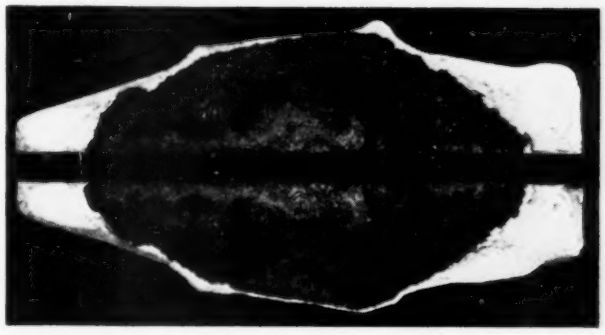
There are three obvious zones on the fractured faces; *A* is the gray fracture typical of normal, ductile metal and composes the zone furthest removed from the concentrated caustic solution in the leak around the rivet hole toward the inside of the boiler. Adjacent to that leaky seam and rivet hole is a zone of badly corroded metal, namely, zone *C*, obviously caused by penetration of the corrodant into the actual crack. In between these two is zone *B*.

Zone *B* is bright and clean, macroscopically and microscopically typical of metal reduced and purified in hydrogen. Zone *B* appears brittle, which is also typical of hydrogen attack. Zone *B* is intermediate between seemingly normal metal and cracked corroded metal; and that zone therefore represents an "advancing front" for this phenomenon of boiler embrittlement. The question: "Does the caustic enter the steel by creating fissures, i.e., selective corrosion, or are fissures created by another agent, such as hydrogen, which then permit the caustic to enter the steel?" seems to be answered clearly in Fig. 27.

Such an order of events is neither untoward nor unique. Long ago it was shown in the case of copper that granular deterioration from oxidation depended upon the grain boundaries first being opened by hydrogen embrittlement (142). Fig. 14 demonstrates the same thing for steel.

To convey the full significance of Fig. 27 as clearly as possible, a stereomacrograph[7] is included in Fig. 28. With the depth afforded by that type of illustration, one can more clearly see the marked porosity of the embrittled zone where nonmetallics have been removed from grain boundaries, seams, and inclusions, though photographic reproduction does this test an injustice. Into that porous mass, the corroding chemical can be seen advancing on one side; and on the other side one may observe that cavities also exist, but that the action is incomplete. Consequently, the metal there still appears ductile, although

[7] This stereograph may be examined with a pocket viewer of the Keystone type from which the back has been removed, or with a matched pair of low-power magnifying glasses. Many people can obtain fusion by holding the prints squarely before the eyes at the shortest possible focal distance and "staring through" them at an imaginary distant object.



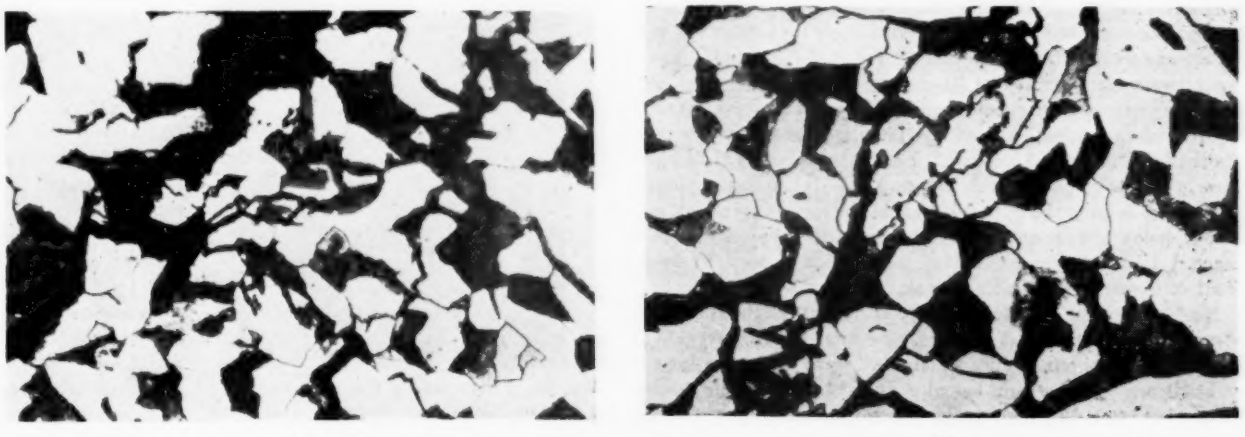


FIG. 29 SECTION OF RAILROAD RAIL FRACTURED THROUGH A CRACK SHOWING DUCTILE METAL, HYDROGEN EMBRITTLEMENT, AND CHEMICAL ATTACK SIMILAR TO BOILER PLATE IN FIG. 27

it must have contained grain-boundary gases under pressures which only lacked attaining that critical pressure at which the grains are forced apart and the metal is embrittled.

The whole appearance is in such exact accord with the present discussion that its importance can hardly be overestimated. The brightness of the brittle zone attests the strong reducing action of hydrogen; and the absence of flat cleavage facets in that zone shows that the attack is predominantly intercrsytalline, and that that fracture type was therefore imposed by the hydrogen function, since the fracture would normally be transcrystalline. The obvious and destructive porosity pervading the entire advance zone is sufficient testimonial *that boiler embrittlement and intercrystalline hydrogen attack are certainly identical.*

Actual cracking, it is well to repeat, is enabled—not caused—by the embrittlement. Use of the term "boiler embrittlement" for cracking is indiscriminate, since "embrittlement" only indicates a susceptibility to cracking, without further implication. Cracking first occurs when embrittled metal is subjected to stress. In boilers, that stress may be operational, or it may possibly arise from volume changes in the metal caused by the gas reactions, or both. The present study does not concern those stresses.

An observation with *trans*crystalline brittleness, directly analogous with that in Fig. 27, is shown in Fig. 29. A railroad rail, annealed in hydrogen for a short period at 1200 C, absorbed so much of the gas that it developed a large transverse crack from its own cooling stresses upon removing it from the furnace.

(*a*) (*b*)

FIG. 30 MICROGRAPHS OF SPECIMEN IN FIG. 27, TAKEN IN CORRODED ZONE *C*; ×500

(Note the thin fingers of gray material in and around the ferrite, which probably represent iron oxide formed from water vapor penetrating fissures opened by hydrogen attack.)

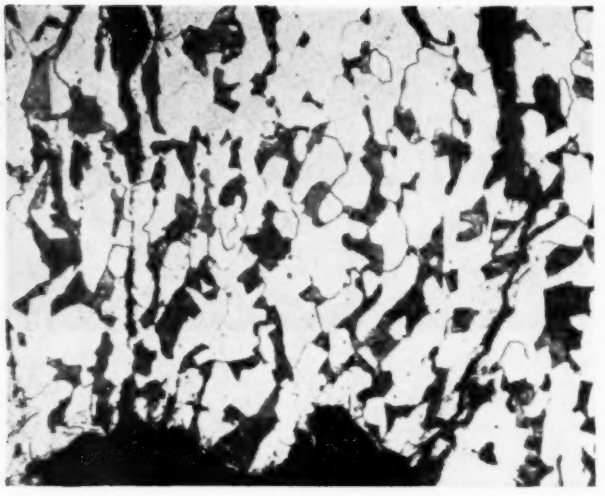

FIG. 31 MICROGRAPH TAKEN CLOSE TO BOUNDARY OF ZONES *A* AND *B* IN SPECIMEN OF FIG. 27, SHOWING ATTACK AND REMOVAL OF NON-METALLICS BY THE GAS REACTION; ×250

After reheating in air to a temperature which confers ductility upon normal rail steel, the specimen was fractured through the crack, just as the boiler plate was fractured. The same three zones were visible, as may be seen in Fig. 29, though their disposition is considerably different, in accordance with the different conditions. Note the thin fibrous rim around the specimen, which is always present in hydrogen-embrittled specimens because the hydrogen cannot be held under embrittling pressure so near to the surface for any appreciable period of time. Then there is the shiny, brittle zone, and next the zone of chemical attack, this time from oxidation during the heating in air. The hydrogen embrittlement, then, enabled both the cracking from the superimposed thermal stress and the subsequent chemical attack.

Micrographic study of the boiler plate in Fig. 27 further confirms the statements which have been made. In the corroded zone *C*, penetration principally along grain boundaries is easy to find. Near the crack, all fissures lead plainly to the surface, and all are filled with corrosion product. Deeper in the metal, the cracks cannot be followed to the surface. Because they are likewise filled with corrosion product, the surmise is well made that they do connect with the surface but that the two-dimensional section does not reveal it. Also, deeper in the metal under zone *C*, the corrosion product is neater, taking on a smooth, gray appearance resembling iron oxide. It is likely that water vapor—steam—penetrates these finer fissures ahead of the liquid. These features may be seen in Fig. 30.

In the hydrogen-embrittled zone *B*, the removal of nonmetallics is everywhere evident, just as was plainly observed in a macro-study of the untouched fracture. Empty holes betray the former presence of inclusions; but there is no trace of chemical corrosion. The action is quite the opposite, in that the metal is purified, and empty holes remain empty. The corrodant definitely has not reached the hydrogen-embrittled zone which is seen to lie in front of the zone of chemical attack.

No attack of the carbide is visible, in contrast to the specimens attacked by hydrogen at higher temperatures. However, C is only one of the nonmetallics which may serve as a basis for gas embrittlement, and reason has already been given for suspecting O in preference to C for boiler embrittlement. The English investigators found visible decarburization in boiler plate subjected to caustic embrittlement at temperatures above those of usual boiler service; and decarburization in high-pressure boilers has already been mentioned. At the temperatures of ordinary

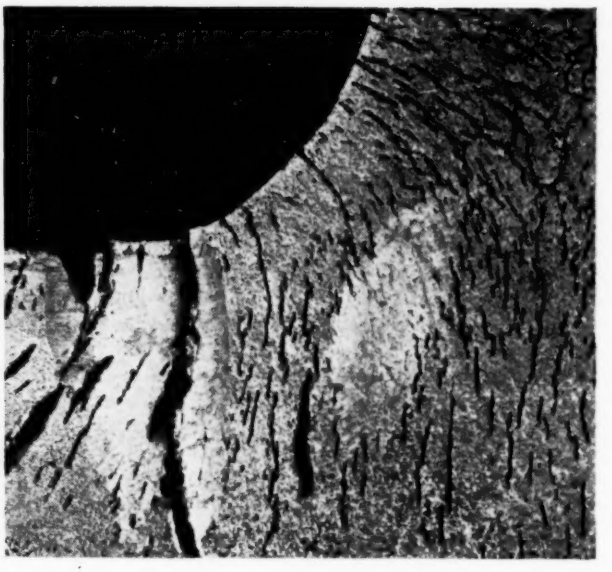

FIG. 32 APPARENTLY SOUND BOILER PLATE AFTER DEEP-ETCHING; COMPARE WITH FIGS. 24 TO 26

boiler service, another equilibrium than that of C-Fe-H may well predominate. Again, the embrittlement is likely due to an accumulation of several gases.

On the other hand, one must recognize that outright visible removal of carbon need not be a prerequisite for embrittlement. The conversion of a gas, such as methane, from a solid state, such as iron containing carbide and dissolved hydrogen, demands a volume increase of roughly 5000 times for 1 atm pressure and at boiler temperatures. If the reaction takes place within the solid, in the absence of a fortuitous cavity, its formation immediately imposes upon the surrounding metal a compression of approximately 75,000 psi, which can account for embrittlement without further ado. The equations already discussed, with their monstrous values for potential methane pressures, clearly indicate that a mere 75,000 psi will do nothing to reverse or discourage the reaction.

FIG. 33 FRACTURE OF CENTRAL PLATE IN A THREE-PLY BOILER SHOWING A BRITTLE ZONE ADVANCING FROM BOTH SIDES WITH A DUCTILE ZONE IN BETWEEN

(The central position of this plate has allowed solutions to concentrate on both sides, with resultant hydrogen attack proceeding from two directions toward the center.)

Nor would the amount of carbide lost by this efficacious reaction necessarily be visible under the microscope. Visible decarburization represents removal of the carbon from the steel, which *follows* embrittlement and,

FIG. 34 MICROGRAPH OF BOILER STEEL EMBRITTLED IN SCHROEDER'S EMBRITTLEMENT TEST
(Note definite presence of both inter- and transcrystalline fissures; ×300.)

consequently is in no way necessary for embrittlement. The higher temperatures of hydrogenation favor removal of the trapped gas, and decarburization becomes visible.

In ductile zone *A*, inclusions are only partly attacked, in agreement with earlier conclusions. In Fig. 31, a single micrograph shows two inclusions lying as close to the boundary of zones *A* and *B* as can be determined. Although it is almost too much to expect, the inclusion on the brittle side is completely removed, and the one on the ductile side is only partly removed. Each is typical of the zone on its side, and no point will be made over the surprising proximity of these two cases. The important thing to note is that the inclusions, and material in the rolling seams, have been attacked and largely removed by the gas reaction, as was surmised from macroscopic observation in the stereograph. The absence of visible decarburization again points to oxygen and oxides as being particularly vulnerable to the conditions for boiler embrittlement. The nature of the crack running from each inclusion out to the fractured face is not clearly understood, but may indicate either brittleness at the time of fracture, or previous rupture caused by the trapped gases. The specimen, incidentally, was polished with care to retain all nonmetallics, though it was perfectly clear from macroscopic observation of the freshly fractured face that zone *B*, and zone *A* to some extent, contained only vacuous pores where nonmetallics formerly were.

In Figs. 24 to 26, the accelerated attack of hydrogen-embrittled metal was demonstrated, and the opinion was advanced that grain-boundary gases should do the same. A section of the boiler plate submitted by Schroeder and Berk was accordingly deep-etched, with the result shown in Fig. 32. The mass of fissures was visible only after the etch treatment, which certainly suggests a close analogy with the action shown in Figs. 24 to 26.

That plate, which happened to be the center strake of a three-ply boiler, was fractured through a visible crack, with the interesting results shown in Fig. 33. In its central position, concentration of the solution could occur on both sides. Consequently, there are two brittle *B* zones, one proceeding from each side of the plate. In between is the ductile *A* zone not yet overrun. The action is plainly stronger on one side than on the other, corrosion being rather limited to the side having the principal concentration of chemicals.

Micrographic study revealed similar conditions to those in the other specimen.

Schroeder and Berk also submitted some boiler plate which had been cracked in synthetic solutions containing 500 ppm of NaOH. Micrographic examination of those specimens revealed a typical example of combined intercrystalline and transcrystalline failure. An example is shown in Fig. 34. In their rigorous, short-time tests does it not now seem reasonable that the compound gases causing intergranular failure should lag and transgranular failure from elemental hydrogen should correspondingly be favored? No further comment should be necessary regarding the balance of gas reactions and its relationship to the failure shown in Fig. 34.

CONCLUSION

A Concise Definition of "Boiler Embrittlement." This preliminary study now affords a new conception of the phenomenon known as "boiler embrittlement," a conception which can be simply stated as follows:

"*Boiler embrittlement is nothing other than an intermediate stage in a naturally occurring hydrogen purification treatment.*"

Thus, one begins with a boiler made of steel, which is the element iron containing certain nonmetallic impurities then:

1 The steam-iron reaction, which is enabled to progress more or less continuously, depending upon various factors, at loci where a caustic solution has concentrated, provides a more or less continuous infiltration of hydrogen through that steel.

2 The hydrogen reacts with the nonmetallics to form gaseous products within the steel.

3 These gases accumulate under pressure within the grain boundaries and at other seats of the nonmetallics until their pressure exceeds the cohesive strength of the grains and the granular structure is stressed to disruption.

That condition is recognized as "boiler embrittlement," and a stress applied to such metal may cause it to crack. The process, if allowed to continue, would then follow these well-established steps in the purification of steel by hydrogen at elevated temperatures:

4 Disruption of the grains extends communication of the gaseous accumulations until a portion escapes into the atmosphere, constituting the first actual removal of nonmetallics and incepting actual purification.

5 That degassing continues until the reactions are complete and insufficient gas remains to force itself through the structure out to the surface.

The material is then no longer steel, but is purified iron containing a small amount of residual gases. Embrittlement has vanished.

Direction and Aims of Future Research. As stated in the introduction as an opening premise, the present paper does not purport to provide a preventative of boiler embrittlement. Instead, it has attempted to interpret the work that has been done to date to show that a rational picture can be developed upon the new basis. With such an understanding, however, the battle is half won.

Simply stated, future research need have only two phases, one concerning a metallurgical study of steel to find an inexpensive

boiler plate for future boilers that will be relatively immune to hydrogen embrittlement from caustic attack, and the other concerning a chemico-metallurgical study of the role of inhibitors and accelerators in controlling hydrogen absorption so that the life of present boilers may be extended.

Both studies would be comparatively simple; and both promise extravagant results, because so little has as yet been done in direct relation to boilers, and yet from related fields a wealth of information is available.

Acknowledgment

Acknowledgment is made to Battelle Memorial Institute for the support of this work as part of its program for fundamental research; to K. G. Jones and H. L. Maxwell of E. I. du Pont de Nemours and Company, and to J. S. Vanick and the Chemical Construction Company of New York City, for their generous cooperation in submitting samples of deteriorated steel from chambers for hydrogenation and ammonia synthesis; to W. C. Schroeder and A. A. Berk for their kindness in supplying embrittled boiler plate; to G. A. Moore, J. L. Yarne, J. A. Finley, and R. W. Tindula, for their co-operation in preparing the metallographic specimens; and to C. E. Sims, under whose valuable supervision this work was conducted.

Discussion

W. C. SCHROEDER[8] AND A. A. BERK.[9] The author is to be congratulated on the very large amount of data he has accumulated for his paper. Part of this information describes the two known effects of hydrogen on steel. Stated briefly these are as follows:

1 Hydrogen may enter or be trapped in steel at temperatures below the atmospheric boiling point of water to cause serious losses of impact strength. Fractures resulting from this brittleness are transcrystalline.

2 Hydrogen, under high pressure, at temperatures considerably above those at which riveted boilers operate will enter and decarburize steel, causing intergranular fissures to develop. At higher temperatures (1000 F), and a hydrogen pressure of 5000 psi, there is also a tendency for the inclusions in the steel to be reduced.

In contrast to the action of hydrogen at room temperatures and at very high temperatures, no intergranular fissure due to this gas has ever been reported to take place at temperatures from 250 to 460 F (15 to 480 psi), which includes the entire range in which embrittlement failures have occurred in boilers. This is particularly evident in the paper under discussion; for despite the very extensive bibliography, there are no illustrations or discussion of failures produced by hydrogen gas in the temperature range in which boiler embrittlement occurs. The author, nevertheless, postulates that such failures could occur by the following mechanism:

1 Boiler water concentrates by extreme evaporation in the boiler seams.

2 The strongly caustic solutions then react with boiler steel to form iron oxide and hydrogen.

3 The hydrogen enters the steel and reacts with carbides, oxides, sulphides, phosphides, and nitrides to form the corresponding hydrogen compounds.

4 The hydrides are not soluble in the grains, so that they congest in the grain boundaries, causing internal stress and fissures.

5 If the metal is externally stressed at the same time, it will crack when the load-carrying ability is sufficiently reduced by the fissures.

6 The crack allows the caustic solutions to penetrate and further corrosion and cracking follow.

Discussion of Proposed Mechanism. Let us examine and critically review each of the major items upon which this postulated mechanism is based. Step 1 relates to the accepted concept of formation of aggressive solutions from dilute boiler water and forms the basis of all modern thought concerning the incidence of intercrystalline cracking. The manner in which concentration occurs is not treated by the author.

Step 2 indicates that steel is attacked by the concentrated caustic solution. However, the author has misinterpreted Stromeyer's experiments to imply that caustic must act indirectly through hydrogen, because it seemed to operate on metal removed from the solution by $^1/_4$ in. of steel. Actually, in all of the embrittlement cracking that has been reported (including Stromeyer's tests) or that the discussers have examined, the failure can be shown to have been started at a metal surface in direct contact with a concentrated solution. This is true both of failures in boiler seams and the failure of specimens in embrittlement detectors. There is therefore no necessity to postulate an agency that can start cracks or fissures from within the metal.

If the postulated agency does tend to produce cracks or fissures from within the metal, it acts in a manner not in accord with known facts. Numerous sections of embrittled boiler seams have been examined microscopically and no such fissures have been found. Cracks that appeared to start and end in the heart of a two-dimensional plane were always traceable in the third dimension to the surface in contact with concentrated solution.

Step 3 demands the reaction of hydrogen in the steel with oxides, carbides, sulphides, phosphides, and nitrides to form corresponding hydrogen compounds. The experimental work cited to support this statement has been reviewed by the discussers. The original papers disclose that Whiteley (130),*

[8] Bureau of Mines, Washington, D. C. Mem. A.S.M.E.

[9] Bureau of Mines, Washington, D. C.

* Numbers in parentheses refer to the Bibliography at the end of the author's paper.

working at 1600 F, checked the results of Le Chatelier and found that hydrogen reduced iron oxide to only a slight depth in solid iron. Baukloh (304) found that while iron sulphide is affected by hydrogen above 750 F, manganese sulphide (the principal sulphur compound present in steel) is stable to 1800 F. Naumann (329) found that under circumstances producing decarburization (4000 psi hydrogen and 650–750 F), hydrogen is not able to remove phosphorus, sulphur, and oxygen. Zapffe and Moore (423), attempting to purify samples of steel with hydrogen at 1800 F found that carbon was readily removed but that oxygen, sulphur, nitrogen, and phosphorus were not removed even after 16-day treatments. This evidence does not support a belief that hydrogen will reduce the impurities in boiler-seam steel to form hydrides, for the temperatures at which these reactions proceed are far above those found in boilers.

The author, in an attempt to show through extrapolated equilibrium data that hydrogen would readily react with inclusions of magnetic oxide at boiler temperatures, made the error of confusing chemical kinetics with chemical equilibrium. What he has shown is that there is slight possibility for oxide to be reduced with the simultaneous formation of water vapor in the temperature range (250–480 F) in which boiler embrittlement occurs.

That the attainment of high pressures of hydrogen in steel at boiler temperatures is most improbable can be shown through calculations based on known diffusion constants. If the boiler steel were being corroded at the very rapid rate of $^1/_{32}$ in. per year, 130 cu in. of hydrogen (measured at standard conditions of temperature and pressure) would be generated per square inch of surface affected. If all of the gas were to enter and be trapped in the steel at 390 F, the rate at which hydrogen was being supplied would be 0.015 cu in. per sq in. of surface per hr. Possibly hydrogen can collect in a rift, cavity, or boundary at this rate. The pressure that would force the gas to leave the cavity by diffusion at the same rate can be calculated from data supplied by many investigators. The experiments of Smithells and Ransley[10] show that molecular hydrogen will diffuse from a cavity at the rate of 0.015 cu in. per sq in. per hr when the pressure is less than 400 psi. The results of experiments by Borelius and Lindblom,[11] by Ham (325), and by Ryder[12] provide figures of the same magnitude. A series of experiments by Naumann[13] also show that a pressure of 500 psi of molecular hydrogen will not only cause the gas to diffuse from a cavity quite rapidly but will cause 0.015 cu in. per sq in. per hr to diffuse through 0.2 in. of standard mild steel. Therefore the hydrogen pressure that may result in the steel of a boiler seam at 390 F cannot be very great.

The fact that boiler material embrittles without evidence of decarburization is shown by Fig. 35 of this discussion. This figure shows a crack in a boiler operated for a period of 9 years at 450 F. There is no evidence of decarburization or hydrogen purification. In contrast, the hydrogen attack that results in intercrystalline cracking is always preceded by decarburization.

Step 4 of the mechanism provides that the hydrides formed during the reduction of inclusions be rejected to the boundaries of the grain because they are insoluble in the grain. If they are not soluble and cannot diffuse in the grain it is difficult to understand why they do not remain in the cavity in which they are supposedly formed. Of course, if they happened to be formed between the grains they would presumably remain there.

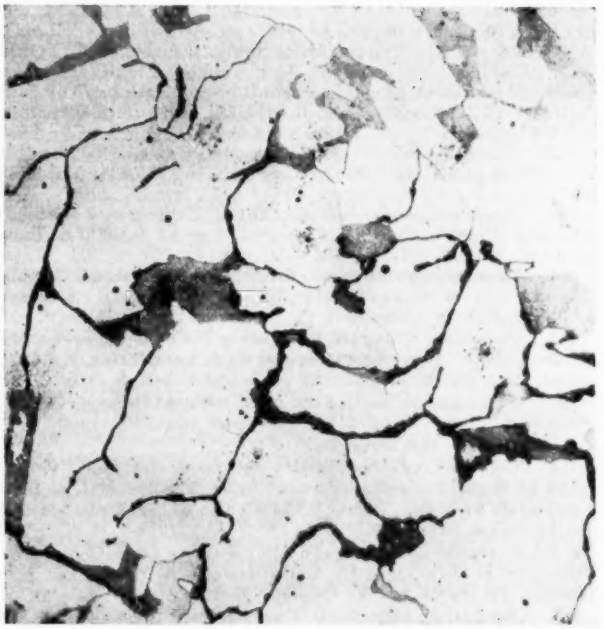

FIG. 35 NO DECARBURIZATION SHOWN IN CRACK IN SEAM OF BOILER OPERATED AT 480 F FOR 9 YEARS
(Surface etched with nital; ×300.)

Step 5 of the theory of cracking as developed in the paper makes it necessary to have not only high temperatures but high pressures of hydrogen or other insoluble gaseous products as well. The combined conditions of high temperature and pressure are believed to cause fissures and loss of load-carrying ability in the steel. The evidence to support this belief is drawn from experiments at much higher temperatures than those at which embrittlement has been encountered in boilers. For example, Naumann (329), working with a hydrogen pressure of 13,000 psi, did not attain fissures or cracking during a test of 2000 hr at temperatures below 480 F. Vanick (203) did not find fissuring below 570 F. Desch (396) still obtained intercrystalline cracks when the temperature was lowered to 570 F, but no cracks were found even after a month at 435 F. Inglis and Andrews (262) found that over 2 years of hydrogen service at 3500 psi and 410 F did not greatly affect the strength of a coarse-grained mild-steel tubing, although all the pearlite areas were slightly decarburized. A fine-grained tube of the same composition was not even decarburized by a year of service at 480 F and 3500 psi of hydrogen.

In contrast with the lack of effect of hydrogen at temperatures below 450 F even over very long periods, repeated experiments have shown that embrittlement can be produced in a few hours at 230 F by concentrated caustic solutions boiling under atmospheric pressure. This difference between the action of hydrogen and the action of caustic is supported by the paper; for, in spite of the search of the literature, there is no evidence of hydrogen cracking at the temperatures in which boiler embrittlement occurs, although a great many industries use hydrogen, or obtain the gas as a by-product, in steel containers at temperatures corresponding to those in boiler operation.

Fig. 27 of the paper is advanced as visual proof of the hydrogen theory of cracking. The gray fracture of normal ductile metal comprises the zone farthest removed from the concentrated caustic solution. The corroded zone was obviously affected by penetration of the solution. In between is a bright, clean, brittle

area. It is inferred that this latter zone is affected by hydrogen, but the corroding liquors had not penetrated to it. Photomicrographs of the three areas are described as proving that hydrogen preceded the corroding agent and did most of the damage. However, no decarburization and no fissuring are evident in any zone although Fig. 31 shows that cracking had penetrated even the gray area. There is no apparent reduction of inclusions in the corroded zone, which indicates either that not enough hydrogen was present to produce any appreciable results on the metal or that the temperature itself was too low to allow it to produce any effect.

If the three distinct areas were not formed by hydrogen, how were they formed? Fig. 36 of this discussion shows a section of boiler plate, which was cut to produce a line of concentrated stress on the surface and was finally broken by impact with a hammer. Again there are three zones in the metal. Obviously none of them is corroded by a caustic solution since neither solution nor hydrogen was present. The example simply shows that three zones can be produced by impact and that any long discussion of what they mean is apt to lead to false conclusions. The characteristics of the surface are more likely to be determined by the way and the rate at which the steel is fractured than by any illusory internal conditions.

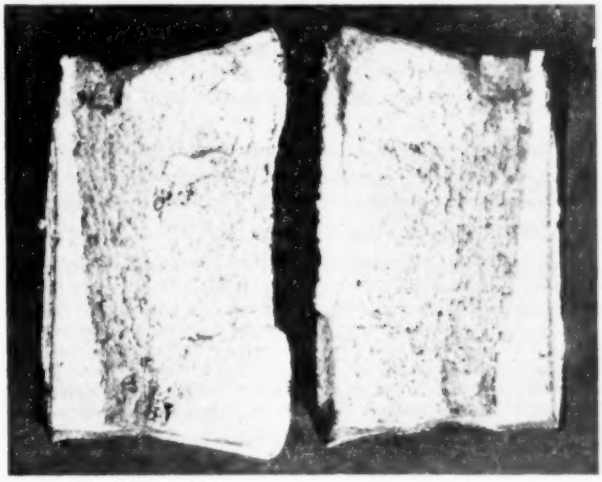

FIG. 36 BOILER PLATE, MILLED AND CRACKED BY SUCCESSIVE IMPACTS

Step 6 completes the author's theory, providing for propagation of the crack through the action of sodium-hydroxide solutions on the newly exposed surfaces. Again the supposition is that a series of fissures are formed through the action of hydrogen on inclusions in the steel and that the fissures are joined to the surface by a crack when the stress exceeds the load-carrying ability of the remaining metal. No such fissure has ever been observed in embrittled boiler seams. It is also interesting to observe that propagation is supposed to take place along grain boundaries, although a piece of steel broken in tension at these temperatures will always break along slip lines in the grains. At the higher temperatures of the ammonia-synthesis and hydrogenation processes from which the author draws his parallel, it is well known that the tensile strength at the boundaries tends to approach that within the grains, permitting the familiar pattern by which the fissures are joined.

This paper points out that certain steels have been developed which will resist the reducing and fissuring action of hydrogen gas. If there is any relationship between hydrogen attack and boiler embrittlement, it would then be expected that these same steels would also be resistant to boiler embrittlement. In the past few months, the discussers have had the opportunity to test steels containing manganese, chromium, and molybdenum of alloy contents which, according to Naumann (346) would greatly increase their resistance to attack by hydrogen. All of these steels were rapidly cracked in the embrittlement detector, and some were found to be particularly susceptible to the action of the caustic solutions. For example, Fig. 37 of this discussion shows a crack in a badly shattered specimen of alloy steel containing 5 per cent chromium and 1.5 per cent silicon. These results do not support the belief that hydrogen is a major factor in the cause of boiler embrittlement. At the same time, they indicate that results from testing with hydrogen gas cannot be interpreted in terms of boiler embrittlement without danger of reaching erroneous conclusions.

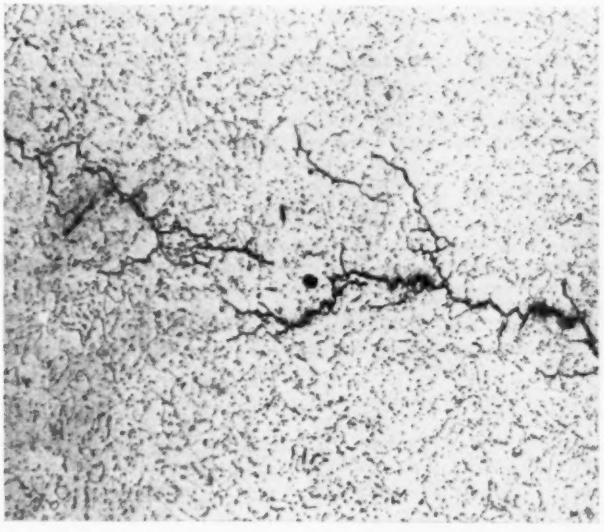

FIG. 37 INTERCRYSTALLINE CRACK IN EMBRITTLEMENT-DETECTOR-TEST SPECIMEN OF ALLOY STEEL CONTAINING 5 PER CENT CHROMIUM AND 1.5 PER CENT SILICON
(Surface etched with nital; ×300.)

Work of Other Investigators. In some instances, important references in the paper seem to have been interpreted improperly. Norton's experiments (377), for example, are cited to prove that sodium silicate, which sometimes accelerates boiler embrittlement, also accelerates hydrogen absorption.

Norton painted the outer surface of a steel radio tube with sodium silicate and measured the quantity of hydrogen penetrating to the interior when the tube was heated. He found that silicate-retained water reacted with the steel tube surface at the comparatively high temperature of 390 F. The experiment in no way measured the action of silicate on hydrogen penetration but instead measured its effect in retaining water at a high enough temperature so that a fairly rapid release of hydrogen could take place.

It is also noted that the work at the Bureau of Mines proved that sodium silicate was an accelerator of embrittlement while the work by Desch (396) in England stated that intercrystalline cracking could be produced in the absence of this salt. If the work at the Bureau of Mines is fully examined, it will be found that it does not disagree with the work in England. In the bulletin (398), cited by the author, appear the following statements:[14]

1 Under certain conditions sodium hydroxide alone can produce

[14] Reference (398), p. 45.

intercrystalline cracking. (See last two U-bend tests in Table 1, and detector tests 51, 29, and 45 in Table 9.)

2 Sodium silicate, especially the crystalline metasilicate, may accelerate cracking in some instances or broaden the range of conditions under which it occurs in others.

3 The effect of the silica in accelerating cracking appears to be more pronounced at 225 C and above than at lower temperatures.

4 The effect of the silica in accelerating cracking depends on the concentration of sodium hydroxide in contact with the steel. At high concentrations (especially at the higher temperatures) this latter material may attack so vigorously that general over-all corrosion proceeds as rapidly as grain-boundary corrosion. The addition of sodium silicate can suppress the over-all corrosion but still allow penetration at the boundaries. The influence of this salt in repressing over-all corrosion has already been illustrated.

5 The effect of silica on intercrystalline cracking depends on the applied or internal stress acting during the test. At the higher stresses any influence of the silica may be difficult to detect.

6 The influence of the silica depends on the physical and chemical characteristics of the steel being tested. On steels very susceptible to embrittlement (especially certain low-alloy steels) it is unnecessary to use this compound to produce cracking. On steels difficult to embrittle the silicate often appears to exert an accelerating effect.

7 At the lower boiler temperatures, certain types of sodium silicate may sometimes retard instead of accelerate intercrystalline cracking.

Particular attention should be directed to items 1 and 7 in this list since these show that Desch and the conditions of his test agree with those of the discussers. It is apparent that the action of the silicate is complex and that any attempt to treat it in too simple terms may lead to false conclusions.

The author's paper calls particular attention to the fact that tests with sodium nitrate are irrelevant in relationship to boiler embrittlement. He also feels that this salt ordinarily is not present in boiler water. It is now known that this belief is in error and simply existed because determinations of nitrate seldom are made in boiler-water analyses. Recent work has shown that high concentrations of sodium nitrate are present in a considerable number of boiler waters.

An interesting side light, concerning the comparison of cracking produced in sodium-nitrate solutions and caustic solutions is the development of the somewhat embrittlement-resisting Izett steel. The tests by which this steel was shown to be more resistant to intercrystalline cracking depended on the use of concentrated sodium-nitrate solutions. It is peculiar that this steel also exhibits increased resistance to caustic embrittlement if there is no relationship between action of the nitrate and the caustic solutions as postulated by the author.

The author in discussing the smooth, adherent, black-oxide scale that generally coats embrittled boiler seams states that these must "be distinguished sharply from the highly localized accumulations one must expect from selective corrosion, as required by the theory of Schroeder and his colleagues." The following quotations from the Bureau of Mines bulletin (398) may perhaps help to explain the term "selective corrosion:"

> If the solutions indicated in Table 2 produce intercrystalline penetration without extensive over-all corrosion of the crystal faces, it should be possible to observe the progress of this selective activity. For this purpose, a specimen was polished for microscopic examination and bent over a bar in the center by means of bolts at the ends, as shown in figure 15. When the specimen was immersed in a boiling sodium hydroxide-lead oxide solution for 1 or 2 days a deep crack developed, as shown in figure 16. If, however, it was removed from the boiling solution after 2 or 3 hours it was found covered with a thin film of oxide. Under the microscope this film, which was blue to the naked eye, appeared gray, as illustrated in figure 17. The fine slip lines apparent in most of the crystals result, of course, from bending of the specimen to create stress. After this blue or gray film has formed, if the specimen is again immersed in the boiling solution for several hours rather broad white lines appear that outline the approximate position of the grain boundaries. These can be seen in figure 17. With further boiling, short, black lines appear in the broader white ones, which ultimately merge to form distinct cracks, as shown in the figure.
>
> These experiments illustrate that development of the initial intercrystalline fissure is not a sudden or instantaneous process. Its growth can be followed over a considerable period. This type of initial attack would be expected from a selective corrosion process.
>
> The silica, under certain conditions at high temperatures, and the oxidizing agents, in the U-bend tests at lower temperatures, probably function in a similar manner to accelerate the cracking: that is, they protect the crystal faces and prevent over-all corrosion while leaving the grain boundaries open to attack. The films they establish on the crystals may also create electrochemical forces that intensify action at the boundaries.

It is also of interest to note that corrosion in solutions starts at grain boundaries[15] but generally quickly spreads so that the over-all corrosion obscures the selective action.

Course of Embrittlement Investigations in the United States. A careful study of the literature, both with respect to boiler embrittlement and hydrogen embrittlement, has often led to the belief that the actions are related or may be identical. This was true in the studies undertaken by Parr and Straub, for their first paper expressed the belief that hydrogen gas was the primary factor in boiler embrittlement. It was not until they had completed many years of study on the subject that they abandoned this concept.

At the start of their investigation, Partridge and Schroeder made a survey of the literature which covered much of the ground now reviewed by the author. Their conclusions contained the following statement:

> A thoroughly logical picture of the way in which the failure of boiler steel may be caused by hydrogen embrittlement may be built up on the basis of the information discussed in this report. When a boiler goes into operation its internal surfaces are immediately covered with a layer of magnetic oxide. This layer under ordinary conditions forms an almost impassable barrier between the boiler water and the steel. As the concentration of hydroxide increases, however, the layer becomes progressively less protective, and the reaction between the water and the steel increases its rate.
>
> This chemical reaction produces hydrogen under condition equivalent to an extremely high gas pressure. The hydrogen diffuses into the steel and causes a definitely brittle condition, probably by setting up internal stresses at grain boundaries and cleavage planes.
>
> Although the steel may be rendered very brittle by the absorption of hydrogen, no serious permanent damage is done until a localized stress at some point reaches a very high value, probably well up toward the ultimate strength of the metal. A piece of normally ductile steel subjected to a high local stress of this sort would yield slightly, automatically reducing the local stress by distributing it over a large section of metal. The embrittled steel, however, instead of gliding along slip planes in the manner of ductile metal, will ultimately crack at the point of high local stress. Although the initial failure may be only the boundary between two grains in the outermost surface layer, it represents a permanent damage to the steel. The high local stress, instead of being reduced in intensity, may then be transmitted to the next layer, with the result that the failure is eventually repeated here. As long as the concentration of hydrogen in the steel is sufficient to cause failure, the process of cracking will continue.

With this belief as a background, experiments were specifically designed to show that hydrogen was one of the primary factors in boiler embrittlement. Each of these experiments gave results in disagreement with preconceived ideas until, after an investigation of about 6 years, the conclusion was inescapable that the theory based on the action of hydrogen gas and developed through a study of the literature was incorrect. In fact, as the experiments were carried further, it was evident that some of the early interpretations of the work in the literature must necessarily be revised to quite different conclusions.

A brief description of one series of such experiments may be of interest. Fig. 38 of this discussion illustrates a piece of equip-

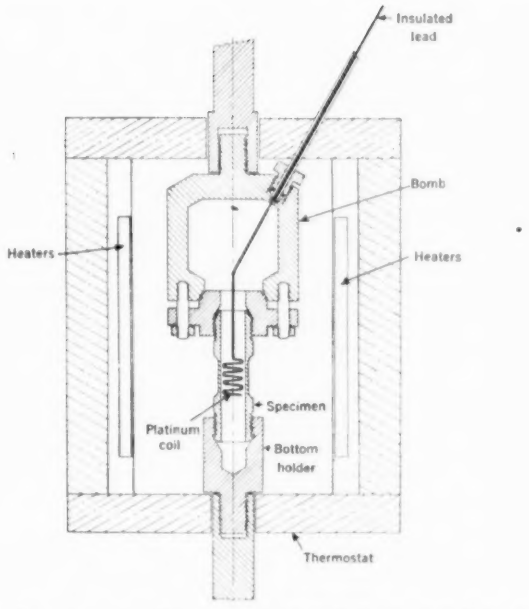

FIG. 38 EQUIPMENT FOR TESTING ACTION OF HYDROGEN AT ROOM OR ELEVATED TEMPERATURE

ment that was used at the Bureau of Mines to study the action of hydrogen gas on stressed steel. Hydrogen was released electrolytically at the surface of the specimen. When the apparatus was tested at room temperature it was found that the gas pressure rose to 1200 psi in 48 hr. The test specimen was then stressed to failure. The very brittle fracture that resulted indicated that the electrode was located satisfactorily with respect to the reduced section of the specimen.

Five specimens were then exposed to hydrogen attack at 250 C (482 F) for periods up to 122 hr. All specimens were stressed at about 50,000 psi during the tests, but no failures resulted. Each specimen was stressed to failure to complete the tests; in no case was any loss of load-carrying ability noted. There was some brittleness in the metal as would be expected from exposure under stress in the blue-brittle temperature region, but the fractures were much less brittle than that produced during the low-temperature test. A caustic solution in the same equipment produced failure in the specimen in 4 to 12 hr. The temperature for the latter tests was 250 C; the load on the test specimen was 50,000 psi; and no hydrogen was generated.

The author may now be in much the same position as were the investigators of the University of Illinois and the Bureau of Mines when they started their studies. Possibly through prolonged experimentation he, too, would revise his ideas and reach the conclusion that hydrogen was not as important as he now thinks it to be. His evident interest in the study of embrittlement, as shown by the large amount of work in the compilation of his bibliography, would certainly justify support for such work as he may wish to undertake. It is, of course, unfortunate that his bibliography does not refer to the important work on selective corrosion of Ulick Evans[16] in England, and Dix,[17] and Mears and Brown[18] at the research laboratory of the Aluminum Company of America.

Since previous investigators have been forced to discard the hydrogen-embrittlement theory, it might be best to undertake further investigation along this line without attempting to justify or prove preconceived ideas developed through literature study. A thoroughgoing investigation which gave equal credence, at least at the beginning, to all of the theories developed to explain boiler embrittlement would be very desirable. Careful experimental study of each of these would allow the investigators to reach conclusions that would be sound. The conclusions would be backed by a set of unprejudiced observations and would carry conviction to the people responsible for boiler operation.

In conclusion, it should be noted that boiler operators in the United States, working in close co-operation with research engineers, have found practical methods of preventing embrittlement cracking of boiler seams. These solutions of the problem have been achieved principally by tests with the embrittlement detector, which directly determines whether a boiler water can or cannot cause cracking. Although theoretical explanations are of considerable interest with relation to complete understanding of causes and effects, practical answers fortunately do not have to await their elucidation. For example, the sodium-nitrate treatment on the Chesapeake & Ohio Railway has effected a decrease in locomotive-boiler cracking, corresponding to a saving of more than 90 per cent of the engine time lost and the material and man-hours required for repair work. Under the present war conditions of transportation, this is indeed fortunate.

THOMAS DE VRIES.[19] There is additional evidence to substantiate the argument of the author that the diffusion of atomic hydrogen into steel is at the basis of the embrittlement phenomena. As early as 1864, Cailletet found that iron absorbed some hydrogen liberated by electrolysis. It has been known for a long time that iron is embrittled in pickling solutions by the hydrogen liberated in the reaction. The work of Bodenstein (153) and others has shown that atomic hydrogen permeates into the steel since the rate of permeation was proportional to the square root of the current density.

Borelius and Lindblom[20] have found a similar result for hydrogen produced by electrolysis. They also studied the permeation of molecular hydrogen into steel at different temperatures and pressures. The rate increased markedly with temperature, approximately as the fifth power of the absolute temperature. The rate also increased with the square root of the pressure thus proving definitely that the hydrogen must be in the atomic state before diffusion can occur.

Post and Ham,[21] investigating the permeation rate-pressure isotherms for hydrogen into nickel, found deviations from the square-root-of-pressure law, which they ascribed to the fact that some of the hydrogen was reacting with impurities in the nickel.

The author refers to Schenck for equilibrium constants for the reaction $Fe_3C + 2H_2 = 3Fe + CH_4$. Since Schenck's data were scattered and did not permit of very definite calculations, reference should be made to Watase,[22] whose data were critically examined by Kelley.[23] From his data for the interval 600–800 deg

K, the equilibrium constant is given by $\log K = -5937/T + 6.836$, whereas the author used the equation $\log K = -7990/T + 8.75$. Fortunately, the difference in the logarithm of the equilibrium constants (—2.69 and —4.07, respectively, at 350 C) calculated by the two equations is not sufficient to modify the author's argument.

However, it should be realized that the simple equation of Schenck is not suitable for extrapolation to higher temperatures and that this should be considered in any argument concerning decarburization. From the equation given by Kelley it can be calculated that the equilibrium constant, $K = (P_{H_2})^2/P_{CH_4}$, is 1.3×10^{-6} at 375 F (190 C), but 1.15 at 1100 F (600 C). Thus intercrystalline decarburization can definitely occur better at lower temperatures than at very high temperatures. This has been the experience of Potter, Solberg, and Hawkins (330).

R. B. MEARS.[24] This paper on boiler embrittlement is a valuable contribution to our knowledge on this subject.

In the paper, several theories of boiler embrittlement and other forms of stress corrosion cracking are described. However, we do not believe that the author has discussed one of the most probable explanations for stress corrosion cracking. As was pointed out by Dix,[25] stress corrosion cracking is often the result of selective attack caused by local potential differences between different portions of the metal or alloy surface. In many cases such potential differences exist between material adjacent to the grain boundaries and the matrix of the grain. In other cases potential differences can exist between slip planes or other metallurgical characteristics of the material and a grain matrix. As a result of these potential differences, the anodic areas suffer electrolytic corrosion and, if the material is under stress, selective attack can cause cracking of the material in a relatively short period of exposure. It has been well established that this is the mechanism of the stress corrosion cracking of the aluminum-base alloys containing copper (Duralumin-type alloys), and it appears to be responsible for the season cracking of brass also.[26]

Furthermore, there is a good indication that the same mechanism applies to the stress corrosion cracking of 18–8 stainless steel.[27] It seems quite possible that the mechanism of boiler embrittlement is also an electrochemical phenomenon of this same type, local differences in potential causing selective attack at certain planes in the metal. Cracking will then occur along these planes.

It has been found in the case of nonferrous alloys that stress corrosion cracking may, in the early stages, follow an intergranular path and then later the metal may fracture transgranularly. Thus, there often exists some confusion of the path of the fracture, since it may start out following grain boundaries and then later on cut through grains themselves. Evidently this same confusion has existed in the case of boiler embrittlement. In any event, whether or not the mechanism of boiler embrittlement is indeed electrochemical, as is the case with many other types of stress corrosion cracking, the electrochemical mechanism of stress corrosion cracking should be mentioned in an extensive review, such as this one by the author.

The stress corrosion cracking of many types of nonferrous materials can be prevented by cathodic protection. The article to be protected is made the cathode, and current is passed to it through the electrolyte from a sacrificial anode. It would seem that a test involving cathodic protection could well be used to examine the hydrogen mechanism of boiler embrittlement. If a boiler steel which cracks readily in the absence of cathodic protection does not crack under the same conditions when it is being cathodically protected, there would appear to be no justification for the hydrogen theory, since during cathodic protection atomic hydrogen is being deposited on the surface of the steel and so should actually accelerate cracking, if the hydrogen theory is correct. We suggest that this experiment should be performed as soon as possible in order to test out the hydrogen mechanism.

The author mentions that the season cracking of brass remains unsolved. We do not believe this statement is correct. Instead there is very conclusive evidence that the season cracking of brass is an electrochemical phenomenon, and actual potential differences between grains and grain boundaries in brass have been measured in solutions which cause season cracking.

The author discusses at some length the results of other workers where occasionally one chemical is found to be an inhibitor of boiler embrittlement under some conditions but a stimulator under others. This type of action is not at all unusual for corrosion inhibitors. In fact, it is the general rule. Most corrosion inhibitors with which this writer is familiar accelerate corrosion under some conditions and retard it under others. In general, inhibitors can localize attack and therefore very often stimulate selective attack which causes intergranular corrosion or stress corrosion cracking. In many cases, very small or very large amounts of an inhibitor will be distinctly beneficial while intermediate amounts will be harmful. An explanation for this behavior can often be obtained from electrochemical measurements, and the mechanism of inhibitor action appears to line up with its effect on the anode and cathode reactions.

In studying the stress corrosion cracking of nonferrous materials, it has been found necessary to investigate the matter on a statistical basis. If a large number of "identical" specimens are exposed to a given corroding environment while under stress, a certain percentage of them only may be found to develop stress corrosion cracking. This percentage is often rather reproducible and may be used to express the probability of stress corrosion cracking of that particular alloy under those particular conditions. Slight changes in the composition of this alloy will affect the percentage of specimens which crack in the test.[28] A change in the nature of the corroding environment will shift the probability of stress-corrosion-cracking figures in one direction or another, so that they may approach either 0 or 100 per cent.

We suggest that in boiler-embrittlement studies it would be desirable to use a statistical picture also, since it seems probable that it will apply in this case as it has in the case of stress corrosion cracking of nonferrous materials.

E. P. PARTRIDGE.[29] Much that might have been presented as hypothesis or opinion by a less enthusiastic protagonist appears in this paper in the guise of indubitable fact. While a point-by-point debate would be as lengthy and as barren of result as the medieval argument over how many devils could dance on the point of a needle, the writer cannot forbear a token challenge on two representative passages.

In Part 3, the author refers to the 1941 Report on "Intercrystalline Cracking in Boiler Plate," by the National Physical Laboratory, England. As is natural, he has mentioned the emphasis placed by the British investigators upon hydrogen as the cause of embrittlement, even though the experiments were conducted at 420 and 470 C, far above the highest temperature, about 250 C, at which intergranular cracking has ever been observed in riveted boiler seams, and were characterized by de-

[29] Director of Research, Hall Laboratories, Inc., Pittsburgh, Pa.

carburization of the steel, which has never been found in actual cases. What the author neglected, in his zeal for the hydrogen theory, was what might be called the "minority report" from the National Physical Laboratory, which described the "oxidizing" type of cracking produced by very concentrated caustic solutions at temperatures more nearly representative of boiler conditions. The following statement appears in the British report: "Cracks of the hydrogen type were often found throughout the whole mass of a cold-worked specimen, while those of the oxidizing type existed in patches always in communication with the outer oxide coat." This latter condition more nearly resembles what is observed in actual cracked boiler plate than does the former.

The second item to be challenged is the discussion, also in Part 3 of the paper, relative to the development of high gas pressures in grain boundaries. The author calculates from the steam-iron equilibrium that very high pressures of hydrogen and fantastically high pressures of methane could develop in a closed boiler by reaction of the boiler water with the steel. He then postulates, however, that a grain boundary may be regarded as a "tiny theoretical boiler" in which the same high pressures previously calculated could develop as hydrogen, diffusing through the steel reduced magnetic iron oxide to produce water vapor.

Actually, the operating boiler is not a closed system, and the partial pressure of hydrogen both inside and outside of it is extremely low. Considering the steel for the moment simply as a solid permeable to hydrogen, the pressure of hydrogen at any point within the metal could scarcely exceed the very small pressure of hydrogen within the boiler, something of the order of 0.1 to 0.001 psi. According to the fundamental equilibrium indicated in Fig. 17, the pressure of water vapor developed in the grain boundary would then be almost vanishingly small.

To the extent that molecular H_2 diffuses less readily through the steel than does atomic H at any temperature, the development of higher gas pressures within the grain boundaries is possible. For example, it has been suggested by others that atomic hydrogen diffusing through steel may combine into molecular hydrogen at the discontinuity created by a grain boundary. Even so, the possible localized pressure, based upon data for the diffusion of molecular hydrogen through steel at boiler temperatures is very low in comparison with those suggested in the present paper.

The author should be given credit for a monumental bibliography, for some exceptional photomicrographs, and for his stimulating insistence that we re-examine our previous concepts concerning embrittlement. The importance of this paper really resides, however, in two suggestions which may be subjected to experiment. These are the predictions (*a*) that an inexpensive steel resistant to hydrogen embrittlement will likewise not be subject to cracking in boiler tube ends or riveted seams and (*b*) that inhibitors which will minimize the absorption of hydrogen by ordinary low-carbon steel will at least prolong its service life under embrittling conditions.

Fig. 15 of the paper, representing the work of Naumann, indicates that the addition of no more than 1 per cent of Ti, V, Zr, or Cb to low-carbon steel confers phenomenal stability against damage by hydrogen up to temperatures far beyond any attained in a boiler. If the author's thesis is correct, such low-alloy steels should not crack in the embrittlement detector devised by Schroeder and his associates when tested under conditions which cause rapid failure of low-carbon steel. Experiments in the detector seem to offer an obvious direct test which may forestall endless bickering over the minutiae of mechanisms by which embrittlement is produced.

P. B. Place.[30] The author presents a very interesting and persuasive argument for the role of hydrogen in boiler embrittlement, together with a rather disturbing vision of ultimate failure of all boiler steel. This paper will undoubtedly revive interest in a problem that has been solved several times but which refuses to stay solved.

Although there may be considerable evidence to indicate that a zone of hydrogen attack precedes chemical attack in many cases of intercrystalline failure, practical experience supports the conclusion of other investigators, that initial chemical attack is necessary. The progress toward failure after this initial attack is of more academic than practical interest.

There does not appear to be any appreciable danger due to attack of normal boiler water on the oxide-coated drum and tube surfaces. Boiler embrittlement has been significantly absent in boilers having welded seams and is usually associated with leaky riveted seams and cracks where chemical can concentrate to sufficient strength to attack the metal and its protective oxide film.

It would be pertinent to determine if excessive amounts of hydrogen accumulate in boilers held on bank for long periods, and particularly in boilers that use colloidal iron as an oxygen scavenger. If dangerous amounts of hydrogen are being generated in boilers, passing through drum shells, and reacting with nonmetallic inclusions to form high-pressure pockets in the steel, it seems logical to expect that the outer surfaces of the drum shells of old boilers would show evidence of blisters caused by rupture of pockets close to the outside surface.

The true mechanism of intercrystalline failure in boiler steel must be left in the hands of students of chemistry and metallurgy. In time, a mutually satisfactory explanation will be forthcoming. In the meantime, progress in welded construction, improvement in rolled joints, elimination of riveted seams, and further experience with inhibitors seem likely to reduce the embrittlement hazard to a minimum and eventually eliminate it as a boiler-operating problem.

D. H. Rowland.[31] In the writer's opinion, the author has made some rather positive statements in his paper considering the fact that he has offered very little irrefutable evidence to substantiate his claims.

Since the writer's knowledge of the subject of boiler embrittlement is general rather than specific, he hardly feels qualified to offer a discussion of the paper as a whole. Yet, from a purely metallurgical standpoint, which includes thermodynamic considerations, it would seem that the author has left himself open to criticism in attempting to draw an analogy between what happens to steel in the ammonia-synthesis process and in the ordinary steam boiler, where temperatures and pressures are not comparable.

On the basis of the author's explanations, it is difficult to understand what relationship, if any, exists between boiler embrittlement and hydrogen embrittlement due to pickling or cathodic treatment. It seems likely, and there has been considerable evidence by various experimenters to support the view, that nascent hydrogen may fill voids in steel, and by becoming molecular exert considerable localized pressure, but the role of hydrogen as a decarburizer at boiler temperatures and pressures has not, to my knowledge, been established. On the basis of decarburization experiments with wet hydrogen at elevated temperatures[32] it appears that hydrogen is a rather weak decarburizer at atmospheric pressure. From a thermodynamic standpoint, the decar-

[30] Research and Development Department, Combustion Engineering Company, Inc., New York, N. Y. Mem. A.S.M.E.

[31] Senior Metallurgist, Research Laboratory, Carnegie Illinois Steel Corporation, Pittsburgh, Pa.

[32] "Grain-Size and Its Influence on Surface Decarburization of Steel," by D. H. Rowland and Clair Upthegrove, Trans. A.S.M., vol. 24, 1936, p. 96.

burizing power of hydrogen should and does become more pronounced as temperature and pressure are increased, but in so far as steam boilers are concerned, it is doubtful if there is a sufficient combination of temperature and pressure materially to increase the decarburizing tendency of hydrogen over that at atmospheric pressure. Certainly there is no apparent evidence of decarburization in Figs. 30 and 31 of the paper, notwithstanding the fact that one would expect to see some indication of decarburization where such a condition exists.

The author's statement, "Accordingly, the whole study of boiler embrittlement seems to lie within the single illustration, Fig. 27," is certainly open to criticism. No "story" as complex as boiler embrittlement can be summed up in one photograph, or in a dozen photographs for that matter. If the mechanism of boiler embrittlement were as simple as the author has inferred, it is astonishing why so many boilers could have been in service for years without failure.

On reading this paper, one gets the distinct impression that the author is indirectly advocating the use of certain low-alloy steels for boiler construction on the basis that their carbides are relatively stable in the presence of hydrogen. Such a conclusion, in the absence of considerable supporting evidence, does not appear to be warranted.

Author's Closure

For several years the author has tried by oral argument to point out, with little apparent success, one principal fact regarding previous studies of boiler embrittlement: That, *whether hydrogen is the cause of boiler embrittlement or not, the hydrogen theory has not as yet been tested by valid means.*

Where the paper seems to overemphasize the hydrogen aspect, it does so purposefully for the reason that other theories have been similarly overemphasized when they eliminated the principal competing theory without full cognizance of the record. By this, reference is made specifically to the complete disregard of the many established cases in which hydrogen does cause intercrystalline failure of a type highly resembling boiler embrittlement, and generally to the many other points made in the paper which need no repetition here.

Which theory is ultimately to be proved is of little consequence; the important thing is to prove one or the other. That depends upon a correct diagnosis, which did not stand in the literature. Admittedly, the present paper may likewise contain errors; but if it does nothing other than to cause the correct answer to be developed, and to bring chemists and metallurgists into agreement on certain basic facts, it is well worth the time and effort spent preparing it.

Consequently, Schroeder and Berk's extended criticism of this paper constitutes a valuable contribution, in that respect, to the study of boiler embrittlement. They are among the foremost chemists in this field; and their careful study of this metallurgical approach promises real advancement.

However, some weaknesses still stand in their argument and warrant mention to prevent continued confusion. Because they present their argument stepwise, let us consider it in turn by its steps.

Step 1. There was no need to review in this paper the manner in which concentration occurs, since that matter is satisfactory to everyone as it stands.

Step 2. This paper does not ". . . postulate an agency that can start cracks or fissures from within the metal." It is plainly stated throughout the paper that hydrogen does not cause observable cracking, but simply renders the metal brittle, preventing a ductile response to stress. The subtle fissures through which the gaseous molecules escape to the surface should not be confused with visible cracking. The crack leading to the surface, which we all see and agree upon, first develops from the operating stresses applied to this brittle metal, and not from chemical leaching of grain-boundary material, which is a secondary, not a primary, reaction, according to the argument.

Consequently, Schroeder and Berk's criticism up to Step 3 is inconsequential.

Step 3. As for Step 3, Schroeder and Berk, who suggest that the author confounded kinetics with equilibrium, persist in overlooking all aspects of equilibrium, especially its relationship to kinetics.

Quoting Lewis and Randall's standard text on "Thermodynamics," we find that ". . . in all thermodynamics there is no concept more fundamental than this [equilibrium]," and that ". . . every system which has not reached a state of equilibrium is changing continuously toward such a state with greater or less speed." This "speed" is the rate of the reaction under consideration, and its study constitutes "kinetics."

Although the equilibrium of a system tells us nothing about the "rate" of the individual reactions comprising it, the equilibrium rigorously dictates the *only possible direction* of each reaction, and the *ultimate goal* toward which those reactions strive. Consequently, because we know little of the reaction rates concerned in boiler embrittlement, our first step should be to determine where those reactions are trying to lead us. That information, fortunately, is available and is discussed in the paper.

For example, let us pursue Schroeder and Berk's own calculations to their logical conclusion. First, however, we find them a bit mystifying, since the diffusion equation

$$D = K/d[p^{1/2} \cdot e^{-E_t/(2kT)}]$$

is expressed in terms of volume of gas per area of surface per period of time per "thickness of plate." Their only mention of plate thickness occurs later in remarking on Naumann's experiment. A check of their calculations, however, shows that the figure they obtain applies to steel about $^1/_5$ in. thick, which is somewhat thin for boiler plate. Increasing thickness as shown by d in the equation decreases the gas loss linearly.

Nevertheless, let us accept the figure of 400 psi of H_2 that they give as a maximum value for the infiltrating gas and study its passage through the steel. The work of Ham (325), which they cite, went on to prove quite conclusively our basic assumption that the dissolved H reacts to some extent with the nonmetallics in the steel in the temperature range of 435 down to 260 F—boiler temperatures.

From the corrected methane equilibrium kindly supplied in the foregoing discussion by De Vries

$$\log K = -5937/T + 6.836$$

for the reaction

$$Fe_3C + 2H_2 = 3Fe + CH_4$$

$$K = (H_2)^2/CH_4$$

we find that 400 psi of H_2 in the steel at 390 F will engage carbon kinetically in an effort to reach the equilibrium pressure of *5,625,000,000 psi of CH_4!*

As for its reaction with iron oxide, we cannot expect such a large contribution. The equilibrium

$$Fe_3O_4 + 4H_2 = 3Fe + 4H_2O$$

$$K = H_2/H_2O$$

lies toward lower H_2O values as the temperature is lowered. The contribution from H_2O would not exceed 50 psi.

But let us re-examine this C-H reaction. The figure of nearly

6,000,000,000 psi wastes itself on the ordinary reader. Whereas Schroeder and Berk selected the H_2 pressure of 400 psi as a maximum value and tried to show its inefficacy, let us calculate what the *minimum* H_2 pressure actually need be to create embrittling stresses from methane alone.

Pressures greater than approximately 45,000 psi will deform ordinary boiler steel. If we use the equation supplied by De Vries and insert 45,000 psi for P_{CH_4} and calculate P_{H_2}, we obtain the enlightening result that $P_{H_2} = 1.1$ psi.

This value actually lies so close to the measured range of hydrogen pressures in boilers that it nearly eliminates the necessity for discussing atomic surface conditions, although the author still believes they may differ considerably from the distant atmosphere and will greatly increase that figure.

At the steel surface underneath concentrated alkali, however, any gaseous H_2 showing as bubbles would have a pressure of at least 1 atm, or 15 psi, still disregarding surface phenomena. Because of the quadratic relationship between H_2 and CH_4, the potential CH_4 pressure within the underlying metal would then be over 200 times 45,000 psi. That added factor may be the one which bridges the kinetic inefficiencies of the various reactions and allows embrittlement only at seats of such alkaline concentration. In any event, that figure is a "safety factor" of 200 in favor of the present argument.

As for the lack of visible decarburization in embrittled boiler steel, that point similarly disintegrates as a proof against the gas mechanism. At higher temperatures, actual escape of the gas from the steel permits decarburization to progress until it is visible at the time of failure. But that is an action which can be subsequent to embrittlement, especially at the lower temperatures of boiler operation where gaseous congestion within the metal is less readily relieved. There the gas necessary to cause the embrittlement may be obtained from a lesser quantity of C than is visible as a solid phase change.

For example, when the C as Fe_3C in pearlite reacts with H to form CH_4 and Fe, the density of the solid phase increases from 7.73 to 7.87 g per cc. That allows 0.0162 per cent of the original volume for the gas phase, which represents a compression of 80,000 atm, or 1,150,000 psi at 390 F. Once again we are faced with the fact that fantastic possible pressures of gas trapped within steel are a commonplace.

Obviously, there are vacuities available within the metal other than the one that might result from the phase transformation. However, under the highest magnification of the light microscope, grain boundaries still appear reasonably sound. If we make the large allowance of 0.1 micron, a figure just beyond microscopic resolution, as the thickness of a flat vacuity in a grain boundary, and consider the decarburization of an adjoining lamella of Fe_3C, then we find that 45,000 psi of CH_4 would develop at 390 F when that single cementite lamella was decarburized to a depth of only 0.25 micron. Such a feature would be entirely unrecognizable with the highest possible magnification of the light microscope. Perhaps with the electron microscope, decarburization can be detected. The matter should be investigated.

Step 4. Here the worry about diffusion is groundless. Carbon *is* removed from steel by hydrogen, and the path *is* intergranular. Whether the C diffuses to the grain boundary to react with H there, or whether it reacts within the grain and then diffuses along the internal surfaces depicted in Figs. 4 and 20 of the paper, is academic.

Step 5. The most unfortunate fallacy in all of Schroeder and Berk's discussion concerns their Fig. 36 and is representative of the severe handicap a chemist is under when studying purely metallurgical problems. The fracture they show is simply a typical metal fracture, as they point out in which the concentration of stress set up by the cut caused a typical fracture type. A metallurgist would not have bothered making that test, since its behavior is rudimentary knowledge.

That is why Fig. 33 of the paper was also presented, because these boiler fractures are not ordinary. It is no news to reproduce their Fig. 36, with its commonplace fracture type; but it is news when the same type of hammer blow reveals a ductile zone *between* two brittle zones, as shown in Fig. 33, especially when the concentration of alkali coincidentally was on two sides of this plate, in contrast to the single-sided attack of the plate in Fig. 27 of the paper.

That was also why the trouble was taken to include a stereographic projection and several micrographs, since the character of the metal was as different as day and night from the normal boiler steel shown in their Fig. 36. It would pay each reader well to "fuse" the stereographs in Fig. 28, and see for himself how ridiculous it is to compare that deteriorated metal with the normal steel of their specimen.

Fig. 39 is added here to explain this zoning phenomenon caused

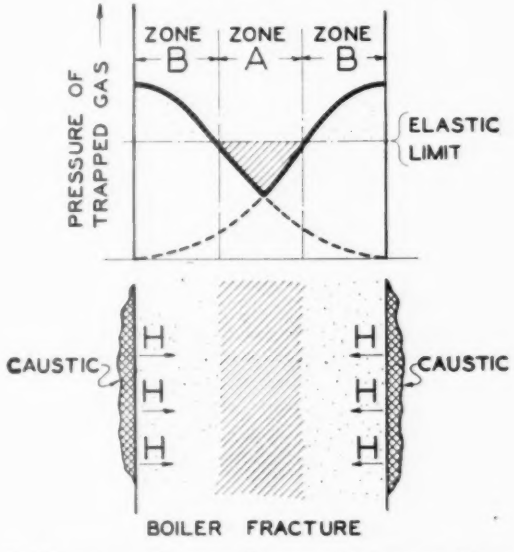

FIG. 39 SCHEMATIC DIAGRAM SHOWING FRACTURED SECTION OF BOILER PLATE (BELOW) ATTACKED FROM BOTH SIDES BY CAUSTIC WITH A DEPICTION (ABOVE) OF THE INTERNAL GAS PRESSURES SET UP BY TRANSFUSING HYDROGEN

(When gas pressures exceed the elastic limit of the steel, brittle zone B results. Ductile zone A includes the metal which is not so stressed.)

by gaseous congestion. Hydrogen, fed into the steel by the alkali, sets up internal gaseous congestion which is a maximum nearest to the source of the hydrogen and tapers off in pressure as it progresses into the steel (refer back to Fig. 3 of the paper). If the pressure exceeds the elastic limit of the steel near the surface of entrance, embrittling that section (zone B), a boundary will later be reached along the line of diffusion beyond which the gas pressure no longer exceeds the elastic limit of the steel and the ductility remains unimpaired. That boundary marks the beginning of the gray zone A. In that zone some cleansing action might be evident, but the gaseous products are not under sufficient pressure to cause embrittlement.

With unilateral diffusion, the gray zone always extends to the opposite surface. The bilaterally attacked specimen in Fig. 33 of the paper pertains to the diagram in full, showing a central ductile zone; whereas the specimen in Fig. 27 pertains only to one half of the diagram, the ductile zone extending to the far surface.

Step 6. Once again Schroeder and Berk are under a misconception concerning the role of hydrogen in causing cracking.

Since this was corrected in discussing Step 2, no further comments will be made.

As for their tests to check Naumann's work, the only alloying elements they used were the ones shown by Naumann to be least effective. Cr, one of the best of this minority group, was not designated by Naumann to contain the unusual silicon content of 1.5 per cent. As for Mo, what alloying content did they use? A misjudgment in similar early tests with vanadium was pointed out in the paper.

Also, if they tested these steels sufficiently to warrant their conclusions, a table of actual results would be valuable. Until satisfactory and systematic tests have been run on Ti and Cb steels, judgment should be withheld.

In closing the discussion of Schroeder and Berk's critique, several items might be mentioned.

1 The disagreement expressed between their work and that of the British was the opinion of the British (361), not the author's.

2 It is *not* peculiar that Al-killed steel should show improvement both to caustic and to nitrate attack. Each is basically intergranular corrosion; but for caustic, the corrosion may be indircet and gaseous, according to the present argument, thereby involving a mechanism distinct from that in nitrate cracking.

3 It is surprising to find these writers referring to the path they followed in testing the hydrogen theory and suggesting that the present paper parallels their first step taken in 1935, a step which finally led to their unfortunate conclusion in 1941 that intergranular failure cannot be caused by hydrogen. Where would the hydrogenation and ammonia-synthesis industries be today if they had proceeded on the basis of such an erroneous conclusion?

If these earlier writers had attempted to prove that boiler embrittlement is not intercrystalline hydrogen attack, the material in the present paper would then more or less represent one man's viewpoint; but they apparently failed completely to recognize that such a thing as intercrystalline H attack even existed. In addition, they were confused on the whole general behavior of gas-metal systems, drawing the numerous wrong conclusions which are discussed throughout the paper.

The author agrees with their decision expressed long ago that a thoroughgoing and sound investigation of the H mechanism be made, and suggests it at last be undertaken, since the subject has never received that treatment. Whether the hydrogen mechanism be proved unimportant or not, it remains to be so proved; and until then the author will hold the conclusion of the paper that by far the most likely mechanism for boiler embrittlement is the gas mechanism.

On the other hand, the present paper does not exclude the fact that caustic, when it does attack steel, may do so preferentially, especially when the grain boundaries are under great stress from trapped gases. Electrochemical corrosion may be a contributing factor to boiler embrittlement.

De Vries, Place, and Mears are to be thanked for their contributions to the discussion. Mears' assumption that boiler embrittlement is synonymous with stress-corrosion cracking is all right, but the present paper is based on the probability that the mechanism is of another type. The electrochemical theory is of little use in explaining the cracking of metals by other liquid metals and has nothing to do with intercrystalline gaseous attack, whether by O, H, S, or other gases. Consequently, every intergranular failure need not be lumped under an electrochemical subheading. If boiler embrittlement does belong there, the matter has already received ample discussion by others.

Mears' proposal for cathodic protection of the steel is very interesting, although the results of such a test might not be so simply interpreted as he suggests.

In Rowland's and De Vries' discussions, we find the interesting situation wherein one says H is a better decarburizer as the temperature goes up, and the other says it's better as the temperature goes down! A quick glance at the methane equilibrium shows that De Vries is the more correct in so far as the driving power or free energy of the reaction is concerned; but consideration of thermal energy shows that at lower temperatures the reaction may become so sluggish that it is quantitatively unimportant in *removing* carbon. Loose usage of the word "decarburization" both for the reaction and for the removal of CH_4 is to blame.

Correspondingly, Rowland is further confused when he speaks of hydrogen as a ". . . rather weak decarburizer at atmospheric pressure," on the basis of experiments he conducted at temperatures where CH_4 is almost nonexistent. And that ". . . from a thermodynamic standpoint, the decarburizing power of hydrogen should and does become more pronounced as temperature and pressure are increased." The *reaction* or the *removal*, and in what temperature range? The reacting power of H should *not* increase with increasing temperature. The free energy of methane formation decreases with increasing temperature. True, the *removal* is favored by heating; but even then that beneficial effect is soon counteracted by the sharp loss in the free energy of the reaction. In boiler embrittlement, the removal of the reaction product is only of secondary interest.

Rowland's objection to the present picture of boiler embrittlement because it is too simple takes the author so unawares, as does his worry about all the boilers which did not fail, that on answer will be made!

Partridge's criticisms, excepting his delightfully diversionary comments on devils and needle points, duplicate the remarks of others and therefore stand answered in the foregoing discussion.

A Sampling Inspection Plan for Continuous Production

By H. F. DODGE,[1] NEW YORK, N. Y.

The plan of sampling inspection, described for individual parts, subassemblies, finished articles, and the like, is intended primarily for use in process inspection where there must be assurance that the percentage of defective units is kept down to a low prescribed figure. The system is particularly applicable to products manufactured by conveyer or similar straight-line continuous processes. The object of the plan is to establish a limiting value of "average outgoing quality," expressed as a percentage of defective units, which will not be exceeded no matter what quality may be submitted to the inspector.

1 INTRODUCTION

THIS paper presents a plan of sampling inspection for a product consisting of individual units (parts, subassemblies, finished articles, etc.) manufactured in quantity by an essentially continuous process.

The plan, applicable only to characteristics subject to nondestructive inspection on a "Go - No Go" basis, is intended primarily for use in process inspection of parts or final inspection of finished articles within a manufacturing plant, where it is desired to have assurance that the percentage of defective units in accepted product will be held down to some prescribed low figure. It differs from others which have been published[2,3] in that it presumes a *continuous flow of consecutive articles or consecutive lots* of articles offered to the inspector for acceptance in the order of their production. It is accordingly of particular interest for products manufactured by conveyer or other straight-line continuous processes.

In operation, the plan provides a corrective inspection, serving as a partial screen for defective[4] units. Normally, a chosen percentage or fraction f of the units are inspected, but, when a defective unit is disclosed by the inspection it is required that an additional number of units be inspected, the additional number depending upon how many more defective units are found. The result of such inspections is to remove some of the defective units, and the poorer the quality submitted to the inspector, as measured in terms of per cent defective, the greater will be the corrective or screening effect. The object of the plan is the same as that incorporated in some of the sampling tables already published,[5] namely, to establish a limiting value of "average outgoing quality" expressed in per cent defective which will not be exceeded no matter what quality is submitted to the inspector. This limiting value of per cent defective is termed the "average outgoing quality limit (AOQL)."

The theoretical solution treats the case of inspecting a continuous flow of individual units and is based on the distribution of *random-order* spacing of defective units in product whose quality is statistically controlled.[6] Part 3 of the paper extends the application of the method to a continuous flow of individual lots or sublots of articles.

2 INSPECTION OF A FLOW OF INDIVIDUAL UNITS

Inspection of One Characteristic. Consider first the inspection of a flow of individual units, offered consecutively in the order of their production. Assume that inspection is to be made for only one quality characteristic, so that interest will be centered on one kind of defect. Subsequently, consideration will be given to the procedures when inspection is made simultaneously for several kinds of defects.

Procedure A. The procedure is as follows:

(*a*) At the outset, inspect 100 per cent of the units consecutively as produced and continue such inspection until i units in succession are found clear of defects.

(*b*) When i units in succession are found clear of defects, discontinue 100 per cent inspection, and inspect only a fraction f of the units, selecting individual sample units one at a time from the flow of product, in such a manner as to assure an unbiased sample.

(*c*) If a sample unit is found defective, revert immediately to a 100 per cent inspection of succeeding units and continue until again i units in succession are found clear of defects, as in paragraph (*a*).

(*d*) Correct or replace with good units, all defective units found.

Protection Provided by Plan. The inspection plan is defined by the two constants, f and i, which can be altered at will. For given values of f, i, and p (incoming fraction defective), there will result for product of statistically controlled quality a definite average outgoing fraction defective (average outgoing quality, AOQ). For given values of f and i, the AOQ will have a maximum for some particular fraction defective p_1 of incoming quality. As already noted, this maximum is referred to as the average outgoing quality limit (AOQL). For all other values of incoming fraction defective p greater or less than p_1, the AOQ will be less than AOQL. Many combinations of f and i will result in the same AOQL.

The protection offered by the plan discussed here can thus be expressed in terms of the AOQL, in per cent defective.

Theoretical Framework. We are concerned with the spacing between defective units when the individual units are arrayed in the order of their production, as shown in Fig. 1. If the manufacturing process is statistically controlled so that the

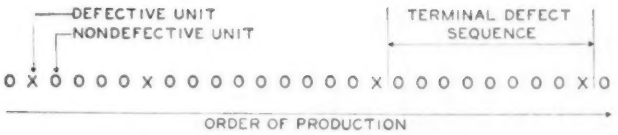

FIG. 1 SPACING OF DEFECTIVE UNITS

probability of producing a defective unit is constant and equal to p, then defective units will have an order spacing of a random character which is expressible in terms of certain probability laws. Product turned out by such a process will be referred to as having a process average fraction defective p. The "event" of particular interest is a "terminal-defect sequence" of $i + 1$ successive units following the observance of a defect, comprising a succession of i nondefective units followed by a defective unit, as shown in Fig. 1. The totality of all possible such sequences, where i varies from 0 to ∞, constitutes the universe of events under consideration.

Each such sequence of $i + 1$ units, comprising i successive nondefective units followed by a defective one, has a definite probability of occurrence, for a process average fraction defective, p. The complete set of such probabilities for all possible sequences, having respectively $i = 0, 1, 2, 3, \ldots \infty$, defines a probability distribution[7] of random-order spacing of defects in uniform product. This is shown in Table 1 in which 0 represents a nondefective unit, X represents a defective one, p is the fraction defective, and $q = 1 - p$.

TABLE 1 PROBABILITIES OF OCCURRENCE OF DEFECT SPACING

Sequence	Defect spacing (No. of units in sequence)	No. of nondefective units before finding the next defect	Probability of occurrence	No. of term in the power series
X	1	0	p	1st
$0X$	2	1	pq	2nd
$00X$	3	2	pq^2	3rd
$000X$	4	3	pq^3	4th
$0000X$	5	4	pq^4	5th
	.	.	.	.
	.	.	.	.
	.	.	.	.
$000\ldots.0X$	$i + 1$	i	pq^i	$(i + 1)$st
.	.	.	.	.
.	.	.	.	.
.	.	.	.	.

These probabilities are the successive terms in the infinite power series

$$\left.\begin{array}{l} p + pq + pq^2 + pq^3 + \ldots \\ \text{or} \\ p(1 + q + q^2 + q^3 + \ldots). \end{array}\right\} \quad \ldots\ldots\ldots\ldots [1]$$

The sum of this series is $p\left(\dfrac{1}{1-q}\right) = 1$; i.e., the total probability for all possible sequences is unity (as it should be).

The sum of the first $i + 1$ terms of the series is the probability of occurrence of a "terminal-defect sequence" (defect spacing) of $i + 1$ units or less. The sum of the first i terms is the probability, P_1, of failing to find the next i units clear of defects, which is

$$P_1 = \sum_{j=}^{j=i-1} pq^j = 1 - q^i \quad \ldots\ldots\ldots\ldots [2]$$

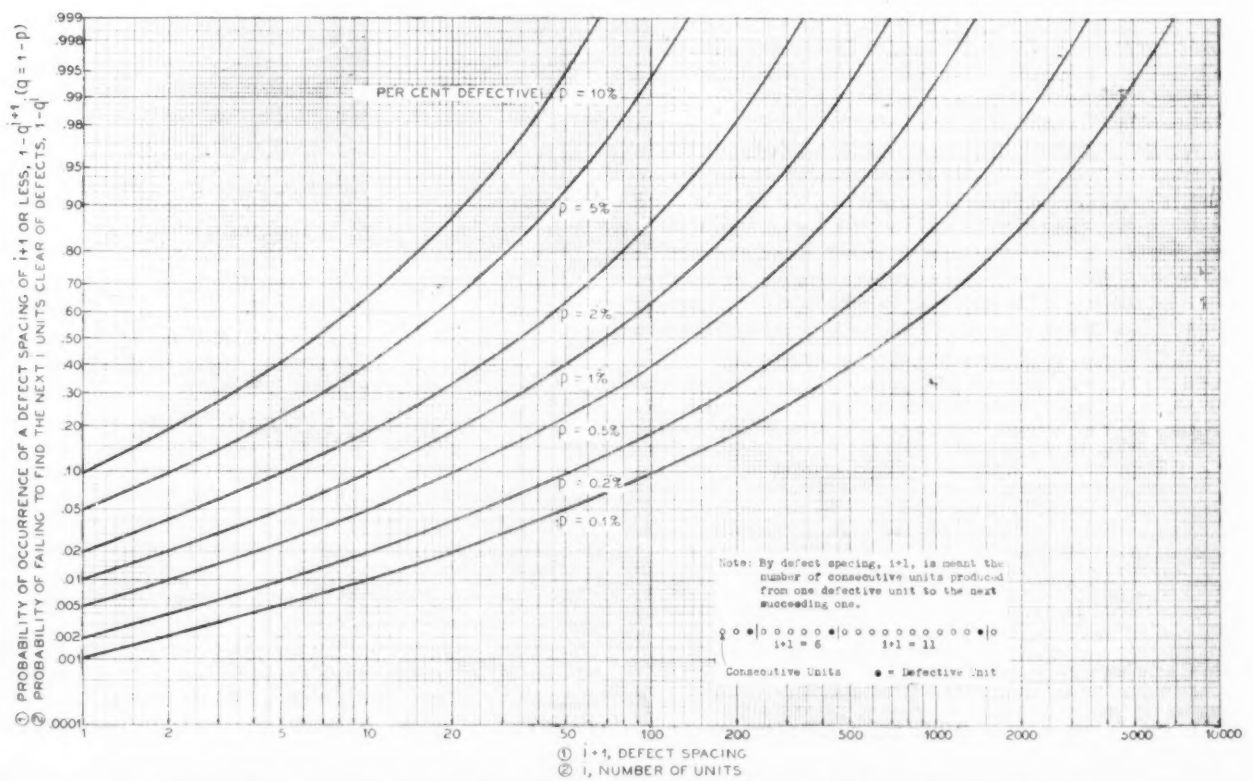

FIG. 2 CURVES DEFINING DISTRIBUTION OF RANDOM-ORDER SPACING OF DEFECTS IN UNIFORM PRODUCT

[7] "Due Nuovi Criteri di Controllo Sull 'andamento Casuale di Una Successione di Valori," by V. Romanovsky, *Giornale dell'Instituto Italiano degli Attuari*, 1932, discusses this probability distribution of spacing of events, referring to the spacing as the "length of a partial series." Our term "terminal-defect sequence" has the same significance as his term "partial series." See also "Note on Theoretical and Observed Distributions of Repetitive Occurrences," by P. S. Olmstead, *Annals of Mathematical Statistics*, vol. 11, 1940, pp. 363–366; "The Distribution Theory of Runs," by A. M. Mood, *Annals of Mathematical Statistics*, vol. 11, 1940, pp. 367–392.

In turn, the sum of all terms beyond the ith term is the probability of finding 0 defects in the next i units, which is

$$Q_1 = 1 - P_1 = q^i \quad [3]$$

These results and the power series [1] enter into subsequent portions of the discussion. The curves of Fig. 2 give values of $1 - q^i$.

Average Outgoing Quality. Suppose a plan is selected, choosing specific values of f and i. For given values of i and p, there will be an expected average number of units, u, inspected following the finding of a defect. Likewise, for given values of f and p, there will be an expected average number of units, v, that will be passed under the sampling procedure before a defect is found. The latter average number includes the sampling units actually inspected as well as the uninspected units produced between successive sample units.

The average fraction of the total product units inspected in the long run is

$$F = \frac{u + fv}{u + v} \quad [4]$$

It is now assumed for purposes of solution that the inspection operation itself never overlooks a defect and that all defective units found during the inspection of f and i will be corrected or replaced by good units.[8]

As a result of the screening effect of the inspection, the average outgoing quality, AOQ, designated p_A, is related as follows to the incoming quality p

$$p_A = p(1 - F) = p\left(1 - \frac{u + fv}{u + v}\right) \quad [5]$$

Determination of u. The average number of units, u, inspected on a 100 per cent inspection basis, following the finding of a defect, is a function of i and p, and may be determined from a consideration of two power series, one limited and the other infinite.

Once the 100 per cent inspection starts, there are several things that can happen before i units are found clear of defects. The first i may be found clear; or 1, 2, 3, or more defects may be found before finally a run of i units is found clear.

One of the quantities to be determined is the *average number of units* inspected in a "failure sequence;" that is, one terminating in a defect and comprising i or less units. This average number, designated as h, is the average of the distribution made up of the first i terms of the power series [1]. The average is

$$h = \frac{p}{1 - q^i}(1 + 2q + 3q^2 + 4q^3 + \ldots + iq^{i-1}) \quad [6]$$

where the denominator is the sum of the probabilities for the first i terms. This may be evaluated as follows

$$h = \frac{p}{1 - q^i} \frac{d}{dq}(1 + q + q^2 + q^3 + \ldots + q^i)$$

$$h = \frac{p}{1 - q^i} \frac{d}{dq}\left[\frac{1 - q^{i+1}}{1 - q}\right]$$

$$= \frac{1}{p(1 - q^i)}[1 - q^i(1 + pi)] \quad [7]$$

Note that if pi is small compared with unity, h is approximately $1/p$.

The next step is to determine the *average number of failure sequences* that will be encountered before finding i units clear of defects. This average number, designated as G, may be found from the probability distribution of all possible numbers of failure sequences, expressed by the infinite series

$$Q_1(1 + P_1 + P_1^2 + P_1^3 + \ldots) \quad [8]$$

where P_1 is given by Equation [2], $Q_1 = 1 - P_1$, as given by Equation [3], and the successive terms are the probabilities of occurrence of 0, 1, 2, 3, etc., failure sequences before finding i units clear of defects. The average number of failure sequences, G, is given by the sum of the infinite series

$$G = Q_1(0 + 1P_1 + 2P_1^2 + 3P_1^3 + \ldots)$$
$$= Q_1P_1(1 + 2P_1 + 3P_1^2 + 4P_1^3 + \ldots) \quad [9]$$

Summing the series, we have

$$G = Q_1P_1 \frac{1}{(1 - P_1)^2} = \frac{P_1}{Q_1} = \frac{1 - q^i}{q^i} \quad [10]$$

Now u, the average number of pieces inspected following the finding of a defect, is made up of a number of failure sequences followed by a run of i units clear of defects. Using the average values of G and h just found, we have

$$u = Gh + i = \frac{1 - q^i}{pq^i} \quad [11]$$

Determination of v. The average number of units, v, that will be passed in a period of sampling inspection will be $1/f$ times the average number of individual sample units inspected in such periods. Here again the solution will depend upon the random-order spacing of defects in uniform product. Whether the individual units selected during the sampling inspection procedure are selected by a random-spacing device, or by any other means which will prevent known bias in the sample, we may assume that defects will be found to occur in accordance with the distribution of random-order spacing, defined by the terms of the power series [1]. The average number of sample units inspected in a period of sampling inspection will thus be the average defect spacing for a product having fraction defective, p, which is given by the infinite series.

$$H = p(1 + 2q + 3q^2 + 4q^3 + \ldots) \quad [12]$$

Summing the series, we have

$$H = \frac{p}{(1 - q)^2} = \frac{1}{p} \quad [13]$$

and the value of v is found to be

$$v = \frac{H}{f} = \frac{1}{fp} \quad [14]$$

Determination of f and i for a Given Value of AOQL. From the considerations previously given, the average fraction of the product inspected, F, and the value of average outgoing quality, p_A, can be determined for any given values of p, f, and i. Substituting in Equation [5], the values of u and v given in Equations [11] and [14], we have

[8] The assumption that the inspection operation is perfect cannot be made without reservation. Machine inspection devices have their margins of error. Also, inspection fatigue prevents 100 per cent manual and visual inspections from insuring perfection, particularly if such inspections continue over a considerable period of time. But the efficiency of the latter inspections is generally higher when an interest incentive is provided as is usually the case in sampling inspection plans where the extent of such inspections hinges on their findings.

The solution given assumes correction or replacement of defective units. Where it is expedient to reject such units and not replace them Equations [19] to [22], inclusive, should be modified by replacing i by $(i - 1)$.

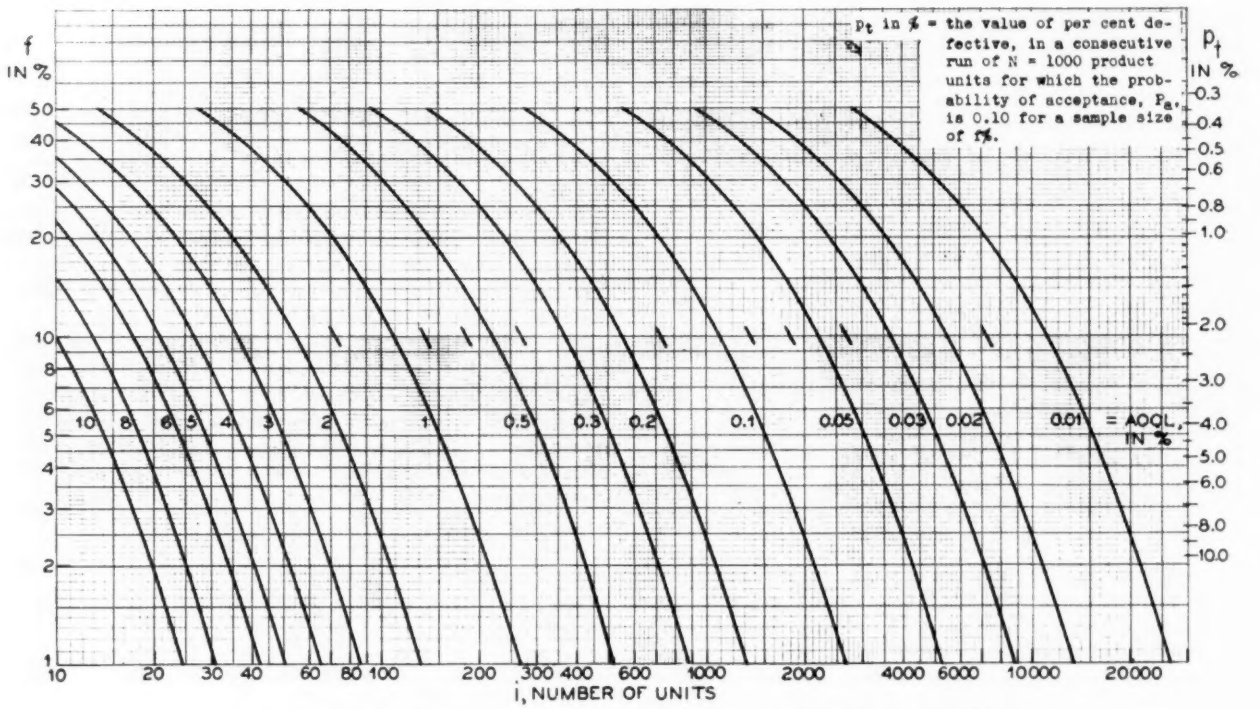

FIG. 3 CURVES FOR DETERMINING VALUES OF f AND i FOR A GIVEN VALUE OF AOQL

$$p_A = p\left[1 - \frac{f}{f + (1-f)(1-p)^i}\right] \quad \ldots\ldots [15]$$

The average outgoing quality limit, AOQL, (p_L) is the maximum value of p_A that will result for any given values of f and i, considering all possible values of p in the submitted product. The value of p for which this maximum value of p_A occurs is designated by p_1, hence

$$p_L = p_1\left[1 - \frac{f}{f + (1-f)(1-p)^i}\right] \quad \ldots\ldots [16]$$

The value of p_1 for which $p_A = p_L$ is determined by differentiating Equation [15] with respect to p, equating to 0, and solving for p, that is

$$\frac{dp_A}{dp} = 1 - \frac{f^2 + f(1-f)(1-p)^i + pfi(1-f)(1-p)^{i-1}}{[f + (1-f)(1-p)^i]^2} \quad \ldots\ldots [17]$$

Simplifying, and using the designation p_1 for the maximizing value of p, gives

$$(i+1)p_1 - 1 = \frac{1-f}{f}(1-p_1)^{i+1}$$

or

$$(1-p_1)^i = \frac{f[(i+1)p_1 - 1]}{(1-f)(1-p_1)} \quad \ldots\ldots [18]$$

Substituting in Equation [16] this value of $(1-p_1)^i$, we have

$$p_L = \frac{(i+1)p_1 - 1}{i} \quad \ldots\ldots [19]$$

hence

$$p_1 = \frac{1 + ip_L}{i+1} \quad \ldots\ldots [20]$$

From Equations [18] and [19], we have

$$p_L = \frac{1-f}{fi}(1-p_1)^{i+1} \quad \ldots\ldots [21]$$

hence

$$f = \frac{(1-p_1)^{i+1}}{ip_L + (1-p_1)^{i+1}} \quad \ldots\ldots [22]$$

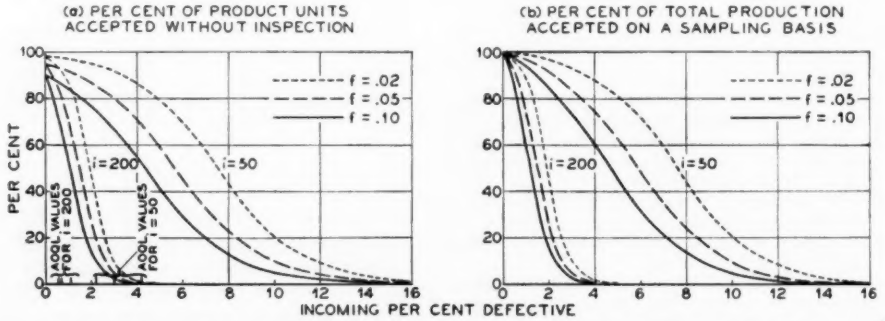

FIG. 4 CURVES SHOWING EFFECT OF f AND i ON OPERATING CHARACTERISTICS OF PLAN

The curves given in Fig. 3 were calculated by choosing values of i for given values of AOQL (p_L) and calculating p_t from Equation [20], and f from Equation [22]. Thus, for a given AOQL value, an i value may be found for a chosen f value and vice versa. It will be noted that for a given value of f, i varies inversely with the AOQL value, to a close degree of approximation.

Operating Characteristics of Plan. Figs. 4(*a*) and 4(*b*) give a picture of the operating characteristics of the general plan as f and i are varied. They indicate, for example, that for a moderate range of f values the factor i has a stronger influence than f in determining the discrimination that the method affords between high and low levels of incoming per cent defective. For the values of f and i shown, Fig. 4(*b*) indicates just what level of incoming per cent defective would force a correction of the manufacturing process, if the percentage of total production that would be accepted on a sampling basis falls below a critical value; often, a value of the order of 80 to 90 per cent.

Fig. 5 gives a comparison of the characteristics of several plans having the same AOQL value, 1 per cent. It indicates, for example, that when the normal level of incoming per cent defective is well below the AOQL, the AOQL value can be assured with less

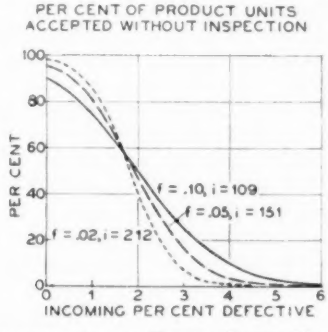

FIG. 5 CHARACTERISTICS OF THREE PLANS HAVING THE SAME AOQL OF 1 PER CENT

inspection by choosing f small and i large. But since, for a given AOQL value, the average amount of inspection approaches a minimum as f approaches 0, factors other than the minimum amount of inspection have a more important influence upon the choice of the most advantageous combination of f and i values for a given set of circumstances. For example, when the inspector is located at the end of the production line, it may be desirable to use a value of i not greater than some small multiple of the number of product units on the line at any one time. Or again, the value of f is often influenced by the normal work loads of the inspector and the operators on the line. Protection against "spotty" quality, such as may arise from temporary irregularities in workmanship or materials, should receive special consideration in connection with the choice of f.

Protection Against Spotty Quality. The p_t scale, at the right in Fig. 3 provides a guide concerning the protection afforded against spotty quality in a continuous run of product. The value of p_t is the per cent defective in a run of 1000 consecutive product units, for which the probability of acceptance by sample is 0.10 for a percentage sample equal to the corresponding f value shown on the chart.

This scale indicates that the protection against spotty quality falls off very rapidly with f and that the protection, considering runs of product of 1000 consecutive units each, becomes quite poor if f is less than 2 per cent.

Effect of Selecting Group Samples. The foregoing development assumes selection of individual sample units one at a time from the flow of product and immediate examination of a unit to determine whether or not it is defective. Deviations from this procedure will in general result in giving values of AOQL higher than those shown in Fig. 3.

For example, the actual AOQL may be higher than the theoretical value (*a*) if the inspector delays looking at the individual units immediately when they are withdrawn from the line, or (*b*) if he selects a group of units at one time from the production line. The effect of either of these two deviations, both constituting a delay, may be quite large if i is small, or if large group samples are taken.

Although the modification of the theoretical AOQL value resulting from the selection of group samples has not been thoroughly explored, this should not be excessive, (*a*) if group samples of $n = 10$ or less are drawn from the line, and (*b*) if $i = 50$ or more, provided there is no delay in examining the group samples drawn from the line.

It should be noted, however, that the effect of these delay factors on the AOQL may be compensated for in part if, when a defect is found, the 100 per cent inspection includes some of the units that have already passed the inspection point.

Where appreciable delays are unavoidable, an alternative is to withhold from acceptance a stipulated number of units pending the examination of the sample units that have been selected to represent this quantity of product. Such a procedure provides in effect a lot acceptance plan, the treatment for which is covered in Part 3.

Administration of Inspection Operations. The inspection plan is most effective in practice if it is administrated in such a way as to provide an incentive to clear up causes of trouble promptly. Such an incentive may be had by imposing a penalty on the operating or manufacturing department when defects are encountered. Normally, no such penalty is imposed if both the sampling inspection and the 100 per cent inspection are performed by the same person or group of persons and the two costs merged; the inspector then merely serves as an agency for screening defects when quality goes bad. It is accordingly recommended that the sampling inspection and the 100 per cent inspection operations be treated as two separate functions.

With this in mind, the inspection work can be performed by two different inspectors, designated inspector C and inspector M. Inspector C may be considered as the *consumer's* representative in that his work is performed as a function independent of the manufacturing group. The term "consumer" is used in the general sense of the recipient of the product after the inspection has been completed. Inspector M is responsible to the manufacturing department and the cost of his work is borne by that department. His work must, however, be subject to the surveillance and approval of inspector C.

The following method of administering the inspection plan can then be used:

1 Inspector C inspects the required fraction f. So long as no defects are found, product is considered acceptable and is passed.

2 When inspector C finds a defect, he proceeds as follows:

(*a*) Continues inspecting the fraction f.

(*b*) Places some identification on the succeeding flow of product to indicate nonacceptance (or diverts it from the regular production line if the design of the line permits), such designation to apply until clearance is obtained in accordance with paragraph (3).

(*c*) Calls inspector M to inspect the succeeding flow of product in accordance with paragraph (3).

3 Inspector M (one or more inspectors as needed) inspects all succeeding units, except those inspected by inspector C in the fraction f, until the required number of units, i, are found clear of defects. Inspector M reports immediately to inspector C all

defects found in the course of his 100 per cent inspection and notifies him when a run of i units has been found clear of defects.

4 When notified that a run of i units has been found clear of defects, inspector C, if satisfied with the work of inspector M, releases inspector M.

5 To facilitate speedy correction of causes of trouble, inspector C, on finding a defect, should promptly notify the production foreman or other designated authority and furnish the latter with detailed information regarding the character of the defect found.

It will be noted that the foregoing procedure requires calling inspector M whenever inspector C finds a defect. To avoid taking such action on the occurrence of a single defect, the procedure can be modified so that inspector M is called into the picture only when two defects in succession are observed by inspector C. Where this feature is desired, paragraph (2) may be modified to read as follows:

2 When inspector C finds a defect, he proceeds as follows:

(a) Immediately inspects all succeeding units up to a total of i units, and if no defects are found therein, he again limits his inspection to the fraction f. If, on the other hand, during the course of inspecting the next i units, inspector C finds a second defect, he immediately discontinues his 100 per cent inspection.

(b) He then places some identification on the succeeding flow of product . . . etc.

While this procedure carries the disadvantage of placing a varying work load on inspector C, it is often preferred since a single defect tends to be regarded as an isolated occurrence, whereas two defects in quick succession (like a first and second offense) are normally accepted as sufficient evidence to justify special action.

Inspection for Several Kinds of Defects Simultaneously. The procedure just given may be applied directly to an inspection covering two or more kinds of defects, provided that the chosen AOQL value applies to all defects collectively and each unit inspected is always inspected for all of the defects under consideration.

It is sometimes desired, however, when a defect of one kind is observed, to confine the 100 per cent inspection to this one kind of defect alone. This requires a modification of the general procedure and the establishment of a separate AOQL for each kind of defect. A similar modification is required, for example, where the inspection is to cover several kinds of defects, but where the defects are grouped into two or more classes, according to their seriousness, and the defects in each class treated collectively.

The following paragraphs outline for illustrative purposes a procedure for use where the defects under consideration are to be classified into two groups, "major" and "minor," and where all major defects are to be treated collectively and all minor defects likewise. By analogy, the procedure to be followed when each kind of defect is to be treated separately will be obvious. In any event, the fraction f is made the same for all classes or all kinds of defects.

Procedure:

Several kinds of defects are grouped into two classes with respect to seriousness; designated "major" and "minor."

All defects of the same class (major or minor) are treated collectively.

Preliminary:

1 Establish an over-all AOQL value for major defects and an over-all AOQL value for minor defects. Select a suitable value for f, applicable to both major and minor defects. From Fig. 3 determine a value of i for major defects, designated i_A, and a value of i for minor defects, designated i_B.

2 At the outset, inspect 100 per cent of the units consecutively for both major and minor defects until i_{max} units in succession are found clear of defects ($i_{max} = i_A$ or i_B, whichever is the larger).

Routine:

3 When i_{max} units in succession are found clear of defects, discontinue 100 per cent inspection and inspect only a fraction f of the units *for both major and minor defects*, selecting individual sample units one at a time from the flow of product.

4 If a major (or minor) defect is observed during sampling inspection, inspect 100 per cent of the succeeding units *only for defects of the class in question* until i_A (or i_B) units in succession are found clear of defects of this class.

(a) During the 100 per cent inspection referred to in paragraph 4, inspect a portion f *for both major and minor defects.*

(b) If during the 100 per cent inspection for a particular class of defect (major or minor), a defect of the other class is observed on an individual unit of product, start 100 per cent inspection for defects of the new class *only* if the new defect is observed on one of the f units that has been inspected for both major and minor defects, and continue such 100 per cent inspection for defects of the new class until i (as determined in paragraph 1 for the new class) units in succession are found clear of defects of the new class. Do not take such action, however, if the new defect happens to be observed on one of the non-f units.

5 When the proper number of successive units are found clear of defects as in paragraphs 4 or 4(b) reinstate sampling inspection as in paragraph (3).

From the foregoing, it may be appreciated that difficulties of administration are introduced in treating a large number of classes of defects or a large number of individual defects separately. How best to group defects together for collective treatment can generally be determined from the nature of the inspection operations, whether visual or gaging, and the expectancy of defects as determined from the quality history. Items involving visual inspection can often be treated collectively to advantage.

As is generally true, the layout of an inspection plan depends to a considerable extent upon the nature of inspection operations to be performed. Simplicity of administration is always to be desired. From the standpoint of minimizing over-all inspection costs, it is often preferable, where several quality characteristics are to be inspected, to break down the inspection work into two or more separate inspection steps, each covering a relatively small number of characteristics.

3 INSPECTION OF A FLOW OF INDIVIDUAL LOTS OR SUBLOTS

Purposes of Inspection. A manufacturer's inspection of his own product serves two purposes:[9]

1 "Process control" providing a basis for action with regard to the production process, with a view to better future product.

2 "Product acceptance" providing a basis for action with regard to the product already at hand.

The plan outlined in Part 2 has both of these purposes in mind, but the provision for selecting sample units continuously from the production line places special emphasis on control. It aids, for example, in the prompt detection of defects and location of causes of trouble in the manufacturing process.

The problem of acceptance of product is often eased, though at some sacrifice to the control aspects of the inspection work, if the product is submitted to the inspector in lots or sublots and a sample taken from each.

[9] See A.S.A. War Standard, Z1.3, "Control Chart Method of Controlling Quality During Production," American Standards Association, New York, N. Y., 1942, pp. 5–6.

Inspection Procedure for Sublots. With minor modifications, the plan and procedure of Part 2 can be extended to the case where material is offered as a *flow of consecutive sublots* of articles. In the inspection of parts, for example, the material may be offered in panloads or trays, each containing a collection of parts produced under essentially the same conditions. Or again, the product from a common source for a given short period of time, such as a $\frac{1}{2}$ hr, 1 hr, etc., may often be treated as a sublot and offered to the inspector as such for his acceptance. In what follows, however, it is essential that such sublots be kept in the *order of their production.*

The theoretical development given in Part 2 makes use of random-order spacing of defects in a statistically controlled product, with the specific provision that the units inspected be selected in the order of their production. In applying the general plan to the inspection of a *flow of consecutive sublots,* we no longer have individual units available in the order of their production. But we can use the same theoretical framework if we consider the random spacing of defects as their spacing in the chain of inspected units arranged in the *order of their inspection.* The probability distribution of the spacing of defects in inspected units will be the same regardless of the manner of selecting the units to be inspected, so long as we hold to the concept of statistical control in our solution.

The "i units in succession to be found clear of defects," discussed in Part 2, will now be defined as "i consecutively inspected units." During sampling inspection, a group sample of units will be selected from each sublot, and the fraction f will relate to the ratio of the number of units in the sample to the total number of units in the sublot. The fraction f will be held constant for all sublots. Furthermore, when it is required under the general plan to find i inspected units in succession clear of defects, the 100 per cent inspection must be allowed to extend into immediately succeeding sublots if i units in succession are not found clear in the current sublot.

Procedure B. The procedure is as follows:

1 At the outset, start inspecting 100 per cent of the units in a sublot and continue such inspection until i inspected units in succession are found clear of defects. Extend the 100 per cent inspection, if necessary, into one or more succeeding sublots in the order of their production.

2 When i inspected units in succession are found clear of defects, discontinue 100 per cent inspection and inspect only a fraction f of the units from each of the sublots, selecting the sample units in such a way as to fairly represent the sublot.

3 If a sample unit is found defective, start a 100 per cent inspection of the remainder of the sublot, and continue the 100 per cent inspection until again i inspected units in succession are found clear of defects, as in paragraph (1), extending such inspection into succeeding sublots, if necessary.

4 In the event the 100 per cent inspection extends into one or more succeeding sublots, if the number of units inspected in the last of such succeeding sublots exceeds a fraction f of the number of units in the sublot, accept this last sublot without further inspection. If on the other hand, the number of units inspected in this last sublot is less than the fraction f, inspect additional units from this same sublot to make up a sample equal to a fraction f of the number of units in the sublot.

5 Correct or replace with good units all defective units found.

As was the case in Part 2, the inspection plan is defined by two constants, f and i, and the protection offered is expressed in terms of AOQL. This sublot inspection plan differs from those already published in that the screening action is not confined to a single sublot but may extend over a succession of sublots, the entire production being regarded as a train of sublots that are linked together for purposes of inspection in the order of their production.

4 REMARKS

It will have been noted that the plan here outlined should be regarded as a "special-purpose" plan applicable under the conditions which have been enumerated: where production is practically continuous, where inspection is to be made during production or immediately thereafter and is to serve not only as a screening *acceptance* agency if necessary, but as an aid to *process control* by disclosing promptly any substandard quality conditions in the product. It is believed that the general plan provides a structure, which with possible variations in procedure to serve particular circumstances, may be found useful in designing additional sampling inspection techniques.

Physical Properties of a Structural Plastic Material

By CECIL W. ARMSTRONG[1]

THE aviation industry is vitally interested in high-strength low-density materials which show promise of utilization in airplane structures. This interest exists because of the following reasons:

1 The need for the further reduction in weight of all types of airplanes in order to obtain better performance characteristics.

2 The need for increasing the rigidity of all thin-gage sections to reduce local failures resulting from vibration and to maintain contours under all flight conditions.

3 The need for reducing the number of man-hours required for the tooling, fabrication, and final assembly of airframes.

4 The need for improvement in the over-all smoothness of all aerodynamic surfaces.

It is generally agreed among aeronautical engineers that the development of a low-density structural plastic material, capable of being molded in large assemblies with inexpensive molds, would help to satisfy the needs listed. The word "structural" necessarily implies that the plastic material will possess certain minimum mechanical properties. For structural use in airplanes, the strength-weight ratios and other mechanical properties must compare favorably with corresponding values of the commonly used aluminum alloys.

Many new resins have recently been developed and without doubt countless others will emerge from the numerous chemical laboratories. These resins are being copolymerized and interpolymerized. They are being cast, molded, and laminated with a large variety of organic and inorganic fibrous fillers, woven fabrics, macerated fabrics, and the like. It has become exceedingly difficult for the engineer to choose from among these thousands of combinations any one material for a specific application. The need exists for reliable engineering data on plastic materials so that an intelligent selection of a material for a specific application can be accomplished. Considerable progress is being made in this direction by the joint efforts of the Army, Navy, and the plastics industry, but much remains to be done.

Among the new resins which have become commercially available (military requirements first, of course), there are several thermohardening resins which are unique in that no external pressure is required during the process of molding a plastic part. These new resins may be used in combination with high-strength filler materials to produce low-density high-strength laminated plastics which soon may fulfill some of the needs which have been enumerated.

Methods of Laminating "No-Pressure" Resins

To produce a laminated-plastic article from one of these "no-pressure" resins, one or more layers of the filler material may be wrapped around or draped over a mold. The filler material may be saturated with the liquid resin either before or after placing in contact with the mold. The laminate then is cured (hardened) by application of heat. Curing temperatures seldom exceed 240 F. The curing period may require from thirty minutes to eight hours, depending upon the requirements of the particular resin, the thickness of the laminate, and the heat conductivity of the mold. If a smooth glossy surface is desired, nonporous cover sheets, such as Cellophane, may be used.

Parts having intricate shapes and double contours may necessitate the use of some pressure (0.1 to 10 psi) to keep the impregnated-fabric filler material in intimate contact with all surfaces of the mold and to prevent free resin from accumulating in localized spots. For application of these pressures, the use of thin transparent films of inexpensive thermoplastic materials has been found to be more suitable than the use of expensive synthetic-rubber bags. Many novel and ingenious techniques already have been developed for the fabrication of complete assemblies, which if made of metal would require the forming and assembly of several contoured parts. Because of the fact that pressures are low, molds may be simple, light in weight, and inexpensive. The primary requirement of molds for fabrication of parts from these new resins is that they be made to correct dimensions and contours.

Physical Test Program

A preliminary study of the limited amount of available data, supplemented by various laboratory tests, indicated that the MR-1A resin,[2] when laminated with certain of the Fiberglas fabrics, possessed better mechanical properties than any of the commercially available "no-pressure" resins. Accordingly, a modest test program was undertaken by the Lockheed Structures Research Laboratory. Results which are reported in this paper are typical of data thus far obtained.

Materials Tested and Methods of Testing

Data presented herewith were obtained from MR-1A resin laminated with Fiberglas-fabric fillers. A brief description of the Fiberglas-filler materials which were used in the preparation of flat sheet laminates, from which test specimens were machined, is given in Table 1.

① Specific Tensile Strength = Ult tensile strength divided by specific gravity.
② Specific Tensile Modulus = Tension modulus divided by specific gravity.
③ Specific Buckling Stability = Flexural modulus divided by (specific gravity)^3
④ Specific Modulus of Rupture = Modulus of rupture divided by (specific gravity)^2
⑤ Specific Ult Bearing Strength = Ult bearing strength divided by specific gravity.

Plastics, L-P-406, dated December 9, 1942. Bearing-stress-deformation data, Fig. 4, were obtained by use of a fixture similar to one developed at the University of Kansas.[4] Ultimate bearing-stress values were obtained from test specimens 2.50 in. wide, with 0.124-in-diam holes centrally located at an edge distance of 0.375 in. The small compression-test specimens were supported and tested in a jig, Fig. 5, designed by L. F. Bonza[5] and made in the Lockheed Structures Research Laboratory. Similar compression jigs have been widely used for some time.

Test Results

Typical test results are given in Table 2 and in Figs. 1 to 4.

[4] "Bearing Strength of Plastics and Plywood," by James Bond, Trans. A.S.M.E., vol. 65, 1943, pp. 9–14.

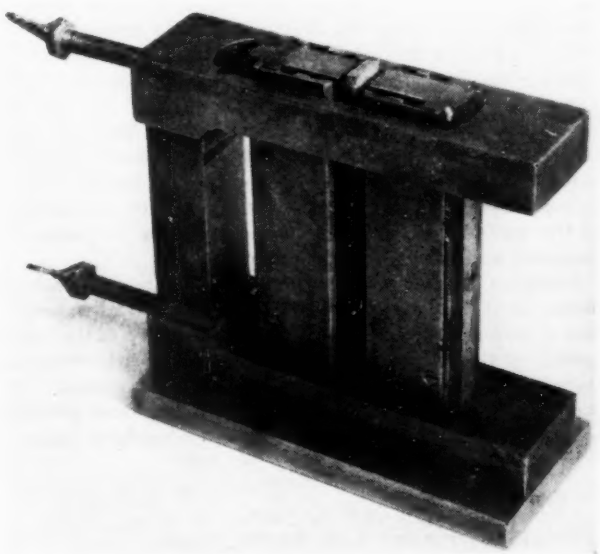

FIG. 5 JIG FOR TESTING SPECIMENS IN COMPRESSION

Certain of these values, adjusted to an equivalent-weight base, are compared with corresponding values of two aluminum alloys in Table 3. The specific-strength properties of the aluminum alloys were computed from previously published values.[6]

Attention is directed to the fact that these laminates are anisotropic, resulting from parallel stacking or cross-stacking (alternate laminae oriented at right angles) of unidirectional materials, such as OC-63 Fiberglas or bidirectional materials, such as are listed in Table 1. Results which are shown in Table 2 were obtained from specimens cut parallel to one of the two principal directions of the laminates.

Preliminary tensile tests made from specimens cut at 45 deg with the principal directions of the cross-stacked MR-1A Fiberglas laminates exhibited ultimate tensile-strength and tensile-modulus values thirty to forty per cent lower than corresponding "with-grain" values.

[6] "Strength of Aircraft Elements," U. S. Army-Navy-Civil Committee on Aircraft Requirements, Publication ANC-5, Dec., 1942.

Tensile tests made at room temperature from unfilled cast MR-1A resin (specific gravity = 1.2) indicated an average ultimate tensile strength of 6200 psi and an average tensile modulus of 370,000 psi.

The following data on other properties of the MR-1A Fiberglas laminates were supplied by the Swedlow Aeroplastics Corporation. Methods of testing were stated to have been in accordance with A.S.T.M. specifications:

Impact strength, notched Izod, ft-lb per in. of notch	25 - 100
Ultimate shear strength, psi	14000–33000
Ultimate compressive strength, flatwise, psi	41000–75000
Moisture absorption, per cent	0.2 - 0.4
Gasoline absorption, per cent	0.01 - 0.15
Burning rate, in. per min	0 - 0.4
Hardness, Rockwell M	71 - 107
Hardness, Barcol impressor	40 - 65
Heat distortion, deg F	300 - 350
Coefficient of linear expansion, 10^{-5} per deg F	2.7 - 5.2

Fatigue- and creep-test data and other physical properties which are not listed have not as yet been determined.

Discussion of Results Obtained

It is interesting to compare test results on a basis of pounds load per inch of width per lamina with corresponding values of the Fiberglas cloth. Note that for the unidirectional laminate (see Table 2, laminate No. 223) the ultimate tensile load per inch of width per lamina is 880 lb; also from Table 1, that the nominal breaking strength of the OC-63 Fiberglas is 875 lb. For cross-stacked laminates of the same material (No. 224 and No. 309) corresponding values of 520 lb were obtained; however, since only one half of the laminae were oriented parallel to the direction of the load, these values could be expressed as 1040 lb per in. of width for each lamina oriented in the direction of the applied load. Similar comparisons may be made with laminates made from the woven fabrics.

Attention is directed to the fact that both the thickness and density of the laminate are dependent upon the relative proportion of resin and filler materials. In tension, most of the load is carried by the filler material. Two laminates, each containing the same number of laminae but varying in resin content might carry equal tensile loads, but because of the greater thickness would have different ultimate unit-stress and modulus values.

Examination of the data will show that the resin content (low resin content results in high specific-gravity values) for optimum tensile properties will not result in optimum bend and compression properties. This fact may be demonstrated by comparing data obtained on laminate No. 224 with corresponding data obtained on laminate No. 309.

Costs of the Processed Materials

The present high prices of Fiberglas cloths impose serious limitations on the use of these materials for simple structural applications. Many high-strength organic and inorganic fibrous materials which recently have been developed, or ones known to be in the developmental stage, may offset this limitation.

For contoured structural shapes which generally begin with flat metal sheets and which require the forming of several parts with expensive dies by drop hammers or hydropress, followed by manual assembly of these parts, the use of a suitable plastic material can save cost and valuable man-hours of production time. Comparative totals of man-hours required for the tooling and fabrication of actual contoured metal parts and corresponding man-hours required for the tooling of the same "no-pressure" plastic parts should be very enlightening.

Conclusions

The MR-1A Fiberglas laminates possess physical properties which enable this material to be used to good advantage in many airplane structural applications. The ability to mold large contoured assemblies with substantially no pressure will, without doubt, result in substantial savings in cost and in man-hours of time required for the tooling and fabrication of many assemblies now made of metal.

Known disadvantages include the anisotropic properties of fabric laminates, the length of time required to complete the curing of each part, the low values of the modulus of elasticity, the low bearing strength, and the present incompleteness of important physical data.

Isothermal Pressure Drop for Two-Phase Two-Component Flow in a Horizontal Pipe

By R. C. MARTINELLI,[1] L. M. K. BOELTER,[2] T. H. M. TAYLOR,[3] E. G. THOMSEN,[4] AND E. H. MORRIN,[5] BERKELEY, CALIF.

The static pressure drop accompanying the isothermal two-phase two-component flow of air and eight various liquids, including benzene, water, and S.A.E. 40 oil, was measured for flow conditions varying from all air to all liquid in a 1-in. glass pipe and a ½-in. galvanized-iron pipe. The flow patterns existing at the various flow rates were studied visually and photographically. A macroscopic analysis of the flow phenomenon is presented, which allows the prediction of two-phase two-component static pressure drop under certain flow conditions. The application of the proposed method to the prediction of pressure drop along a pipe in which a fluid is evaporating is tentatively outlined.

Nomenclature

THE following nomenclature is used in the paper:

A_p = cross-sectional area of pipe of diameter D_p, sq ft
A_l = cross-sectional area of liquid flow, sq ft
A_g = cross-sectional area of gas flow, sq ft
D_H = hydraulic diameter, ft
D_g = hydraulic diameter for gas flow, ft
D_l = hydraulic diameter for liquid flow, ft
D_p = inside diameter of pipe, ft
f_c = unit thermal convective conductance, Btu/hr sq ft deg F
F_1, F_2, F_3, F_4 = functions utilized in Appendix 1
g = gravitational force per unit mass

$$= 32.2 \frac{\text{lb}}{\left(\frac{\text{lb sec}^2}{\text{ft}}\right)}$$

L = length of pipe, ft
m = exponent of Reynolds modulus in the Blasius expression for friction factor for the gas phase
n = exponent of Reynolds modulus in the Blasius expression for friction factor for the liquid phase
p = average static pressure in pipe, psi
P = average static pressure in pipe, psf
r = latent heat of vaporization of liquid, Btu per lb
t = average fluid temperature, deg F
T = average fluid temperature, deg R
v_g = velocity of gas, fps
v_l = velocity of liquid, fps
W_g = weight rate of gas, lb per sec
W_l = weight rate of liquid, lb per sec
W_T = total weight rate (vapor + liquid), lb per sec
Z = co-ordinate measured along pipe axis, ft
γ_g = weight density of gas, lb per cu ft
γ_l = weight density of liquid, lb per cu ft
ΔL = finite difference of length, ft
ΔP = finite difference of static pressure in length ΔL psf
$\left(\frac{\Delta P}{\Delta L}\right)_g$ = pressure drop per unit length due to gas flowing at a rate W_g, with density γ_g in a pipe of diameter D_p (lb per sq ft) per ft
$\left(\frac{\Delta P}{\Delta L}\right)_{T\text{-}P}$ = pressure drop per unit length for two-phase flow, (lb per sq ft) per ft
Δt = difference in temperature between tube wall and fluid being evaporated, deg F
μ_g = absolute viscosity of gas, lb sec per sq ft
μ_l = absolute viscosity of liquid, lb sec per sq ft

Dimensionless Moduli

α = flow-type modulus for liquid $= \dfrac{A_l}{\frac{\pi}{4} D_l^2}$

β = flow-type modulus for gas $= \dfrac{A_g}{\frac{\pi}{4} D_g^2}$

$\chi_{tt} = \left(\frac{\mu_l}{\mu_g}\right)^{0.111} \left(\frac{\gamma_g}{\gamma_l}\right)^{0.555} \left(\frac{W_l}{W_g}\right)$ = two-phase flow modulus for mechanism in which flow of both liquid and gas is turbulent

$\chi_{vt} = \dfrac{C_l}{C_g} (Re_g)^{-0.8} \dfrac{\gamma_g}{\gamma_l} \cdot \dfrac{\mu_l}{\mu_g} \cdot \dfrac{W_l}{W_g}$ = two-phase flow modulus for mechanism in which flow of liquid is viscous and that of gas is turbulent

$\chi_{vv} = \dfrac{\mu_l}{\mu_g} \cdot \dfrac{\gamma_g}{\gamma_l} \cdot \dfrac{W_l}{W_g}$ = two-phase flow modulus for mechanism in which flow of both phases is viscous

ζ_g = friction factor for gas (see Equation [2])
ζ_l = friction factor for the liquid (see Equation [1])
Φ_{tt} = function of χ_{tt} utilized in calculation of two-phase pressure drop
Φ_{vt} = function of χ_{vt} utilized in calculation of two-phase pressure drop
C_g = constant in empirical equation for friction factor for gas. Note that for turbulent flow $C_g = 0.184$ for smooth pipes
C_l = constant in empirical equations for friction factor for liquid. Note that $C_l = 64$ for viscous flow

Re = Reynolds modulus $= \dfrac{4}{\pi} \cdot \dfrac{W}{D\mu g} = \dfrac{vD\gamma}{\mu g}$

$Re_g = \dfrac{4}{\pi} \cdot \dfrac{W_g}{D_p \mu_g g}$ = Reynolds modulus for gas phase

Introduction

Many flow systems in engineering design involve the simultaneous transport in pipes of a gaseous (or vapor) phase and a liquid phase. Examples of such systems are numerous; among them are water-steam mixtures in boiler tubes, petroleum liquids and their vapors in tube stills, liquid-vapor mixtures in refrigeration systems, oil-laden compressed air, condensate-return lines, gasoline-engine manifolds, and partial condensers in fractionation equipment. Air flow in cooling towers and steam flow in the low-pressure stages of turbines are more complex examples of this type of hydrodynamic problem. A considerable amount of experimental work in the field of two-phase flow has been reported in the literature but no satisfactory analyses of the data have been accomplished. This paper presents further data on the subject of static pressure drop in two-phase flow and outlines a macroscopic analysis of the test data, which allows prediction of the pressure drop under certain flow conditions.

Previous experimental work had indicated that the variables affecting the pressure drop per unit length for two-phase flow were the pipe diameter, the rate of liquid flow, the rate of gas (or vapor) flow, the liquid viscosity, and perhaps the surface tension of the liquid. A preliminary analytical analysis indicated that the liquid density and the gas density and viscosity were also pertinent variables.

To note the effect of these variables, a series of tests was performed in which the pressure drop along a 1-in. glass tube (1)[6] and a ½-in. galvanized-iron pipe (2), resulting from the two-phase two-component flow of air and various liquids, was measured. The range of variables covered by the tests is shown in Table 1. The data on the 1-in. glass tube include the greater range of variables, and the major portion of the discussion will be concerned with these results. The tests on the ½-in. pipe were found to substantiate the data obtained on the glass pipe.

The test arrangement for the 1-in. glass tube is shown in Fig. 1. The liquid and the air were mixed several feet before the test

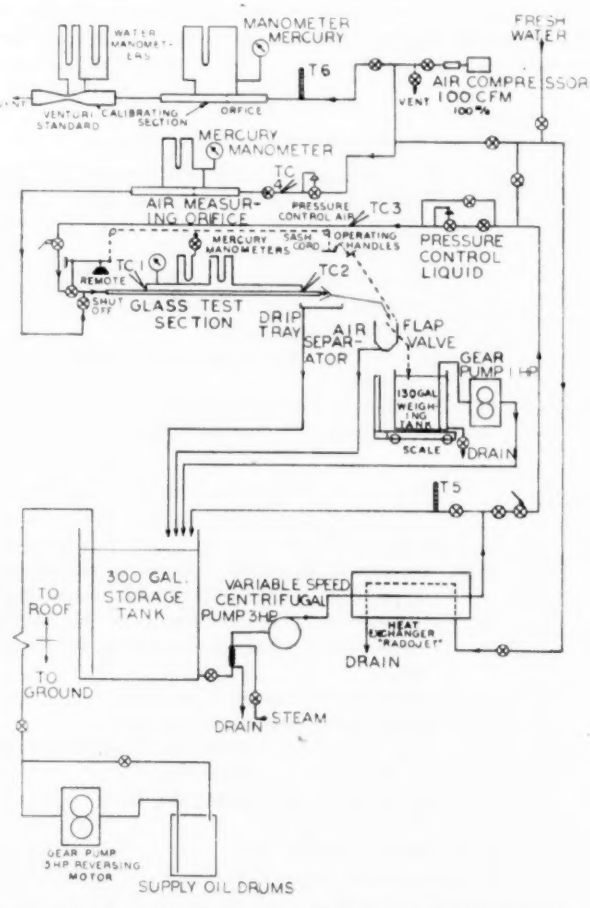

FIG. 1 SCHEMATIC DIAGRAM OF EXPERIMENTAL EQUIPMENT

[6] Numbers in parentheses apply to references at the end of the paper. A comprehensive Bibliography is also included.

section proper. The method used for mixing the two phases was chosen as a result of considerable experimentation. Trials were made with both air injected into the liquid and liquid injected into the air. These different modes of injection were tried to minimize "slugging," which is the name given a stream of alternate plugs of liquid and air. Such plugs were from a few inches to several feet long, depending upon the rates of flow. The arrangement necessary for minimum "slugging" required the introduction of the air into the upper surface of the liquid and perpendicular to it. Furthermore, any bends, valves, or other obstructions between the injection point and the measuring section must be avoided.

After being mixed, the fluids passed through a glass test section in which the flow pattern could be observed and the static pressure drop measured across the taps[7] shown in Fig. 1. The mixture of liquid and air exhausted into a separator, the liquid returning to the reservoir and the air exhausting to the atmosphere. Air rates were measured by means of calibrated orifices, and liquid rates were determined by gravimetric means. The average temperature and static pressure in the pipe were also recorded. The static pressure drops due to the flow of the two pure components, i.e., all air or all liquid, were carefully measured at intervals throughout the two-phase test runs.

The equipment utilized for the tests on the smaller pipe was practically identical to that just described.[7]

Data and Results

The experimental results obtained on the 1-in. glass tube are shown in graphical form in Figs. 2 to 8,[8] inclusive. Inspection of the data indicates the effect of the variables mentioned previously. Figs. 2 to 7, inclusive, reveal the pressure drop as a function of the gas and liquid rates for air and water, kerosene, Diesel fuel oil, two blends of Diesel fuel oil and S.A.E. 40 oil, and S.A.E. 40 oil. The data for water with a surface-tension-reducing additive are shown in Fig. 8 and indicate that the change of surface tension had no apparent effect on the pressure drop, although it influenced the flow pattern appreciably, as will be discussed later. The decrease in the surface tension of the water due to the additive was, however, only 36 per cent and it is possible that a greater change would influence the results.

The following general trends are evident in Figs. 2 to 7, inclusive:

1 The static pressure drop for two-phase flow is always greater than the pressure drop for each phase flowing alone at the weight rates which obtain in the two-phase flow.

2 For a given gas rate, adding liquid increases the pressure drop, the pressure drop becoming greater as more liquid is added.

3 When the air flow approaches zero for any constant liquid rate, the static pressure drop due to the flow of the pure liquid is approached. Thus the lines of constant liquid rate become horizontal as the gas rate is decreased.

4 As the gas flow is increased, for any constant liquid rate, the static pressure drop increases and approaches the 100 per cent gas line as an asymptote.

5 The flow for both the air and the liquid may be turbulent. Figs. 2, 3, 4, and 8 indicate this type of flow mechanism, for both the 100 per cent liquid and 100 per cent air data reveal a variation of pressure drop with the 1.8 power of the rate of flow.

6 The flow may be turbulent for the air and viscous for the liquid. Curves 5, 6, and 7 reveal this type of flow, for the pressure drop due to the liquid alone is seen to vary directly with the weight rate, while the pressure drop for the air alone varies with the 1.8 power of the air rate. The case in which both the air and the liquid flow was viscous was not observed in these tests.

7 The greater the viscosity of the liquid, the greater is its effect on the pressure drops for two-phase flow. This effect is particularly evident when the liquid is flowing viscously, Figs. 5, 6, and 7.

Simultaneously with the static pressure drop measurements, visual and photographic observations of the flow mechanism were made. These are of considerable interest because they reveal the complexity of the microscopic phenomena occurring during two-phase flow. As would be expected, two distinct types of flow phenomena were observed, one when the flow of both fluids was turbulent, the other when the flow of the liquid was viscous and the flow of the gas was turbulent.

The results of the observations are given in Table 2 and the flow types are illustrated in Fig. 9. In this figure, flow type 1 indicates air alone, and flow type 9, liquid alone. Type 2 is a frothy mixture of liquid and air and did not exist when the liquid flow was viscous. In type 3 the fluid moved along the bottom of the pipe, with the air above, waves of definite wavelength moving at the gas-liquid interface.[9] In the case of viscous flow of the liquid phase, the wavelengths were somewhat greater than in the case of turbulent flow of the liquid. Type 4 followed type 2 at medium air rates as the liquid rate was reduced, and consisted of definite liquid waves on both the bottom and top of the pipe traveling at different velocities. As the liquid rate was decreased further, the upper waves disappeared and type 6 appeared. In this interesting flow type, the crests of the waves point, as shown, in the direction opposite to the direction of fluid flow. When the air rate was very low and the liquid rate was reduced, type 2 flow was followed by type 7 in which small air bubbles collected in the upper half of the pipe. As the liquid rate was further reduced (at low air rates) type 5 appeared in which long bubbles, occupying almost one half the pipe cross-sectional area, moved along the pipe. At very low liquid rates and high air rates, "annular" flow occurred (type 8). The liquid flowed in the form of an annulus, even though the pipe was horizontal, and the liquid surface was covered with small capillary waves. When the surface tension of the water was lowered by adding Nekal BX, much foaming was observed, type 2 being prominent in the results.

It is then evident that the microscopic behavior of the two-phase flow system is extremely complex. Since, however, the static pressure drops for the water and the water-Nekal blend were almost identical, although the detailed flow patterns were quite different, it appears that it should be possible to analyze the problem from a macroscopic point of view and obtain results which are of utility from an engineering standpoint, even though the details of the flow mechanism are not clarified. This method of attack is of course the one employed whenever the "friction factor" is utilized, i.e., the "friction factor" allows prediction of static pressure drops in turbulent flow without the need for consideration of the complex details of turbulence.

Analysis of Results

The analysis of the static pressure drop accompanying two-phase flow results from the application of two basic postulates. The first postulate is that the static pressure drop for the liquid

[7] The static pressure taps for the 1-in. glass pipe were 21.6 ft apart and those for the 1/2-in. galvanized-iron pipe 50 ft apart. The pressure in many cases fluctuated severely due to the unavoidable "slugging" of the fluid. During these runs the differential manometer deflection was recorded at the estimated mid-point of the oscillation. The static pressure manometer was "throttled" to reduce oscillations.

[8] The pressure drops shown in Figs. 2 to 8, inclusive, have been corrected to atmospheric pressure conditions by the approximate method outlined in Appendix 2. Points for zero gas flow (100 per cent liquid) are plotted on the 0.0001 lb/sec gas rate abscissa for convenience.

[9] Such waves form at the interface of two fluids moving with different velocities (4).

Medium liquid rate...	7	7	4	4	4	4
High liquid rate.....	2	–	2	–	2	–

[a] See Fig. 9 for sketch of flow types.

phase must equal the static pressure drop for the gaseous phase regardless of the details of the flow, as long as appreciable static pressure differences do not exist along any pipe diameter. The second postulate is that the volume occupied by the liquid plus the volume occupied by the gas at any instant must equal the total volume of the pipe. The expression of these two propositions in algebraic form leads to the following equations for the prediction of two-phase-flow static pressure drop:

The static pressure drop due to the liquid flow may be written by the usual Weisbach equation as

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \zeta_l \frac{\gamma_l}{D_l} \cdot \frac{v_l^2}{2g} \quad \ldots\ldots\ldots\ldots\ldots [1]$$

where D_l is the unknown "hydraulic diameter" of the liquid flow pattern. Similarly, for the gas flow

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \zeta_g \frac{\gamma_g}{D_g} \cdot \frac{v_g^2}{2g} \quad \ldots\ldots\ldots\ldots\ldots [2]$$

The pressure drop in two-phase flow is greater than that for the flow of either single phase alone for various reasons, among which are the irreversible work done by the gas on the liquid and the fact that the presence of the second fluid reduces the cross-sectional area of flow for the first fluid. Thus, during two-phase flow the hydraulic diameters D_l and D_g will always be less than the pipe diameter D_p, and as noted in Equations [1] and [2], this reduction of hydraulic diameter will increase the pressure drop greatly. It should be observed that for a given weight rate of fluid the pressure drop varies inversely as the fourth or fifth power of the hydraulic diameter, depending upon the type of flow.

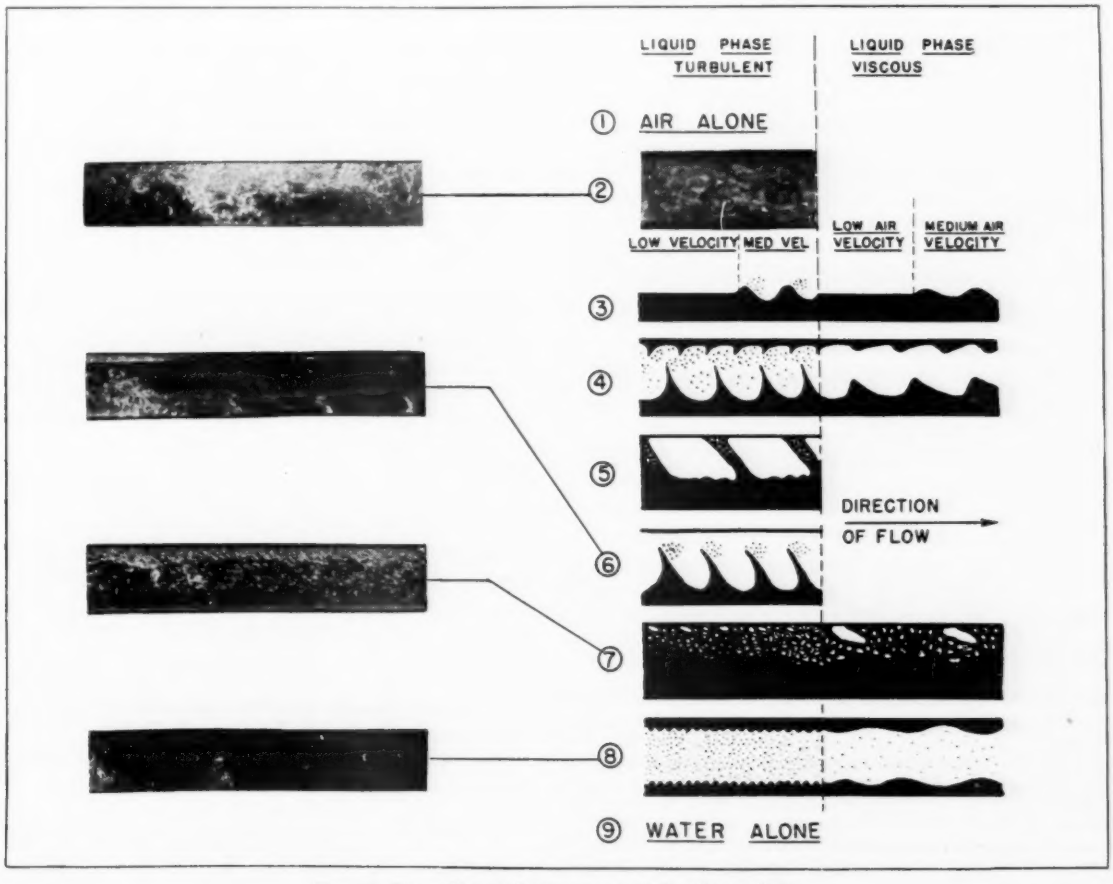

FIG. 9 FLOW TYPES OCCURRING IN 1-IN. GLASS PIPE

The hydraulic diameter of the flow pattern is related to the cross-sectional area through which the fluid is flowing at any instant. For a cylindrical flow pattern the simple relation

$$\frac{\pi}{4} D^2_H = A_c \quad [3]$$

applies. For a more complex cross-sectional area, such as that possessed by the fluids in the pipe, the following relations may be written

$$A_l = \alpha \left(\frac{\pi}{4} D^2_l \right) \quad [4]$$

$$A_g = \beta \left(\frac{\pi}{4} D^2_g \right) \quad [5]$$

where α and β are, in effect, the ratio of the actual cross-sectional area of flow to the area of a circle of diameter D_l and D_g, respectively. A consideration of the air flow indicates that as a first approximation, the cross-sectional shape of the air flow is approximately circular at all times, so that β can be considered as 1. On the other hand, at high rates of gas flow and low rates of liquid flow, the liquid can assume a thin annular shape, and thus, for this case, α is much greater than unity. As a reasonable approximation, therefore, α will be left as an unknown in Equation [4] while β is taken as unity.[10]

Equations [4] and [5] may be utilized to evaluate the respective velocities v_l and v_g: thus

$$v_l = \frac{W_l}{\alpha \left(\frac{\pi}{4} D_l^2 \right) \gamma_l} \quad [6]$$

$$v_g = \frac{W_g}{\left(\frac{\pi}{4} D_g^2 \right) \gamma_g} \quad [7]$$

The velocities, v_l and v_g, calculated from Equations [6] and [7], are the mean absolute velocities of the two fluids. The velocities v_l and v_g in Equations [1] and [2] involve the "relative" velocities between the fluids, and thus substitution of the magnitudes of the velocities from Equations [6] and [7] into Equations [1] and [2] is not exact.[11] This difficulty is not as serious as it first appears, for the ratio α is evaluated from experimental data and thus includes the effect of relative motion as well as the fluid geometry. A more precise analysis of the problem of two-phase pressure drop should include a consideration of the matter of relative motion in greater detail.

The friction factors ζ_l and ζ_g may be expressed in the generalized Blasius form

$$\zeta_l = \frac{\left(\frac{\pi}{4} \right)^n C_l}{\left(\frac{W_l}{\alpha D_l \mu_l g} \right)^n} \quad [8]$$

and similarly

$$\zeta_g = \frac{\left(\frac{\pi}{4} \right)^m C_g}{\left(\frac{W_g}{D_g \mu_g g} \right)^m} \quad [9]$$

For viscous flow, the constants C_g, C_l are equal to 64 and the exponents n and m are both unity. For turbulent flow C_l and C_g and n and m vary with the Reynolds modulus, but an average magnitude (3) for C_g and $C_l = 0.184$, and n and $m = 0.20$ may be utilized for smooth tubes for a range of the Reynolds modulus from 5000 to 200,000.

The proper choice of C_l, C_g and n, m depends upon the type of flow occurring in the pipe. Four distinct flow mechanisms are possible, as follows:

1 The flow of both the liquid and gas may be turbulent ($C_l = C_g = 0.184$ and $n = m = 0.2$).

2 The flow of the gas may be turbulent, and the flow of the liquid viscous ($C_l = 64$, $C_g = 0.184$, $n = 1$, $m = 0.2$).

3 The flow of both the liquid and gas may be viscous ($C_l = C_g = 64$ and $n = m = 1$).

4 The flow of the gas may be viscous and that of the liquid turbulent ($C_l = 0.184$, $C_g = 64$, $m = 1$, $n = 0.2$).

Of these four possible cases, the fourth is very improbable and thus has not been analyzed in detail, although the analysis would be almost identical to that of the second flow mechanism. The third case was not observed experimentally but has been analyzed since this mechanism may arise in practice (viz., flow in porous media). As discussed previously, both the first and second flow combinations were observed experimentally and are analyzed in the following sections of the paper.

Flow Mechanism 1. Liquid Turbulent, Gas Turbulent

In flow mechanism 1, in which both fluids are in turbulent motion, the magnitudes of C_l and C_g are equal to 0.184 for smooth pipes, and the exponents m and n are both equal to 0.2. Substitution of these magnitudes in Equations [8] and [9], and a further substitution of Equations [8], [9], [6], [7] into Equations [1] and [2] results in the equation

$$\left(\frac{D_l}{D_g} \right)^2 = \left(\frac{\gamma_g}{\gamma_l} \right)^{\frac{2}{5-n}} \left(\frac{\mu_l}{\mu_g} \right)^{\frac{2n}{5-n}} \left(\frac{W_l}{W_g} \right)^{\frac{2(2-n)}{5-n}} (\alpha)^{\frac{2(n-2)}{5-n}} \quad [10]$$

It is noted that, since the constants C_l and C_g are equal for both fluid phases, they cancel in the derivation of Equation [10], while the exponent n remains. In Equation [10], the three unknowns are D_l, D_g, and α. Equation [10] is the result of the first basic postulate previously discussed, i.e., the equality of the pressure drops for the two phase of flow. Substitution of $n = 0.2$ yields

$$\left(\frac{D_l}{D_g} \right)^2 = \left(\frac{\gamma_g}{\gamma_l} \right)^{0.416} \left(\frac{\mu_l}{\mu_g} \right)^{0.083} \left(\frac{W_l}{W_g} \right)^{0.75} \alpha^{-0.75} \quad [11]$$

Application of the second basic postulate, equating the sum of the liquid and gas volumes to the pipe volume yields

$$\alpha \left(\frac{\pi}{4} D_l^2 L \right) + \left(\frac{\pi}{4} D_g^2 L \right) = \frac{\pi}{4} D_p^2 L$$

$$\alpha D_l^2 + D_g^2 = D_p^2 \quad [12]$$

In Equation [12], the variables D_g and D_l are unknown. One of the unknown "hydraulic diameters," D_l, may be eliminated between Equations [11] and [12]. The resulting expression for D_g is

$$D_g = \frac{D_p}{\sqrt{1 + \alpha^{1/4} \left(\frac{\gamma_g}{\gamma} \right)^{0.416} \left(\frac{\mu_l}{\mu} \right)^{0.083} \left(\frac{W_l}{W} \right)^{0.75}}} \quad [13]$$

[10] A more precise analysis can be performed in which both α and β are left as unknowns. The modulus β can be assumed equal to unity and α estimated. By rearranging the equations, β can then be solved for approximately, utilizing the approximate magnitudes of α. A repetition of this trial-and-error procedure will finally yield magnitudes of both α and β. The present analysis, in effect, includes any variations of β in the modulus α. This may be one explanation of the scattering of the experimental points observed in Figs. 10 and 14.

[11] Noted by V. Skoglund in a verbal discussion of this paper at the 1943 Semi-Annual Meeting in Los Angeles, Calif.

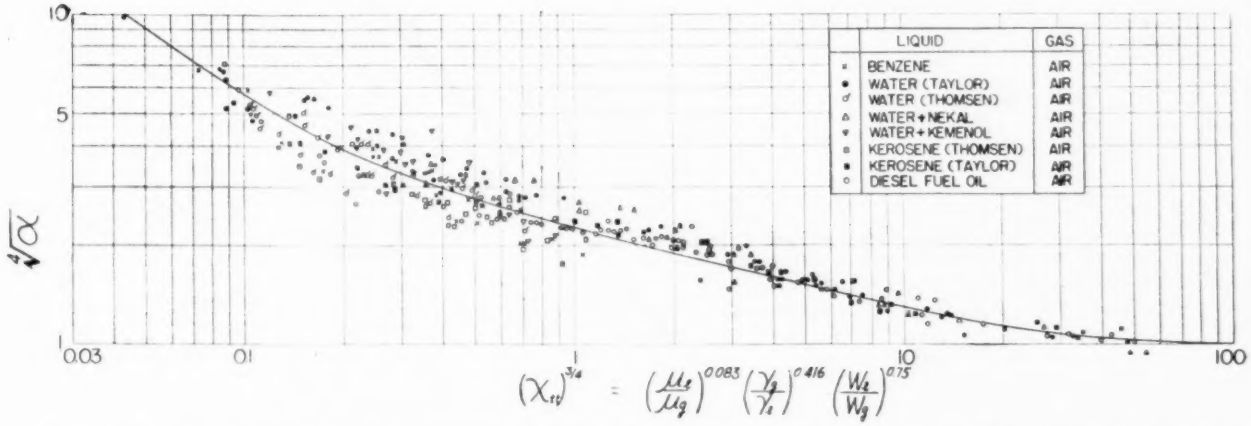

FIG. 10 FLOW TYPE MODULUS $\alpha^{1/4}$ AS A FUNCTION OF THE TWO-PHASE FLOW MODULUS $(\chi_{tt})^{3/4}$. FLOW MECHANISM IN WHICH BOTH LIQUID AND GAS ARE IN TURBULENT MOTION

It may be shown by reference to Equation [2] that the static pressure drop for the gas phase during the two-phase flow is:

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \frac{\left(\frac{4}{\pi}\right)^{2-m} C_g}{\left(\frac{W_g}{D_g \mu_g g}\right)^m} \cdot \frac{1}{D_g} \cdot \frac{W_g^2}{2gD_g^4\gamma_g} \quad \ldots\ldots [14]$$

$$= \left[\frac{1}{2}\left(\frac{4}{\pi}\right)^{2-m} \frac{C_g \mu_g{}^m}{g^{1-m}\gamma_g} \cdot \frac{W_g{}^{2-m}}{D_p{}^{5-m}}\right]\left(\frac{D_p}{D_g}\right)^{5-m} \quad \ldots [14]$$

$$= \left(\frac{\Delta P}{\Delta L}\right)_g \left(\frac{D_p}{D_g}\right)^{5-m} \quad \ldots\ldots [15]$$

For the case under consideration $m = 0.2$, thus

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \left(\frac{\Delta P}{\Delta L}\right)_g \left(\frac{D_p}{D_g}\right)^{4.8} \quad \ldots\ldots [16]$$

The term in brackets in Equation [14] may be demonstrated to be the pressure drop for the gas phase alone flowing with a weight rate W_g and density γ_g, in a pipe of diameter D_p. Thus, the pressure drop for two-phase flow is obtained by multiplying the static pressure drop for the gas phase alone (corresponding to W_g, γ_g, and D_p) by the ratio $(D_p/D_g)^{5-m}$. When both fluids are in turbulent motion, this ratio can be obtained from Equation [13] and substituted in Equation [16].

The final equation for the static pressure drop per unit length, when both the fluids are flowing in the turbulent regime, is then

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \left(\frac{\Delta P}{\Delta L}\right)_g \left[1 + \alpha^{1/4}\left(\frac{\mu_l}{\mu_g}\right)^{0.083}\left(\frac{\gamma_g}{\gamma_l}\right)^{0.416}\left(\frac{W_l}{W_g}\right)^{0.75}\right]^{3.4} \quad \ldots [17]$$

Inspection of Equations [17] and [14] reveals that, as W_g approaches zero, the equation reduces to the expression for the pressure drop of the liquid flowing alone with a weight rate W_l through a pipe of diameter D_p.

In order to establish the cases for which Equation [17] is applicable, the Reynolds modulus for each fluid is calculated utilizing the rates W_g and W_l, the fluid viscosities, and the pipe diameter D_p. If the magnitude of both of these Reynolds moduli is greater than 2000, Equation [17] is applicable. An example of the method of calculation is shown in Appendix 1.

Evaluation of α for Flow Mechanism 1. In Equation [17] the function α is still unknown. This function, as mentioned earlier, represents the ratio of the actual cross-sectional area of liquid flow to the area calculated by the product $\frac{\pi}{4} D_l^2$ and should equal unity when the liquid completely fills the pipe and be greater than unity when the liquid flows along the pipe in a thin annulus. The function α was calculated from experimental data by substituting known magnitudes of the variables into Equation [17] and then solving for $\alpha^{1/4}$. The magnitudes of $\alpha^{1/4}$ varied from unity when the pipe was filled with liquid to about 10 when the liquid was flowing in an annulus.

In order to generalize the test results, a parameter was sought which would allow the correlation of the magnitudes of $\alpha^{1/4}$ for the various fluids and pipe diameters for which data were available. Many dimensionless groups were tried, but the best correlation of the data was obtained when the multiplier of $\alpha^{1/4}$ in Equation [17] was utilized. This parameter represents the ratio of shearing forces in the two fluid phases, and thus is a logical basis for the correlation of the magnitudes of α.

For simplicity in calculation, the dimensionless group

$$\chi_{tt} = \left(\frac{\mu_l}{\mu_g}\right)^{0.111}\left(\frac{\gamma_g}{\gamma_l}\right)^{0.555}\left(\frac{W_l}{W_g}\right) \quad \ldots\ldots [18]$$

was defined. The multiplier of $\alpha^{1/4}$ in Equation [17] is thus $(\chi_{tt})^{3/4}$. The subscript *tt* refers to the turbulent flow of the liquid and gas.

In Fig. 10 is shown the plot of $\alpha^{1/4}$ as a function of $(\chi_{tt})^{3/4}$. The scattering of the experimental points is rather severe at low magnitudes of the parameter χ_{tt}, but when it is observed that five different liquids, and data from two experimenters are plotted, the correlation is, on the whole, satisfactory. The scattering of the points is in part due to the use of a constant exponent of 0.20 in the empirical equation for the friction factor; the actual exponent varies with the Reynolds modulus. Further, due to the "slugging" flow of the liquid during certain runs, the pressure drop varied periodically with time, and the recorded mean pressure drop may not represent a true time average. Finally, the fact that $\alpha^{1/4}$ includes the effect of relative motion between the fluids, as well as the flow geometry, may cause some scattering. There seems to be some slight evidence that a third parameter may enter the correlation since the points for water are on the average somewhat higher than the points for the hydrocarbon liquids. The variation of surface tension obtained in these tests seems to be of little importance in the evaluation of $\alpha^{1/4}$, since the points for water, and the water-Kemenol, and water-Nekal mixtures are almost coincident.

From the point of view of ease in calculation, an interesting

point is to be noted; since $\alpha^{1/4}$ is a function of χ_{tt}, inspection of Equation [17] reveals that

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \left(\frac{\Delta P}{\Delta L}\right)_g [1 + \alpha^{1/4}\chi_{tt}^{3/4}]^{2.4}$$

$$= \left(\frac{\Delta P}{\Delta L}\right)_g [1 + f(\chi_{tt})(\chi_{tt})^{3/4}]^{2.4} \quad \ldots\ldots\ldots\ldots [19]$$

Thus the pressure drop in two-phase flow depends only upon the product of the pressure drop of the gaseous component flowing alone, and a function of χ_{tt}. The latter function may be readily evaluated. A curve was faired through the experimental points

TABLE 3 MAGNITUDES OF THE FUNCTION Φ_{tt}

$\sqrt{\chi_{tt}}$	Φ_{tt}
0	1.00
0.10	1.50
0.20	1.68
0.40	2.13
0.70	3.03
1.00	4.08
2.00	8.30
4.00	19.6
7.00	42.3
10.0	71.0
20.0	222
40.0	770
46.2	1000

For $\sqrt{\chi_{tt}} > 46$ $\quad \Phi_{tt} = (\sqrt{\chi_{tt}})^{1.8}$

of Fig. 10. For each magnitude of χ_{tt} a value of $\alpha^{1/4}$ was established. Then

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \left(\frac{\Delta P}{\Delta L}\right)_g [1 + \alpha^{1/4}\chi_{tt}^{3/4}]^{2.4} = \Phi_{tt}^2 \left(\frac{\Delta P}{\Delta L}\right)_g \quad [20]$$

where

$$\Phi_{tt} = [1 + \alpha^{1/4}\chi_{tt}^{3/4}]^{1.2}$$

Table 3 presents magnitudes of Φ_{tt} versus $\sqrt{\chi_{tt}}$. The square-root form was utilized in order to reduce the range of the variables to facilitate plotting. Fig. 11 presents Φ_{tt} versus $\sqrt{\chi_{tt}}$ and may be utilized directly for the calculation of two-phase pressure drop.

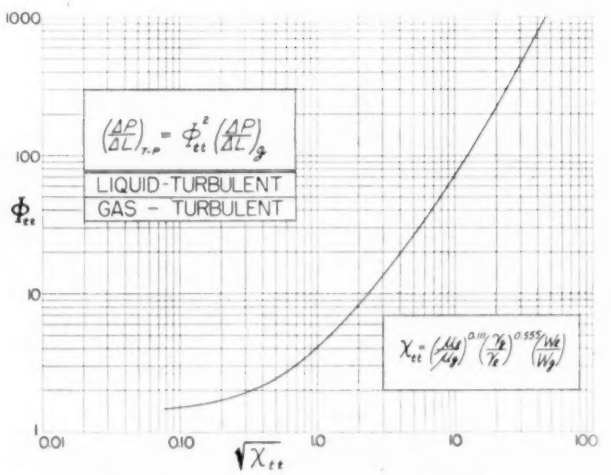

FIG. 11 MODULUS Φ_{tt} AS A FUNCTION OF TWO-PHASE FLOW MODULUS $\sqrt{\chi_{tt}}$ FOR FLOW MECHANISM IN WHICH BOTH LIQUID AND GAS ARE IN TURBULENT MOTION. THE MODULUS Φ_{tt} MAY BE UTILIZED DIRECTLY TO CALCULATE THE PRESSURE DROP OCCURRING IN TWO-PHASE FLOW

Fig. 11 reveals that, as χ_{tt} approaches zero, Φ_{tt} approaches unity very slowly due to the rapid increase of $\alpha^{1/4}$ at low magnitudes of χ_{tt}. It follows that, even if the fluid just wets the pipe wall (low values of χ_{tt}) the two-phase pressure drop is increased appreciably over that due to the gaseous components alone. For $\sqrt{\chi_{tt}}$ equal to 0.10 which corresponds to a reasonable liquid flow, the two-phase pressure drop is 2.25 times that of the gas alone. At high magnitudes of $\sqrt{\chi_{tt}}$ the curve of Φ_{tt} approaches an asymptote with a slope of 1.8.

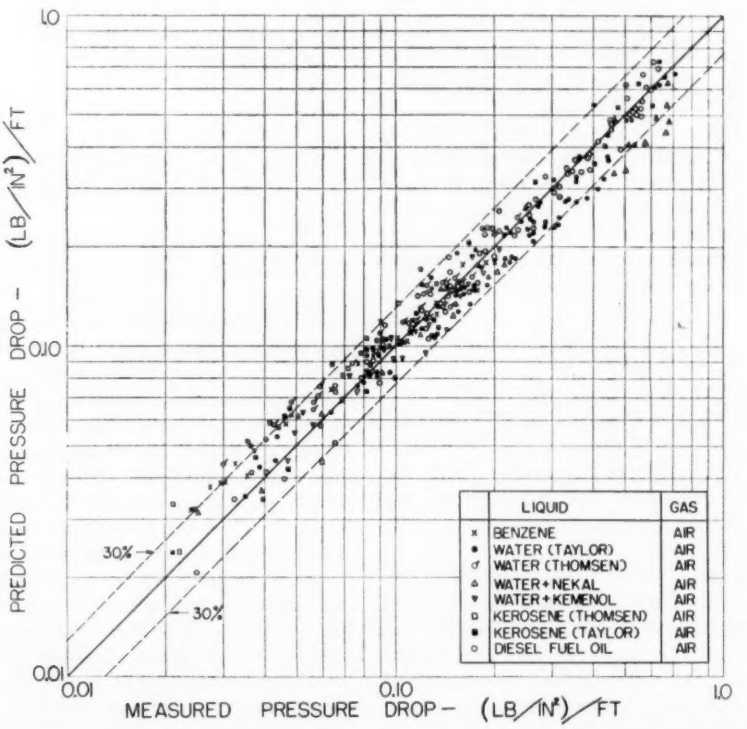

FIG. 12 COMPARISON OF PREDICTED AND MEASURED PRESSURE DROP FOR TWO-PHASE TWO-COMPONENT FLOW. FLOW MECHANISM IN WHICH BOTH LIQUID AND GAS ARE IN TURBULENT MOTION. PREDICTION BY MEANS OF FIG. 11

Fig. 11 was utilized to predict the pressure drops observed in the laboratory by calculating χ_{tt} based on experimental values of μ_g, μ_l, γ_g, γ_l, W_g, and W_l. The results of these calculations are shown in Fig. 12. The prediction is seen to be well within ±30 per cent for a large majority of the points. Thus, within the range of the experimental variables which are listed in Table 1, Equation [17], or its equivalent Fig. 11, may be utilized to predict the pressure drop accompanying two-phase two-component flow when both phases are in turbulent motion. Extrapolation of Equation [17] to magnitudes of the variables greatly different from those utilized in the tests should be made with caution until the general applicability of the parameter χ_{tt} is tested by further research.

In order to determine how well Equation [17] could predict the curve shapes obtained experimentally, Fig. 11 was utilized to predict the pressure drop along a 1-in. glass pipe in which air and water were flowing at an average pressure of 14.7 psia and a temperature of 66 F. The resulting predicted curves of pressure drop versus air rate for several constant liquid rates are shown in Fig. 13. The agreement between these curves and the experimental points shown in Fig. 2 is satisfactory. Lack of agreement at some points is no doubt due in part to the rather arbitrary method utilized to correct the experimental data shown in Fig. 2 to standard conditions (see Appendix 2).

Flow Mechanism 2. Liquid Viscous, Gas Turbulent

The equation for the two-phase pressure drop for the second flow mechanism is derived by substituting $m = 0.2$ and $n = 1$ in Equations [8] and [9]. Further substitution of Equations [8], [9], [6], [7] into Equation [1] and [2] yields

$$\frac{D_l^4}{D_g^{4.8}} = \left(\frac{\pi}{4}\right)^{0.8} g^{0.8} \frac{C_l}{C_g} \cdot \frac{\gamma_g}{\gamma_l} \cdot \frac{\mu_l}{\mu_g^{0.2}} \cdot \frac{W_l}{W_g^{1.8}} \cdot \frac{1}{\alpha} \quad \ldots\ldots [21]$$

or

$$\left(\frac{D_l}{D_g}\right)^4 = \left(\frac{\frac{\pi}{4} g \mu_g D_p}{W_g}\right)^{0.8} \frac{C_l}{C_g} \cdot \frac{\gamma_g}{\gamma_l} \cdot \frac{\mu_l}{\mu_g} \cdot \frac{W_l}{W_g} \left(\frac{D_g}{D_p}\right)^{0.8} \frac{1}{\alpha} \quad [22]$$

$$\left(\frac{D_l}{D_g}\right)^2 = (Re_g)^{-0.4} \sqrt{\frac{C_l}{C_g} \cdot \frac{\gamma_g}{\gamma_l} \cdot \frac{\mu_l}{\mu_g} \cdot \frac{W_l}{W_g}} \left(\frac{D_g}{D_p}\right)^{0.4} \alpha^{-1/2} \quad [23]$$

Both C_l and C_g appear in Equation [23] in contrast to Equation [10], in which neither constant appeared. For smooth pipes, magnitudes of $C_l = 64$ and $C_g = 0.184$ may be utilized as a good approximation.

It is convenient at this point to define a variable χ_{vt} which will be utilized to correlate the magnitudes of $\alpha^{1/2}$ for the second flow mechanism.

$$\chi_{vt} = (Re_g)^{-0.8} \left(\frac{C_l}{C_g} \cdot \frac{\gamma_g}{\gamma_l} \cdot \frac{\mu_l}{\mu_g} \cdot \frac{W_l}{W_g}\right) \quad \ldots\ldots [24]$$

Then Equation [23] may be written as

$$\left(\frac{D_l}{D_g}\right)^2 = \sqrt{\chi_{vt}} \left(\frac{D_g}{D_p}\right)^{0.4} \alpha^{-1/2} \quad \ldots\ldots [25]$$

The second fundamental relation, equating the sum of the gas and liquid volumes to the pipe volume yields, as before

$$\alpha D_l^2 + D_g^2 = D_p^2 \quad \ldots\ldots [26]$$

Eliminating D_l between Equations [25] and [26] results in the equation

$$\left(\frac{D_p}{D_g}\right) = \left[\left(\frac{D_p}{D_g}\right)^{0.4} + \alpha^{1/2} \sqrt{\chi_{vt}}\right]^{1/2.4} \quad \ldots\ldots [27]$$

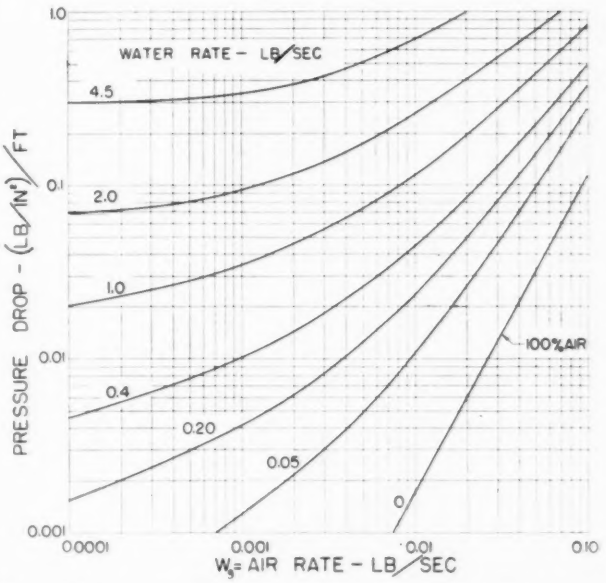

Fig. 13 Predicted Pressure Drop in Two-Phase Flow as a Function of Fluid Rates. Air-Water Flow in a 1-In. Glass Pipe, p = 14.7 Psia, t = 66 F. Both Fluids in Turbulent Motion. Prediction by Means of Fig. 11
(Compare with experimental curves in Fig. 2.)

Equation [15] is again applicable; thus

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \left(\frac{\Delta P}{\Delta L}\right)_g \left(\frac{D_p}{D_g}\right)^{5-m} \quad \ldots\ldots [28]$$

The exponent $m = 0.2$, since the gas is flowing with turbulent motion. Substituting Equation [27] into Equation [28] yields

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \left(\frac{\Delta P}{\Delta L}\right)_g \left[\left(\frac{D_p}{D_g}\right)^{0.4} + \alpha^{1/2} \sqrt{\chi_{vt}}\right]^2 \quad \ldots [29]$$

When the term $\left(\frac{D_p}{D_g}\right)^{0.4}$ is important in Equation [29], χ_{vt} is small. This occurs when W_g is large and W_l small, i.e., when the pipe is filled with gas. Thus, it is permissible, with little error, to replace $\left(\frac{D_p}{D_g}\right)^{0.4}$ by unity. The equation for two-phase pressure drop, for the case when the liquid is flowing viscously and the gas is in turbulent motion, then becomes

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \left(\frac{\Delta P}{\Delta L}\right)_g \left[1 + \alpha^{1/2} (Re_g)^{-0.4} \sqrt{\frac{C_l}{C_g} \cdot \frac{\gamma_g}{\gamma_l} \cdot \frac{\mu_l}{\mu_g} \frac{W_l}{W_g}}\right]^2 \quad [30]$$

In order to establish the applicability of Equation [30] the Reynolds modulus for each fluid phase must be calculated, utilizing the rates W_g and W_l, the fluid viscosities, and the pipe diameter. If the Reynolds modulus for the liquid (Re_l) is less than 2000, and if the Reynolds modulus for the gas (Re_g) is greater than 2000, Equation [30] is applicable. An example of the method of calculation is shown in Appendix 1.

Evaluation of α for Flow Mechanism 2. Equation [30] was utilized to evaluate $\alpha^{1/2}$ from experimental data. The function $\alpha^{1/2}$ was found to vary from 1 at high liquid rates and low gas rates to about 5 at low liquid rates and high gas rates. The magnitudes of $\alpha^{1/2}$ for the three fluids employed in the test were correlated by means of χ_{tt}, as defined by Equation [24]. The

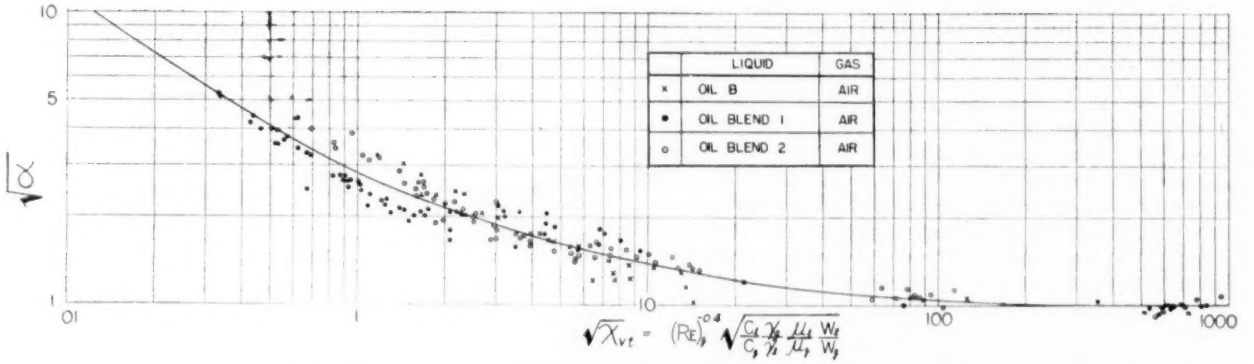

FIG. 14 FLOW TYPE MODULUS $\alpha^{1/2}$ AS A FUNCTION OF TWO-PHASE FLOW MODULUS $\sqrt{\chi_{vt}}$. FLOW MECHANISM IN WHICH THE LIQUID FLOWS VISCOUSLY AND THE GAS IS IN TURBULENT MOTION

70.0	75.8
100	105
200	203
400	400
1000	1000
For $\sqrt{\chi_{vt}} > 1000$	$\Phi_{vt} = \sqrt{\chi_{vt}}$

resulting plot of $\alpha^{1/2}$ versus $\sqrt{\chi_{vt}}$ is shown in Fig. 14. The scattering of the data is about the same as in Fig. 10, evidence of a third parameter again being present, but the trend is not conclusive. A single curve was faired through the experimental points, and Φ_{vt} defined by

$$\Phi_{vt} = [1 + \alpha^{1/2}\sqrt{\chi_{vt}}] \quad [31]$$

was calculated. The resulting curve is shown in Fig. 15 and the data are tabulated in Table 4.

Fig. 15 reveals that, again, due to the rapid rise of $\alpha^{1/2}$ at low magnitudes of χ_{vt}, the curve of Φ_{vt} approaches unity slowly. Thus, even at very low liquid rates and high gas rates (walls just wetted) the two-phase pressure drop is increased greatly over that due to the gas phase alone. A small amount of viscous oil flowing along the walls of a pipe ($\sqrt{\chi_{vt}} = 0.10$) may quadruple the pressure drop. The curve of Φ_{vt} versus $\sqrt{\chi_{vt}}$ reaches an asymptote with a slope of unity at high magnitudes of $\sqrt{\chi_{vt}}$.

A plot of the predicted pressure drops versus the measured pressure drops is shown in Fig. 16. The prediction was accomplished by calculating χ_{vt} for the experimental conditions, obtaining Φ_{vt}, and calculating

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \Phi_{vt}^2\left(\frac{\Delta P}{\Delta L}\right)_g \quad [32]$$

The shape of the experimental curves, shown in Fig. 7, are well predicted by Equation [30]. Fig. 15 was used to calculate the pressure drop along a 1-in. glass pipe in which air and oil *B* were flowing at an average pressure of 14.7 psia and a temperature of 66 F. The predicted curves of pressure drop versus air rate at constant oil rates are shown in Fig. 17 and agree very well with the experimental data of Fig. 7.

It may be concluded that Equation [30], or its equivalent Fig. 15, can be utilized to predict pressure drop in two-phase flow when the gas is flowing with turbulent motion and the liquid with viscous motion. Extrapolation to magnitudes of the variables very much different from those covered by the tests are to be made with caution until the general applicability of the parameter χ_{vt} is tested by further research.

FLOW MECHANISM 3. LIQUID VISCOUS, GAS VISCOUS

Although the type of two-phase flow in which both phases are flowing with viscous motion was not observed in the tests on the 1-in. and $^1/_2$-in. pipe, the analysis of this phenomenon will be presented. Flow of two phases in porous media is of this viscous character, and perhaps an application of the equations which have been developed to this type of problem is possible.

It will be readily seen that Equation [10] is directly applicable to this problem, with the exponent $n = 1$. This substitution yields

$$\left(\frac{D_p}{D_g}\right)^2 = \left(\frac{\gamma_g}{\gamma_l}\right)^{1/2}\left(\frac{\mu_l}{\mu_g}\right)^{1/2}\left(\frac{W_l}{W_g}\right)^{1/2}\frac{1}{\alpha^{1/2}} \quad [33]$$

Substitution of Equation [33] into Equations [12] and [15] results in the equation for pressure drop in two-phase flow when both phases are flowing with viscous motion

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = \left(\frac{\Delta P}{\Delta L}\right)_g\left[1 + \alpha^{1/2}\left(\frac{\mu_l}{\mu_g}\right)^{1/2}\left(\frac{\gamma_g}{\gamma_l}\right)^{1/2}\left(\frac{W_l}{W_g}\right)^{1/2}\right]^2 \quad [34]$$

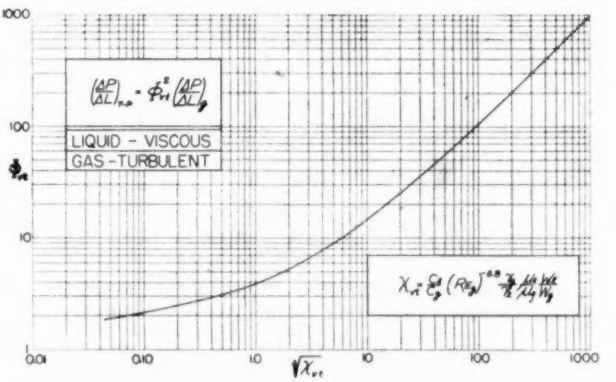

FIG. 15 MODULUS Φ_{vt} AS A FUNCTION OF TWO-PHASE-FLOW MODULUS $\sqrt{\chi_{vt}}$, FOR FLOW MECHANISM IN WHICH THE LIQUID FLOWS VISCOUSLY AND THE GAS IS IN TURBULENT MOTION. THE MODULUS Φ_{vt} MAY BE UTILIZED DIRECTLY TO CALCULATE THE PRESSURE DROP OCCURRING IN TWO-PHASE FLOW

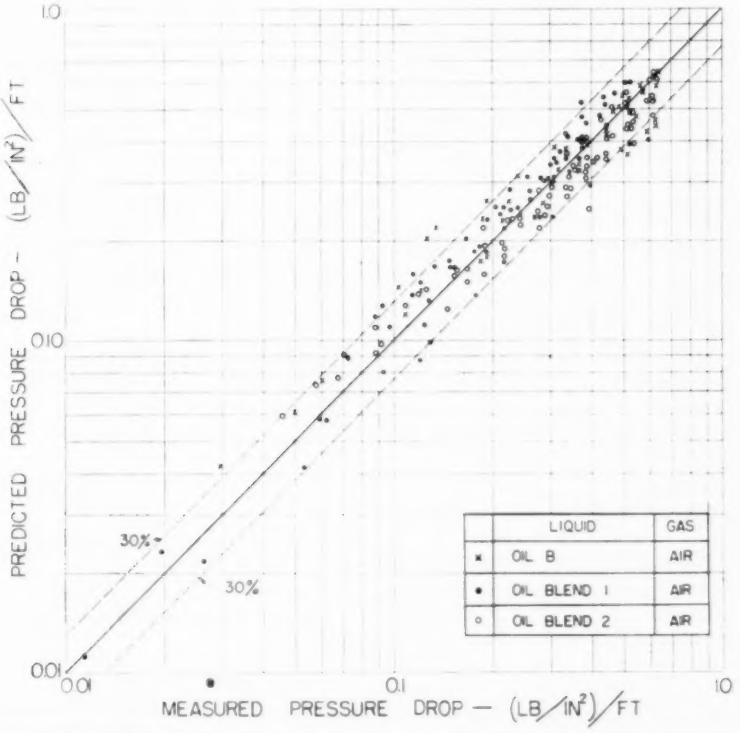

FIG. 16 COMPARISON OF PREDICTED AND MEASURED DROP FOR TWO-PHASE, TWO-COMPONENT FLOW. THE LIQUID FLOWS VISCOUSLY AND THE GAS IS IN TURBULENT MOTION. PREDICTION BY MEANS OF FIG. 15

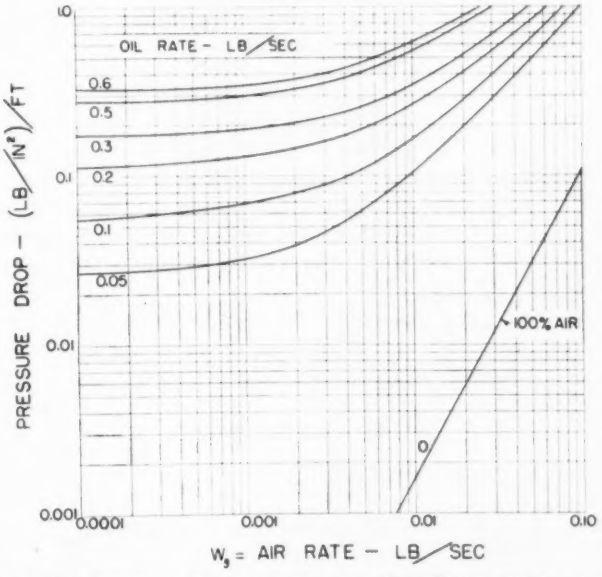

FIG. 17 PREDICTED PRESSURE DROP IN TWO-PHASE FLOW AS A FUNCTION OF FLUID RATES. AIR-OIL B FLOW IN A 1-IN. GLASS PIPE p = 14.7 PSIA, t = 66 F. OIL FLOWING VISCOUSLY, AIR IN TURBULENT MOTION. PREDICTION BY MEANS OF FIG. 15
(Compare with experimental curves in Fig. 7.)

Again $\left(\frac{\Delta P}{\Delta L}\right)_g$ is the pressure drop which would exist if the gas alone were flowing through the pipe of diameter D_p with weight rate W_g and density γ_g. In the case of flow through porous media $\left(\frac{\Delta P}{\Delta L}\right)_g$ would probably be the pressure drop through a given medium for the gas phase flowing alone with a rate W_g.

The function $\alpha^{1/2}$ will probably be correlated by means of the parameter $\chi_{tt} = \left(\frac{\mu_l}{\mu_g} \cdot \frac{\gamma_g}{\gamma_l} \cdot \frac{W_l}{W_g}\right)$.

FLOW MECHANISM 4. GAS VISCOUS, LIQUID TURBULENT

The fourth flow mechanism, in which the gas is flowing viscously and the liquid has turbulent motion, is very unlikely to exist in practice. The solution of this problem would, however, follow in detail the solution for the second flow mechanism, by merely interchanging the exponents of the gas and liquid phases.

CONCLUSIONS

1 There are four flow mechanisms possible in two-phase flow, as follows:

(*a*) Both gas and liquid may flow in turbulent motion.
(*b*) Gas may flow turbulently, liquid viscously.
(*c*) Both gas and liquid may flow viscously.
(*d*) Gas may flow viscously, liquid turbulently.

2 The first two mechanisms have been noted experimentally and have been analyzed macroscopically in this paper. The third type has been analyzed but has not been observed by the authors, although this mechanism undoubtedly exists in practice.

3 Equation [17], or Fig. 11, allows the prediction of two-phase pressure drop for the flow mechanism in which both phases flow with turbulent motion. Equation [17] predicts the experimental pressure drop with a maximum error of about ± 30 per cent.

4 Equation [30], or Fig. 15, allows the prediction of two-phase pressure drop for the flow mechanism in which the liquid is flowing viscously and the gas turbulently. Equation [30] predicts the experimental pressure drop with a maximum error of about ± 30 per cent.

5 Extrapolation of the equations to variables with magni-

tudes which are much different from those tested must be made with caution until the general applicability of the parameters X_{tt} and X_{vt} has been tested by further research.

6 Equation [34] is suggested as the equation to be utilized to predict two-phase pressure drop for the flow mechanism in which both phases are flowing viscously. The relation between α and χ_{vv} is still to be established.

Acknowledgments

The authors wish to thank E. A. Martinelli for many pertinent suggestions on experimental techniques, R. W. Ravenscroft, M. L. Taylor, and R. Guillou for experimental assistance, W. J. Cummings, H. L. Eagles, and J. DeCosta for aid in the construction of the equipment, and J. Rademacher, L. M. Grossman, and G. Young for assistance in computations. The authors also express their gratitude to the Shell Oil Company, Inc., for its 1941 Shell Fellowship, under which some of this work was done, and for the donation of the oils used in the tests.

Appendix 1

In order to illustrate the application of the method outlined in the paper, three examples will be presented. The first is an example of the prediction of the pressure drop in a 2-in. horizontal pipe in which both air and water are flowing at known rates. The second is an example of the calculation of the pressure drop along a 2-in. pipe in which air and an oil are flowing simultaneously. The third example presents a tentative outline for the application of the proposed method to the prediction of the pressure drop along a horizontal tube in which a liquid is being evaporated.

Example 1

It is desired to estimate the pressure drop in 100 ft of 2-in. pipe, in which air is flowing at a rate of 0.50 lb per sec, and water is flowing at a rate of 6 lb per sec. The temperature of the fluids is 77 F and the average pressure in the line is 100 psia.

(*a*) *Determination of properties and type of flow:*

W_g = 0.50 lb per sec
γ_g = 0.502 lb per cu ft at 100 psia and 77 F
μ_g = 0.388×10^{-6} lb-sec per sq ft at 100 psia and 77 F

Reynolds modulus for gas considered as a single phase (Re_g) = 295,000

W_l = 6.0 lb per sec
γ_l = 62.2 lb per cu ft at 77 F
μ_l = 1.87×10^{-5} lb-sec per sq ft at 77 F

Reynolds modulus for liquid considered as a single phase (Re_l) = 73,500

Equation [17] may be utilized since both phases are flowing turbulently.

(*b*) *Calculation of pressure drop due to air alone* = $(\Delta P/\Delta L)_g$:

The usual calculation reveals that the pressure drop resulting from the flow of 0.50 lb per sec of air at 77 F, 100 psia, in a 2-in. pipe is 1.03 psi per 100 ft of pipe. (For the flow of the gas in commercial pipe at Re_g = 295,000 the friction factor (3) is equal to 0.018).

(*c*) *Calculation of* X_{tt}:

$$X_{tt} = \left(\frac{\mu_l}{\mu_g}\right)^{0.111} \left(\frac{\gamma_g}{\gamma_l}\right)^{0.555} \left(\frac{W_l}{W_g}\right) = 1.28$$

(*d*) *Calculation of* Φ_{tt}:

$$\sqrt{\chi_{tt}} = 1.13$$

thus

$$\Phi_{tt} = 4.6 \text{ (Fig. 11)}$$

(*e*) *Calculation of* $(\Delta P/\Delta L)_{T-P}$:

$\left(\frac{\Delta P}{\Delta L}\right)_{T-P}$ = $(4.6)^2$ (1.03) = 21.8 psi per 100 ft of pipe, which is about 21 times the pressure drop for the air alone and 14 times the pressure drop for the water alone. (For the flow of the liquid in commercial pipe at Re_l = 73,500, the friction factor, reference 3, is equal to 0.0232.)

Example 2

It is desired to estimate the pressure drop in 100 ft of 2-in. pipe in which air is flowing at a rate of 0.50 lb per sec, and an oil (whose properties will be given) is flowing with a rate of 0.30 lb per sec. The temperature of the fluids is 77 F and the average line pressure is 100 psia.

(*a*) *Determination of properties and type of flow:*

W_g = 0.50 lb per sec
γ_g = 0.502 lb per cu ft (at 100 psia and 77 F)
μ_g = 0.388×10^{-6} lb-sec per sq ft (at 100 psia and 77 F)

Reynolds modulus for gas considered as a single phase (Re_g) = 295,000

W_l = 0.30 lb per sec
γ_l = 55 lb per cu ft (77 F)
μ_l = 600×10^{-5} lb-sec per sq ft (77 F)

Reynolds modulus for oil considered as a single phase filling the pipe (Re_l) = 11.5.

Since the liquid is in viscous motion and the gas in turbulent motion, Equation [30] must be utilized.

(*b*) *Calculation of* X_{vt}:

$$X_{vt} = \frac{C_l}{C_g} (Re_g)^{-0.8} \frac{\mu_l}{\mu_g} \cdot \frac{\gamma_g}{\gamma_l} \cdot \frac{W_l}{W_g}$$

Take C_l = 64 (see text for discussion)
C_g = 0.216 (for commercial pipe (3), the constant C_g is greater than 0.184 which applies only to smooth pipes)

Then χ_{vt} = 1.07

(*c*) *Evaluation of* Φ_{vt}:

$$\sqrt{\chi_{vt}} = 1.03$$

Thus

$$\Phi_{vt} = 3.9 \text{ (Fig. 15)}$$

(*d*) *Calculation of* $(\Delta P/\Delta L)_{T-P}$:

$$\left(\frac{\Delta P}{\Delta L}\right)_{T-P} = (3.9)^2 (1.03) = 15.7 \text{ psi per 100 ft}$$

Thus, the pressure drop for the two-phase case is about 15 times the pressure drop of the air alone and 15 times the pressure drop due to the oil flowing alone. Comparison of examples 1 and 2 reveals that 0.30 lb per sec of the oil had almost as much effect on the pressure drop as 6 lb per sec of water.

Example 3

It is desired to predict the pressure as a function of distance along a horizontal tube in which evaporation is occurring. If it is assumed that at each section of the tube, the steady-state results discussed in the paper are applicable, the method of procedure is as follows:

(*a*) *Determination of amount of vapor present at any point in tube:*

From a heat balance on an element of tube of length dZ

$$f_c(\pi D_p dZ)\,\Delta t = 3600r\,dW_g \quad \ldots\ldots [1a]$$

Thus

$$W_g = \int_0^Z \frac{\pi f_c D_p \Delta t}{3600r}\,dZ = F_1(Z) \quad \ldots\ldots [1b]$$

Where $F_1(Z)$ represents the pounds of vapor per second flowing at any point Z feet from the entrance to the heating section.

(*b*) *Ratio of W_l/W_g:*

Since the total fluid rate is constant at any point along the tube

$$W_T = W_l + W_g$$

Thus

$$\frac{W_l}{W_g} = \left(\frac{W_T}{F_1(Z)} - 1\right) \quad \ldots\ldots [1c]$$

(*c*) *Pressure gradient of any point Z due to vapor flow alone:*

$$\left(\frac{dP}{dZ}\right)_g = \frac{1}{2}\left(\frac{\pi}{4}\right)^{-1.8} \frac{C_g \mu_g^{0.2} W_g^{1.8}}{g^{0.8}\gamma_g D_p^{4.8}} \quad \ldots\ldots [1d]$$

$$= F_2(Z) W_g^{1.8} = F_2(Z)[F_1(Z)]^{1.8} = F_3(Z) \quad \ldots\ldots [1e]$$

(*d*) *Pressure gradient with two-phase flow:*

From Equation [17] (assuming turbulent flow of both phases)

$$\left(\frac{dP}{dZ}\right)_{T-P} = F_3(Z)\left[1 + \alpha^{1/4}\left(\frac{\mu_l}{\mu_g}\right)^{0.082}\left(\frac{\gamma_g}{\gamma_l}\right)^{0.416}\left(\frac{W_T}{F_1(Z)} - 1\right)^{0.75}\right]^{2.4}$$

$$= F_3(Z)\left[1 + F_4(Z)\left(\frac{W_T}{F_1(Z)} - 1\right)^{0.75}\right]^{2.4} \quad \ldots\ldots [1f]$$

(*e*) *Pressure at any point:*

Integrating Equation [1*f*]

$$P = \int_0^Z F_3(Z)\left[1 + F_4(Z)\left(\frac{W_T}{F_1(Z)} - 1\right)^{0.75}\right]^{2.4} dZ \quad \ldots [1g]$$

The graphical evaluation of Equation [1*g*] is tedious, but not difficult.

Appendix 2

The measured pressure drops for two-phase flow were corrected approximately to standard conditions by the following equation

$$\left(\frac{\Delta P}{\Delta L}\right)_{corr} = \left(\frac{\Delta P}{\Delta L}\right)_{meas}\left[1 + \frac{\left(\frac{\Delta P}{\Delta L}\right)_{meas} - \left(\frac{\Delta P}{\Delta L}\right)_l}{\left(\frac{\Delta P}{\Delta L}\right)_{meas}}\left(\frac{\gamma_m}{\gamma_{std}} - 1\right)\right]$$

where

$\left(\frac{\Delta P}{\Delta L}\right)_{meas}$ = measured two-phase pressure drop for W_l lb per sec liquid, and W_g lb per sec gas

$\left(\frac{\Delta P}{\Delta L}\right)_{corr}$ = two-phase pressure drop corrected to "standard" conditions

$\left(\frac{\Delta P}{\Delta L}\right)_l$ = pressure drop due to W_l lb per sec of liquid flowing alone

γ_m = density of air at conditions of test

γ_{std} = "Standard" air density (66 F and 1 atm)

The points shown on Figs. 2 to 8, inclusive, were corrected to standard conditions by this approximate method.

The Differential Shrinkage of Wood

By W. L. GREENHILL,[1] SOUTH MELBOURNE, AUSTRALIA

This paper was prepared originally as discussion of a paper by A. J. Stamm and W. K. Loughborough (1),[2] but because of war conditions was not received until some months after publication of that paper and discussion. The results of shrinkage measurements made with the aid of the microscope on wood samples, consisting of thin radial sections cut entirely from rays, are of such interest that the Wood Industries Division considered their publication advisable. A discussion of the subject paper is also presented by A. J. Stamm and W. K. Loughborough.

THE fact that wood shrinks less in the radial than in the tangential direction is normally attributed to the restraining effect of the medullary rays. However, Stamm and Loughborough (1), mainly from the results of investigations by Ritter and Mitchell (2), state: "There can be no restraining action on the shrinking and swelling of wood in the radial direction by the ray cells." The work referred to consisted of a study of single cells of basswood holocellulose by polarized light, when it was found that the ray cells behaved differently from the fibers. The ray cells showed the same coloration as the fibers when their axes were perpendicular to the fibers, whereas when parallel one type of cell showed blue and the other yellow. It was concluded from these observations and from actual shrinkage measurements on isolated ray cells that rays have a large axial and small transverse shrinkage.

This explanation has already been challenged by Barkas (3), who points out that, in the examination of cells with polarized light, the preponderance of thickness determines the color in the microscope, whereas the strength of the fibrils in the different directions determines the swelling. In other words, the spirally wound fibrils in the primary walls of the ray cells may consist of a very thin layer which does not show in the microscope but which may exert considerable restraint on the lateral expansion of the secondary fibrils.

The use of shrinkage measurements on isolated fibers would in itself appear of doubtful value when applying the results to groups of fibers. To overcome this objection, shrinkage measurements have recently been made by the author on thin radial sections cut entirely from rays. In size these were up to 1/2 in. square and measurements were made with a microscope. Normal tangential and radial shrinkage values were determined for the same wood samples from thin cross sections. The results obtained are given in Table 1.

These results completely substantiate those of Clarke (4), and justify his conclusion that the axial shrinkage of the rays is less than the radial shrinkage of the wood as a whole, but that their transverse shrinkage is much greater than the longitudinal shrinkage of the wood as a whole. The evidence available thus appears to throw considerable doubt on Ritter's and Mitchell's conclusions. On the other hand, although the shrinkage of the rays axially is almost certainly less than the radial shrinkage of the wood as a whole, and therefore that the rays exert a restraining effect is indisputable, there is also some indication that, even without the restraining effect of the rays, radial shrinkage would still be less than tangential. To demonstrate this experimentally, shrinkage measurements have been made on small samples of three *Casuarina* species, some samples containing a normal proportion of the prominent rays in these species and some being prepared free from all but uniseriate rays. The results obtained, which are given in Table 2 show that by eliminating the large rays there is a definite increase in the radial shrinkage, but on the other hand an even greater increase would have been expected had the rays been solely responsible for the difference between the normal tangential and radial shrinkages.

TABLE 1 SHRINKAGE MEASUREMENTS ON THIN RADIAL SECTIONS

(Soaked to oven-dry; per cent soaked dimensions)

Species	Tangential[a]	Radial[a]	Longitudinal[a]
Casuarina luehmanni:			
Normal cross section	11.9	3.3	0.14
Rays	...	1.2	4.8
Grevillea robusta:			
Normal cross section	9.5	3.7	0.08
Rays	...	1.2	5.7
Xylomelum pyriforme:			
Normal cross section	8.0	2.0	0.17
Rays	...	0.7	1.8

Normal cross section	9.2	4.9	0.32
Rays	...	3.2	3.5

[a] Actual directions in tree in all cases.

TABLE 2 SHRINKAGE MEASUREMENT ON CASUARINA SPECIES

(Soaked to oven-dry; per cent soaked dimensions)

Species	Tangential	Radial
Casuarina cunninghamii:		
Normal	10.6	2.6
Free from large rays	10.8	3.9
Casuarina torulosa:		
Normal	9.0	2.0
Free from large rays	9.1	5.0
Casuarina luehmanni:		
Normal	11.9	3.3
Free from large rays	12.0	4.3

Possible factors in addition to the ray cells which may be responsible for the differential shrinkage are as follows:

1 The presence of a greater number of pits on the radial than the tangential faces of the fibers, resulting in the fibrils on the radial faces being less perfectly oriented than on the tangential faces. This explanation, according to Stamm and Loughborough (1) is due to Ritter and Mitchell (2), although nothing to this effect can be found in the reference given.

2 The effect of bands of wood of varying density, such as early and late wood or wide bands of parenchyma adjacent to bands of normal wood fibers. This explanation is suggested by Frey-Wyssling (5).

Collapse

An explanation of the excessive and irregular shrinkage known as collapse was first given by Tiemann (6). His "liquid-tension" theory has been generally accepted and satisfactorily explains the phenomenon and its effects, although some criticism of the theory has been made from time to time. The alternative "stress" theory propounded by Stamm and Loughborough certainly cannot be accepted without question as the main cause of collapse, but on the other hand it is quite probable that drying stresses assist in producing collapse. Some of the evidence which

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

favors the liquid-tension theory and which appears to have been overlooked by Stamm and Loughborough is as follows:

1 The fact that the presence of air prevents the occurrence of collapse, according to the tension theory, can be used to demonstrate the validity of this theory. Using two matched samples of green timber of a species subject to collapse, such as mountain ash (*Eucalyptus regnans*), carefully air-dry one of the samples so that the "free" water is removed from the cells. This sample should then be thoroughly soaked until its moisture content is at least as high as that of the green sample which, incidentally, should be kept green meanwhile. Both samples should now be dried at a temperature of about 140 F and a relative humidity of 80 per cent, conditions which favor collapse. It will be found that collapse occurs to a much greater extent in the green than in the resoaked piece. The reason for this is that in the soaking after drying, the entrapped air in the cell cavities is removed completely only with great difficulty so that very few of the cells become liable to collapse. In the original green condition a considerable number of the cells may, quite conceivably, be completely filled with water. Furthermore, it is found that any trees of such species as mountain ash, with an unusually high green-moisture content are particularly liable to collapse.

2 The statement by Stamm and Loughborough (1) that collapse is not randomly distributed throughout the wood but is located in the central zone under compression shows a lack of knowledge of even the appearance of timbers which collapse. Indeed one of the most usual features of collapse is its extremely irregular nature. The effect of the collapse of a cell is not, of course, shown in an isolated cell, as it is not possible without disruption of the fibers, for one cell to collapse without distorting those cells surrounding it. However, the most logical explanation of the variation in the degree of collapse in different portions of a board is surely the random distribution of areas of collapse-producing cells.

3 By cutting successive cross sections of a piece of wood of a species such as mountain ash, starting with sections about $^1/_4$ in. thick and gradually reducing the thickness it will be found that on drying the sections the tangential and radial shrinkages gradually decrease with decrease in thickness. However, this does not continue indefinitely and for thicknesses below about 0.05 in., the shrinkage is constant. Tests of this nature, made on various species, have been reported previously (7), and it has been shown that the thickness at which the shrinkage becomes constant bears a fairly constant ratio (1.6–1.8) to the fiber length. At such a thickness the great majority of the fibers would be cut at one end, evaporation of the free water could then proceed from this end, and internal tensions would not be possible.

A similar effect suggested by Tiemann can be observed by cutting a wedge-shaped sample of green wood tapering from a fine edge to 5 or 6 times a fiber length in the grain direction. On drying such a sample under conditions producing collapse, it will be found that the thin end shrinks uniformly, but where the thickness has increased to about $1^1/_2$ fiber lengths, the shrinkage becomes much greater and irregular in nature. No convincing explanation of this behavior seems possible from a consideration merely of simple drying stresses.

Discussion

A. J. Stamm[3] and W. K. Loughborough.[4] Ritter and Mitchell (2),[5] as a result of their optical and swelling measurements, concluded that "they (the ray cells) at least have a less restraining effect on radial swelling of wood than was previously believed." The author's data lead to the same conclusion. The matter of controversy thus rests on the degree to which ray cells can restrain radial swelling.

The author's data for the swelling of sections made up entirely of rays, show a swelling in the radial direction of the tree ranging from one third to two thirds of the swelling of the wood as a whole in the same direction. Ritter's and Mitchell's data (2), on the other hand, show a smaller difference between the swelling of individual ray cells and the wood as a whole in the same direction. These differences may be due to species differences, differences between measurements on single ray-cell fibers and ray-cell bundles, or differences in technique. In any case, the author's data indicate that the ray cells swell quite differently in their longitudinal direction (radial direction in the tree) from the longitudinal swelling of tracheids (10 times as much). This difference is explained by Ritter's and Mitchell's optical measurements.

Ritter and Mitchell recognize the fact that thickness of section in their optical measurements does affect the color to some extent. They have, however, taken this into consideration in drawing their conclusions. Their explanation of the retardation of radial swelling of wood by the pits did not, as the author states, appear in the article referred to. It appears elsewhere.[6]

The effect of pits on the swelling and shrinking will explain the differences obtained by the author between the radial swelling of normal wood and wood free from large rays. It is known that tracheids tend to end chiefly at junctions with ray cells and that the pits are more highly concentrated near the ends of tracheids. The tracheids of sections relatively free from ray cells will thus tend to have less pits on their surfaces and, as a result, will show a smaller swelling restraint along their radial walls.

Hence the writers feel that, on the basis of both the author's data and those of Ritter and Mitchell, the old concept of the ray cells furnishing the major restraint to radial swelling is not substantiated.

Collapse. Here again the controversy rests on a matter of differences in the extent to which two different mechanisms are effective in causing a certain phenomenon, rather than a complete difference in the mechanism. We believe that collapse in some cases is due to liquid tension, but in the case of North American

[6] "Structural Factors Contributing to the Directional Shrinking and Swelling of Wood," by G. J. Ritter and R. L. Mitchell, unpublished report of the Forest Products Laboratory, U. S Department of Agriculture, March, 1941.

woods, with which we are familiar, we feel that collapse is more frequently due to stresses than to a liquid tension. We include in our definition of collapse all cases where the shrinkage is abnormally high in contrast to some who consider that collapse has taken place only when groups of fiber cavities have completely caved in. Part of the difference of opinion as to the importance of the two forms of collapse rests on these two different definitions.

The author cites an experiment in which wood subject to collapse is carefully air-dried to remove free water and let air into the structure. Free water, however, cannot be removed from fibers which meet the requirements for liquid-tension collapse without causing the fibers to collapse. If air is admitted without collapse occurring, it is due to the fact that some air existed in the fiber cavities. In either case, stresses are set up during the initial drying. Decreased shrinkage after resoaking and again drying could be due either to a decrease in liquid-tension collapse, as maintained by the author, or to a decrease in stress collapse, as described in the writer's paper (1).

Experiments have been made at the Forest Products Laboratory in which sodium carbonate is allowed to diffuse into green blocks of wood, followed by the diffusion of acid into the structure to liberate carbon dioxide. This pretreatment did not reduce collapse when the block was dried under collapsing conditions. On the basis of the liquid-tension theory, the presence of gas in the cells should have eliminated collapse.

The writers have also made measurements on thin cross sections of wood. Under favorable drying conditions, it is true that collapse is decreased, but it is not eliminated as it would be if it were entirely due to liquid tension. The fact that the amount of collapse occurring in such sections can be varied appreciably under different drying conditions, makes us feel that it is largely due to stresses even in such sections. The existence of stresses in these thin sections can be observed by the way free water is first removed around the edges, giving a circular wet zone on the surface of each of the faces.

Collapse of the readily visible extreme type, we appreciate, may be somewhat randomly distributed, due to conditions for liquid-tension collapse, or due to groups of cell walls which have abnormally low compressive strengths. From our experience, however, the general decrease in fiber-cavity sizes seems to be chiefly concentrated in compression zones.

The writers wish to emphasize that the chief object of the latter part of their paper (1) was to point out that all collapse is not due to liquid tension, as so many believe, and that it can be logically explained on the basis of stresses. It is believed that the stress theory is more generally applicable than the liquid-tension theory.

ADVANCED-TRAINING PLANE, THE FAIRCHILD AT-21

Problems of Construction and Alternate Substitutions in Wood Aircraft

BY J. M. STEVENS,[1] HAGERSTOWN, MD.

Some of the problems coincident with the greatly expanded use of wood and plywood in aircraft construction are discussed in this paper. A greater use of certain approved alternate wood species in place of spruce and other critical aircraft materials is advocated. Several specific examples of what can be accomplished in the way of simplifying and standardizing the construction of flat and molded plywood constructions are presented.

WITH the advent of the present world conflict the demands made upon wood and plywood for use in aircraft manufacture have increased tremendously. As a result, these materials, first considered as noncritical, can now be considered only as less critical. In some instances they cannot be obtained at all in the quality and quantity required for our strategic offensive effort.

The magnitude of the demands that are being made upon the aircraft industry can be more readily understood when we recall President Roosevelt's speech made in the spring of 1940, in which he announced that the United States was going to produce 50,000 airplanes a year. This figure was subsequently boosted to 125,000 a year. It was soon apparent that our aluminum supply was not adequate to meet these requirements, so immediate plans were made for the expansion of our aluminum-producing facilities. In the meantime, manufacturers of light aircraft were requested to use nonstrategic materials wherever possible. As a result wood, in either laminated or plywood form rapidly gained a position of paramount importance in aircraft manufacture.

WOOD APPLIED SUCCESSFULLY TO TRAINING PLANES

One of the outstanding examples of the successful use of wood in aircraft construction is in the primary-training field, a typical example of which is the Fairchild designed PT-19.

The wings are constructed of two built-up spars with thin face-plating, and the ribs are constructed of square spruce capstrips reinforced by three-ply mahogany plywood gussets at all corners and joints. The outer wing covering is made of two sections of $^3/_{32}$-in. mahogany plywood with poplar core. This three-ply plywood is preformed to conform with the shape of the leading edge, and the bottom is flat, the two sections being joined at the trailing edge.

At present the rear cowling deck, formerly made of metal, is constructed of light veneers bonded by the Duramold process. Covers for the gas tanks on the underside of the center section formerly of aluminum alloy are also now made of wood. The

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

flaps which on the first production models were made of aluminum alloy, are now constructed of plywood.

These PT-19's, have withstood hundreds of thousands of hours of grueling flight-training work under many climatic conditions. In most cases hangar facilities are not sufficient to house all these aircraft every night, and a large percentage must be left to the mercy of the elements. Even under such extreme conditions, very encouraging service reports have been obtained.

The Fairchild AT-21, a two-engined trainer announced recently, is another example of how wood is being used successfully to meet the expanding training requirements of the AAF. The Beech AT-10 is similar in size while the Curtiss C-76 cargo plane, contract now canceled, was to have been many times larger.

It can be readily seen that as the size of wooden airplanes is increased the quantities of wood required to construct them is also proportionately increased. For example, 220 fbm of spruce lumber are required to construct the PT-19 airplane, whereas 1260 fbm are required to construct the AT-21 airplane. On the plywood side of the bill of material, a comparison shows 850 sq ft of plywood used for the PT-19, 3000 sq ft for the AT-21, while an estimated 12,000 sq ft would have been required for the C-76 cargo. When volume is taken into consideration, these plywood differences may become even greater. In 1942, the aircraft industry used 6,000,000,000 fbm of aircraft plywood. In view of the trend to more and larger types of wood aircraft, it can be expected that in 1943 the production of aircraft-grade wood and plywood will have been doubled in order to meet production schedules.

Coincident with this rapid expansion in number and size of wooden airplanes has been the problem of procuring material in sufficient quantity that would meet AN specifications. Supposedly inexhaustible supplies of aircraft woods simply were not available. The chief contributing factor to this situation is that only the very best quality of wood can be used in aircraft construction. This limits the quantity suitable for aircraft use to a very small percentage of actual production. In addition, there is a shortage of precision milling equipment that can cut to the varied and peculiar demands of the aircraft industry; service demands plus the lure of better paying defense jobs have created a shortage of skilled woods labor; there are not sufficient lumber kilns and veneer driers to maintain rapid delivery schedules. Aircraft grades are practically always cut to special order and rarely, if ever, are carried in stock by producing sawmills. This is due to the highly specialized nature of such grades and the wide ranges of sizes and lengths required by various aircraft manufacturers. Also, there has been a lack of specific information on potential sources of supply for these aircraft grades of lumber and veneer.

Wood Fabrication Problems

In 1941, the production of Douglas fir lumber was 8,000,000,000 ft or a weekly average production of 150,000,000 ft; 1942 production was the same. In contrast, the 1941 production of Sitka spruce lumber was only 1,300,000,000 or a weekly average of 25,000,000 ft which by 1942, had dropped to 7,000,000 ft, a decrease of over 350 per cent. Further, according to the West Coast Lumberman's Association, not over 1 per cent of fir is going into aircraft production at the present time, but probably another 3 or 4 per cent now going into pontoon lumber, ship decking, and so on, would meet aircraft specifications. The Forest Product's Laboratory estimates that only 2 per cent of fir lumber and 5 to 6 per cent of spruce will meet aircraft specifications.

TABLE 1 FIR AND SPRUCE AVAILABLE FOR AIRCRAFT PRODUCTION

	Average weekly production fbm	Aircraft grade per cent	Average weekly amount available aircraft fbm	Rating (spruce 100)
Spruce.....	7,000,000	5	350,000	100
Douglas fir.....	150,000,000	2	3,000,000	860

Taking 2 per cent of the present production of fir and 5 per cent of the present production of spruce as representative averages of the foregoing data, the amounts available for aircraft use are given in Table 1.

Because spruce combines the qualities of lightness, great strength, and stiffness per unit of weight, and also a considerable degree of toughness, it has always been of great value in the manufacture of wood airplanes where just such qualities are demanded. It is now chiefly used in the construction of spars for wings, bulkheads and stringers for fuselages, and so on, which parts are usually made of solid or laminated spruce in preference to other species.

Faced with a declining spruce production, it became apparent as early as 1940 that there would not be sufficient high-quality aircraft spruce to meet the requirements of an expanding aircraft industry. At that time three possible solutions to the problem were investigated by the Civil Aeronautics Authority, as follows:

1 A possible broadening of the interpretation of current spruce specifications by establishing a mechanical method of judging the quality of the basic material and a more intelligent judging of the weakening effects of surface defects.

2 The use of varying thickness and short-length material through laminating and splicing.

3 The use of substitute material.

That the first method is still a subject of much controversy is evidenced from the report of a meeting held at Longview, Wash., February 26, 1943, and at Chicago, Ill., October 13, 1943, to discuss the problems involved in the inspection of aircraft lumber. At this meeting were representatives of the War Production Board, West Coast Lumberman's Association, West Coast Bureau of Lumber Grades and Inspection, Pacific Lumber Inspection Bureau, Army Air Force, U. S. Dept. of Agriculture, manufacturers of aircraft lumber, and interested aircraft manufacturers. (A discussion of their findings is not considered pertinent at this time since this paper is chiefly concerned with the last method.)

The second method, permitting the use of short lengths and narrow widths, has been in effect with most companies for some time; for example, laminations are being made of pieces edge-glued together to obtain a given width with the restriction that edge joints in adjacent laminations shall be not closer than the thickness of the lamination. Short lengths are joined by scarf joints provided that the slope is not steeper than 1 in 15 for softwoods or 1 in 15 for hardwoods.

Authority Given to Use Alternate Woods for Spruce

By so doing, the available supply of aircraft-grade spruce was greatly increased. However, a critical shortage still appeared imminent, so in June, 1942, wood-aircraft manufacturers were advised that certain alternate woods could be used in place of spruce without change in design. The alternate woods suggested were western hemlock, noble fir, and yellow poplar.

It was soon discovered that the lumber industry was not prepared to supply these alternate woods in the quality called for in AN specifications. Some of the reasons for this situation have already been outlined. The following month (July, 1942) Port Orford cedar, Douglas fir, Southern cypress, Alaska cedar, and Norway pine were also given approval as direct substitutes for spruce without change in design. However, spruce continued to be available, whereas the alternates were not.

In September, 1942, the use of Douglas fir was again recommended specifying normal Douglas fir with a specific gravity range of not less than 0.45. This was followed by an announce-

THE FUSELAGE SHELL, WINGS, TAIL SURFACES, AND MANY OTHER PARTS OF THE AT-21 ARE OF PLYWOOD CONSTRUCTION

ment, made in January, 1943, of a new classification of Douglas fir known as light Douglas fir, having a specific gravity of 0.38 to 0.47. As this latter class requires special selection and is therefore limited in quantity, its use has been restricted to certain types of wood aircraft. Latest information indicates that sufficient quantities of aircraft spruce, noble fir, western hemlock, and yellow poplar will be available to meet scheduled production requirements.

Thus it can be seen that, with the decline in the supply of aircraft spruce, the problem of what woods can or cannot be used as alternate materials has assumed ever greater importance. This is particularly true in the case of subcontractors, most of whom are having their first experience in aircraft construction and are frequently experiencing considerable difficulty in obtaining specified materials. In an attempt to clarify this somewhat confused situation a "Wood and Glue Alternate and Substitution Chart" was prepared by the author's company.

On this chart are listed all woods commonly used in aircraft construction. In one section are listed all alternates that may, without specific engineering approval, be used as replacements for the material specified on the drawing. In the second section is another group, classed as "substitutes," no one of which may be used as a replacement for the material specified on the drawing without specific engineering approval. Similar procedure has been adopted to aid in the proper selection and use of synthetic-resin adhesives. The current specifications are listed in order to provide an exact means of quality control.

In the preparation of this chart weight or specific gravity was the most important controlling factor in making each choice. Ease of working was also given consideration. As the availability of a given material cannot readily be determined and may change from day to day, this aspect was not considered pertinent in the analysis.

Weight is extremely important in all aircraft construction. For example, a complete change from spruce to western hemlock without any change in design would increase the weight of the PT-19 airplane by approximately 21 lb and the AT-21 airplane by approximately 92 lb. This is not overly serious. However, a complete change to Douglas fir (normal type) would increase the weights of these two airplanes by 70 and 294 lb, respectively. For this reason, Douglas fir cannot be considered as a desirable substitute for spruce without changes in design. Once an airplane is in production, any change in design is costly and time-consuming and should be avoided wherever possible.

PLYWOOD CONSTRUCTION PROBLEMS

Until quite recently, only a few woods, notably mahogany and poplar, were considered to be entirely satisfactory for flat and molded aircraft plywood constructions. Birch veneer has been used extensively for highly stressed plywood parts and for parts subject to excessive abrasion or wear. Other woods commonly but not extensively used for aircraft veneer are spruce, sweet gum, walnut, Douglas fir, and basswood.

The problems of veneer procurement and large molded-shell manufacture have long been complicated by the use of veneers under $^1/_{32}$ in. in thickness. Very flat veneers are required in the molding processes to permit accurate edge-fitting and fast laying of the veneer strips that are used to make up the large fuselage shells. Both gapping and overlapping which result from poor fitting subject these shells to extensive rework and occasionally to rejection. When veneers intended for layup into shells of simple curvature become buckled they cannot be joined and spliced successfully in the Diehl machines made for this purpose.

When veneer is cut and dried to $^1/_{48}$-in. thickness, only approximately 10 per cent of the total mahogany aircraft-veneer output, 7 per cent of the sliced-poplar aircraft-veneer output, and 3 per cent of the birch aircraft-veneer output are of suitable flatness for Duramold work. Use of any veneer other than flat stock results, as noted, in rework and rejection coupled with an increase in layup time ranging from 50 to 100 per cent. By increasing the cut thickness to $^1/_{32}$ in., it was found that approximately 25 per cent of the dried aircraft mahogany veneer, 20 per cent of the sliced-poplar veneer, and 10 per cent of the birch veneer could be efficiently utilized for Duramold work. This increase results from the following: (1) the thicker veneer, being stiffer, will remain flat when subjected to internal stresses developed during cutting and drying that would buckle a thinner veneer; (2) most modern veneer driers are so constructed that

they will flat-dry good veneer down to $^1/_{32}$ in. thick at a reasonable percentage of full capacity; full capacity being achieved when handling $^1/_{28}$-in. or thicker veneers. In order to get comparable results with $^1/_{48}$ in.-thick veneer, it is necessary to cut the drier capacity to 25 to 30 per cent of its total. In these times, veneer companies are unwilling to do this for even a 50 per cent premium.

Another factor, apart from that of thickness and flatness, complicating the present veneer situation, is the rapidity with which the various kinds of veneer fluctuate from noncritical to critical and back again. Several months ago mahogany appeared to be scarce, poplar and birch abundant. Today mahogany appears to be relatively plentiful, birch seems practically nonexistent, and poplar is very scarce. All veneer and plywood manufacturers are experiencing these difficulties, so these shortages can in no sense be considered as merely local.

Douglas fir and red gum provide two specific examples of procurement difficulties coincident with the manufacture of aircraft plywood. Douglas fir is only acceptable when quarter-sliced because vertical-grain fir veneer has more uniform strength properties than does rotary-cut veneer. Also, $^1/_{16}$ in. is about the usual minimum thickness that can be rotary-cut. As only three mills in the Pacific Northwest are equipped with slicing equipment, logs intended for aircraft veneer have to be shipped to the Midwest for processing. Red-gum veneer can be either sliced or rotary-cut but here again the rotary lathes located at the source of supply cannot cut aircraft veneers in quantity to the tolerances allowed, so it also becomes necessary to process these logs in the Midwest.

A third problem in the use of plywood has been, in the past, the lack of standardization of specifications. An example in point was the original Army and Navy plywood specification AN-NN-P-511 which did not specify the exact thicknesses of veneers that should be used in any given flat-plywood construction. This has since been corrected by revision "b" of this specification which calls out the exact thickness of faces, cross-bands, and cores for all standard aircraft plywood. These sizes are shown as decimal equivalents based on the kiln-dry-veneer thickness and will run slightly less than those given in the Wood Aircraft Fabrication Manual which are based on the green-veneer thickness.

Advantages of Standardization

To comply with a recent request of the Army Air Forces, who are attempting to increase production of plywood an estimated 80 per cent by standardization of veneer thicknesses and plywood constructions, and also to satisfy numerous and repeated requests from production departments, a detailed study was made of the plywood requirements of the AT-21 airplane with a view toward simplification of construction and species requirements wherever structurally possible. Such a study was made and the data prepared in chart form. Similar plywood charts have been prepared for other airplanes manufactured by the author's company.

In this chart, the plywood-construction preferences listed are based upon the following factors:

1 Minimum use of veneers under $^1/_{32}$ in. thick.
2 Adherence to standard veneer thicknesses.
3 Proper balance of finished plywood.
4 Availability of material.
5 Application to which material is put.
6 The use of over-all thicknesses and constructions that would give approximately the same strength as the original.

All-mahogany constructions have been given first preference in this chart. This reflects the relative ease of working and, apparently, of procuring this kind of veneer at this time as contrasted with the present scarcity of poplar. To offset to some extent the fluctuating supply of poplar, and to supplement the approved list of substitutes for poplar, it was recommended, wherever feasible, that the all-mahogany constructions be given preference over the mahogany-poplar constructions.

A detailed study, substantiated by test data on the fuselage assemblies, indicated that these simplified plywood constructions would offer the following advantages:

1 A net over-all decrease in weight on the airplane ranging from 9 to 19 lb, without any sacrifice in strength at highly stressed areas.

2 The procurement of satisfactory veneer would be simplified and use of critical material substantially reduced.

3. The time of layup and amount of glue (Tego film) used per unit would be materially reduced.

4 Production time per unit would be correspondingly decreased, thereby permitting the manufacture of more units than is now possible.

On this chart, in addition to the simplified plywood constructions, there is also an alternate and substitution chart for veneers. This is made up in the same manner as the wood chart previously described.

To check the comparative strengths of all the recommended alternate constructions, a series of tests was conducted of the various plywoods considered.

The results which follow are based upon comparative tests made from sample test panels constructed on a flat die by the bag-molding method. Process conditions were identical with those used in the manufacture of full-size shells. All veneers of a given thickness were taken from the same flitch in order that the variables inherent in tests of a nonhomogeneous material such as wood might be reduced as much as possible. It can be assumed therefore that the test results shown are reasonably indicative of what could be expected from any given Duramold shell.

Scope and Method of Testing Plywood

Tension Tests. Tests were made to determine the tensile strength of each plywood construction both parallel and perpendicular to the grain of the faces. Specimens 1 × 5 in. were used, with the center portion trimmed down to $^1/_2$ in. diam (radius $4^3/_4$ in.). The specimens were held by ordinary flat grips and tested in direct tension to rupture in a Riehle plywood-testing machine.

Shear Tests. Shear tests were made in the standard picture-frame-type shear-test fixture used by the Forest Products Laboratory. In all tests, face grain direction was either parallel (0 deg) or perpendicular (90 deg) to the direction of load.

Bending Tests. Bending tests, using strips of plywood 1 × 12 in. long, were used to obtain the modulus of rupture and the modulus of elasticity. Each plywood construction was tested in cross-bending as a simple beam. Bolts of $^1/_4$ in. diam mounted in roller bearings were used as end supports. This eliminated the effect of friction as the specimen bowed under load. Loads were applied by adding shot, in $2^1/_2$-lb increments, to a small container suspended from the center of the test specimen. Deflections at each increment of load were obtained from a Starrett gage, mounted directly over the point of application of load. Face-grain direction was either parallel (0 deg) or perpendicular (90 deg) to the long axis of the test specimen.

Summary of Test Data

Tables 2 and 3 summarize details of the test results. In these tables strengths have been averaged on both a pounds-per-square-inch and a total-load basis. The percentage comparison

made on the basis of total load is more applicable to this type of analysis since the thicknesses of the alternates are not always the same as those of the original constructions.

The alternate plywood constructions shown in Tables 2 and 3 were found to be acceptable from the standpoints of balance and strength. A proposed revision (2) for the rear uselage, also a 5-ply construction, and several proposed revisions for the outer wing panel, substituting 3-ply for 5-ply, were tested but were not considered acceptable, and were therefore not given further consideration.

Analysis of Strength Data

(*a*) *Front Fuselage.* Tests at 45 deg grain direction were not considered necessary in tension, compression, and shear, because in a balanced plywood construction these results would be directly proportional to those obtained at 0 deg and 90 deg. Inspection of test results for revisions (1) and (2) show that both alternate constructions are balanced in tension parallel and perpendicular to the grain and are equivalent in actual tensile strength to the original. Shear and bending strengths are higher as are the moduli of elasticity (based upon pounds per square inch) except for revision (1), an all-mahogany construction which at 90 deg, is 7 per cent lower. It was concluded that both revisions could be considered as entirely satisfactory replacements for the present construction.

(*b*) *Rear Fuselage.* A comparison of actual test values between the present construction and proposed revision (1) shows that the 5-ply construction is better balanced in tensile strength parallel and perpendicular to the grain and considerably stronger, particularly perpendicular to the face grain. Shear strength at 0 deg and 90 deg, and modulus of rupture at 0 deg are equivalent to the present constructions. The modulus of elasticity at 0 deg is somewhat higher owing to the thicker face plies.

Both modulus-of-rupture and modulus-of-elasticity values at 90 deg are lower than those obtained from the construction now in use. However, this difference is not too pronounced and is to be expected when fewer plies are used, because, in the 5-ply construction, the cross-bands which provide most of the stiffness perpendicular to the face grain, are closer to the core or neutral axis. From a structural standpoint, this 5-ply construction can also be considered as a satisfactory replacement for the 8-ply construction.

(*c*) *Wings.* Tests were not made to substantiate the proposed revisions to the wing-shell constructions. While it is true that the proposed revisions in the outer panel shells will introduce plywood of lower strength than the originally used birch-face constructions, these shells are not critically stressed, and the consequent reduction in strength, in part offset by using a $^1/_{32}$-in. instead of $^1/_{48}$-in. core, can be safely taken. The same is true of the center-section leading edge. In the highly stressed center-section top panels, however, the birch faces have been maintained and thickened. The additional thickness of the birch faces will adequately offset the slight reduction in over-all thickness. Also, at the highly stressed points, the alternate reinforcement construction is thicker than was the original. This will additionally offset the decrease in thickness of the outer plywood.

(*d*) *Fin.* The proposed substitution of mahogany-core material for the present poplar will increase the strength slightly.

(*e*) *Secondary Structures.* The proposed alternate constructions for the nose-wheel door, bomb-bay doors, wing tip, gun-turret fairing and tail cone are all on the side of increased strength.

Conclusions

In conclusion, it is felt that most of the difficulties being experienced by plywood-aircraft manufacturers can be traced directly to a lack of specific information on the part of the lumber manufacturer, the veneer and plywood manufacturer, and the subcontractor on the exact requirements of the aircraft industry.

To prevent further unnecessary delays in production of wood aircraft, the following recommendations are made:

1 That suppliers of basic materials give more consideration to the production of larger quantities of aircraft grades in conformance with current AN Specifications.

2 That the use of acceptable alternate materials to replace critical species be more widely adopted by the industry.

3 That aircraft manufacturers, wherever it is structurally possible, simplify and standardize the design and construction of flat- and molded-plywood parts.

Analysis of Stretch-Forming Double-Curved Sheet-Metal Parts

By R. B. GLASSCO[1] and N. O. MYKLESTAD[2]

Double-curved surfaces, typical in airplane design, are classified according to direction of curvature. A qualitative stress analysis is made of stretch-forming (process of clamping metal sheet at two opposite edges and forcing a punch into the taut sheet) each class of surface, with special reference to the stress transverse to the direction of restraint. It is shown that there are two distinctly different sources of transverse stress during stretching. The resultant stress may be tension or compression, depending upon the direction and amount of curvature. When the resultant transverse stress is compression, undesirable wrinkling of the sheet may occur.

Introduction

STRETCH-FORMING is a process of forming sheet metal into a curved surface by clamping the sheet at two opposite edges and forcing a punch of the desired shape into the taut sheet. A typical application of the process is the forming of the skin or outer surface of the modern metal airplane.

There are two limiting conditions in the application of the stretch-forming process. These limitations depend upon the amount of curvature in the desired surface. The first and more obvious limitation is tearing or rupturing of the sheet before it has been stretched over the entire surface of the punch. This limitation of tearing is a function of the ductility properties of the particular metal being formed. Some work has already been done to determine and improve the limit of stretch-forming with regard to tearing (1, 2).[3]

The second limitation in the application of the stretch-forming process is buckling of the sheet. This buckling results from compressive stresses transverse to the direction of restraint and leaves the formed sheet with undesirable permanent wrinkles. The factors determining whether a particular curved surface is subject to wrinkling or not are more obscure than they are for the limitation of tearing. In order to understand and, in some cases, eliminate wrinkling, it is desirable to make a qualitative stress analysis of a sheet subjected to the stretch-forming process. This is done by determining the effect of the surface shape upon the deformations and loads in the stretched sheet.

Classification of Shapes

Double-curved surfaces may be classified by considering variations in the two principal curvatures which define the shape, that is, a surface may be convex, concave, or flat in one direction for a particular curvature in the other direction. In this report the curvature will refer to the top side of the sheet being stretch-formed, so that in the schematic illustration at the top of Fig. 1, both the curvatures $1/R_1$ and $1/R_2$ are concave as shown. The curvature $1/R_1$ will be called the transverse curvature, and $1/R_2$ the longitudinal curvature. In Fig. 1 (*a* to *i*) are shown the different combinations of curvature, defined in the foregoing manner. The longitudinal direction is the direction of restraint as determined by the location of the clamps. This location is the same for all sketches in Fig. 1 and is indicated by the schematic illustration at the top of the figure.

It is not possible to form all of the shapes shown in Fig. 1 with a punch approaching from above. Shapes with longitudinal convex curvature, illustrated in (*c*), (*f*), and (*i*) of Fig. 1 cannot be formed this way, as the area of the formed part of the sheet will be above the ends of the punch. However, the elimination of these three types does not limit the number of shapes which can be stretch-formed, since they are merely the inverted images of the three types (*g*), (*d*), and (*a*), diametrically opposite in Fig. 1. In addition, type (*e*) in the center of Fig. 1 may be disregarded since it is a flat sheet that requires no forming.

There remain only five cases, namely, (*a*), (*b*), (*d*), (*g*), and (*h*), to be considered in this analytical study of stretch-forming of curved parts. Of these five cases, (*b*), (*d*), and (*h*) have only single curvature and are considered special cases having zero curvature in one of the two principal directions. The other two types, (*a*) and (*g*), the real double-curved shapes, may be considered as combinations of these three, that is, (*a*) is a combination of (*b*) and (*d*), while (*g*) is a combination of (*d*) and (*h*). Thus, if a study is made of the three simple types,[4] (*b*), (*d*), and (*h*), first, and then of the effect of combining them, all simple types of double-curved surfaces will be covered.

Qualitative Analysis

The following qualitative analyses explain how wrinkles may occur during stretch-forming of the shapes shown in Fig. 1:

Case 1—Concave Cylindrical Part. Take as the first case the stretching of the concave cylindrical part shown in Fig. 1 (*b*). This would be a difficult part to form by stretching in the direction indicated because of the variation of longitudinal strain across the width. When the punch descends, it first touches the sheet along the longitudinal line *AB*, as shown in Fig. 2. If the sheet is flat, there is no punch pressure exerted in this position because a flat horizontal sheet can have no vertical reaction at its clamps.

As the punch descends farther, the part of the sheet that is in contact with it will be forced down below the clamps, as shown in Fig. 3. Since the longitudinal center line of the sheet now slopes down at the clamps, the restraining force will have a vertical component the total amount of which is the punch load *P*.

The longitudinal center line of the sheet has now been stretched a small amount which gives rise to a longitudinal stress determined by the stress-strain diagram of the material. As stretching of the sheet progresses, this stress is soon brought above the yield point at the middle of the sheet while it is still zero at the sides

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[4] The cylindrical surfaces (*b*), (*d*), and (*h*) would not actually be formed by stretching in practice but probably would be bent by rolling; however, it is the analysis of the cylindrical parts which forms the basis for the analysis of double-curved parts.

(Condition just after stretching begins.)

where the punch has not yet contacted the sheet. This variation of strain across the width of the sheet is the cause of the tendency to wrinkle as explained later. Between points *A* and *B* there will be no pressure between the punch and the sheet, as such pressure could be only brought about by a tendency on the part of the sheet to bend up and press against the punch. Such a tendency is of course not present. This lack of pressure between the sheet and the punch means that the sheet has no support against wrinkling in this central portion between points *A* and *B*.

Transverse Stress Due to Uneven Stretching. How a transverse

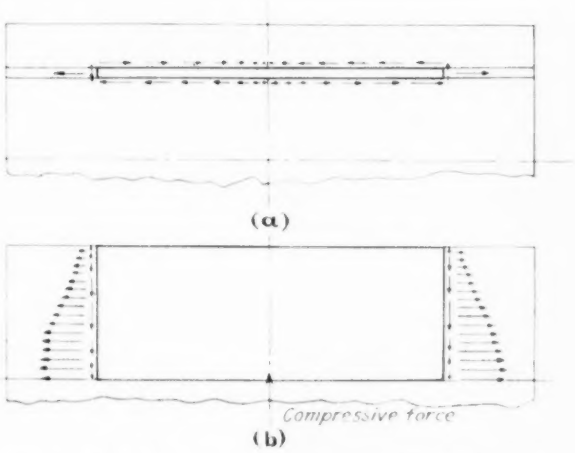

FIG. 4 FREE BODY SKETCHES, ILLUSTRATING TRANSVERSE COMPRESSION

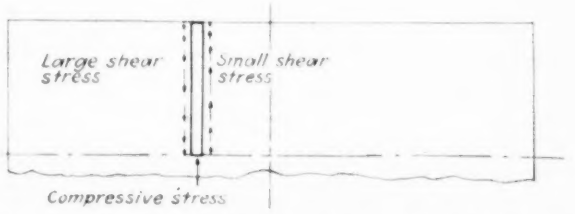

FIG. 5 TRANSVERSE HALF-STRIP, ILLUSTRATING HOW TRANSVERSE STRESS DEPENDS ON CHANGE IN SHEAR STRESS

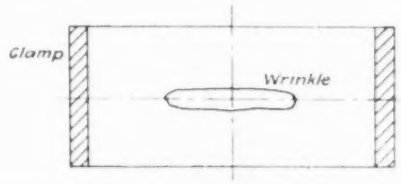

FIG. 6 LENGTHWISE WRINKLE CAUSED BY UNEVEN LONGITUDINAL STRETCHING

compressive stress can result from the uneven longitudinal stretching may be seen as follows: Consider the middle part of a narrow longitudinal strip of the sheet as a free body; it will have shear stresses along its sides as shown in Fig. 4 (*a*) in order to make its sides conform to the adjacent strips which were stretched different amounts. At the end of the strip there will be a transverse shear stress equal to the longitudinal one. When all adjacent strips are considered, from the edge of the sheet to the middle, a free body such as shown in Fig. 4 (*b*) will be obtained. It is seen from this that there must be a transverse compressive force on the sheet balancing the transverse shear forces.

The distribution of this transverse compression depends upon the longitudinal rate of change of shear stress. This is illustrated by the transverse half-strip shown in Fig. 5. The increase in the shear stress from the right side to the left side of the strip determines the magnitude of the transverse compression on this strip.

From symmetry the shear stress must be zero halfway between the clamps. It increases toward the ends of the punch, as shown in Fig. 4. This produces transverse compression over this region, resulting in a tendency to develop lengthwise wrinkling, as shown in Fig. 6.

Transverse Stress Due to Slope of Punch. At the ends of the punch, where the sheet bends up toward the clamps, the stretching force on a longitudinal strip will have a vertical component as shown by force S in Fig. 7. Since the side of the punch slopes, the normal pressure N between the punch and the strip will not be vertical but at an angle. To balance these forces S and N on the strip, there will have to be a third force which in this case must be a transverse tension T in the sheet.

The force T will be tangent to the punch and will be diminished by the friction force μN, where μ is the coefficient of friction. It is seen that as long as the slope of the strip is less than μ, the transverse stress remains zero. It must be remembered also that for a cylindrical punch this transverse tension is confined entirely to the part of the sheet which is pressed against the end edges of the punch, as there is no pressure between the punch and the sheet along the straight middle part. For a long cylindrical punch, then, this transverse tension will have little effect at the middle of the sheet and its influence on the wrinkling due to unequal tension, Fig. 6, will be but slight.

Case 2—Double Concave Part. Consider now the type of part which has a concave curvature in the longitudinal direction as well as in the transverse direction as shown in Fig. 1 (*a*). The longitudinal view, corresponding to Fig. 3, will now be as shown in Fig. 8. Due to the longitudinal curvature there will be normal pressure between the punch and the sheet all along its length, and the condition shown in Fig. 7 will hold true all along the length of the punch. The resulting transverse tension will, therefore, be effective in opposing the wrinkling shown in Fig. 6. The friction resulting from the normal pressure will also help to prevent wrinkling as it resists any relative motion between the punch and the sheet. Finally, the normal pressure also affords support to the middle of the sheet, which greatly increases its resistance to wrinkling.

The magnitude of the normal pressure between the punch and the sheet at any point is directly proportional to the longitudinal curvature at that point. How sharp this longitudinal curvature must be in order to avoid the wrinkling due to nonuniform stretching can best be determined by experiment. The minimum longitudinal curvature will be a function of the transverse curvature and the sheet thickness, as well as the dimensions of the punch, the method of support of the sheet, and the coefficient of friction.

For a longitudinal curvature too small to prevent wrinkling, it has been found that rubber pads stacked under the sheet give enough support to prevent wrinkling in many cases. This is illustrated by the two aluminum-alloy parts shown in Fig. 15.

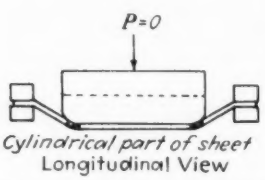

FIG. 12 FORMING OF CONVEX CYLINDRICAL PART (SHADED PORTION) FROM SAGGING SHEET
(Condition just before stretching begins.)

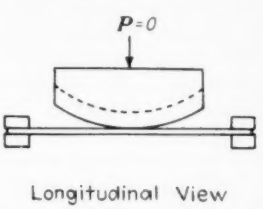

FIG. 13 FORMING OF SADDLEBACK PART
(Condition just before stretching begins.)

This expedient can be used in certain types of stretching machines only.

Case 3—Convex Cylindrical Part. Consider now the stretch-forming of a convex cylindrical part with the direction of restraint parallel to the axis of the cylinder as shown in Fig. 1 (*h*). Such a part would not be formed in this manner in actual production but is important as the limiting case of saddleback parts.

This case of the convex cylindrical part is entirely different from Case 1, the concave part. The uneven tension now varies in the opposite manner across the width of the sheet and consequently produces transverse tension where Case 1 produced compression. Similarly, the transverse stress in the sheet due to the slope of the punch now becomes compression, rather than tension as in Case 1.

Assume first that the sheet is clamped perfectly flat before stretching begins. Then the picture will look like Fig. 9, just as the punch touches the sheet.

As the punch descends farther, it puts pressure on the four points, *A*, *B*, *C*, and *D*, of the sheet. No pressure is exerted between points *A* and *C* nor between points *B* and *D* for the same reason as explained in Case 1. The descent of the punch now stretches the sheet along the sides, rather than along the center line, and in the transverse section there will be two arcs of contact as shown in Fig. 10. The bending moments due to the curvature of these arcs will have a tendency to bend the center of the sheet also and actually raise the center of the sheet an infinitesimal amount above the clamps, as shown exaggerated in Fig. 10.

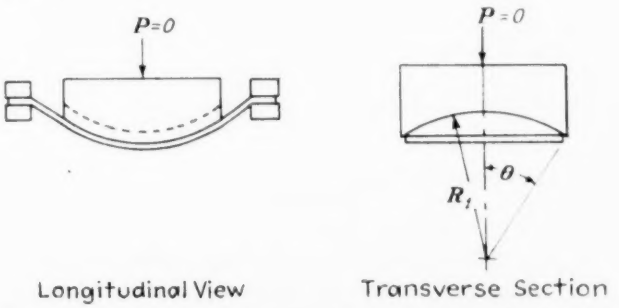

FIG. 14 FORMING OF SADDLEBACK PART FROM SAGGING SHEET
(Condition just before stretching begins.)

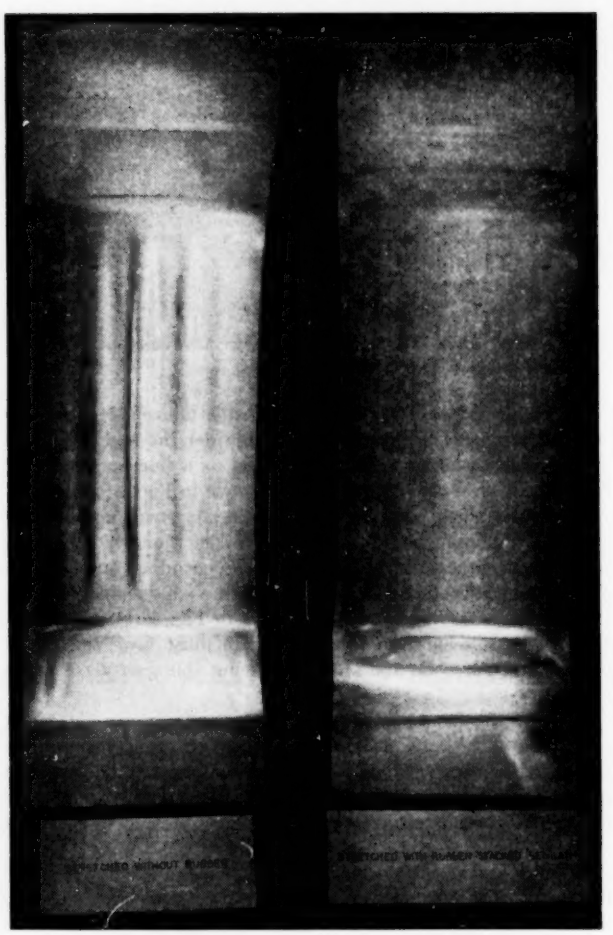

FIG. 15 CONCAVE CYLINDRICAL PARTS

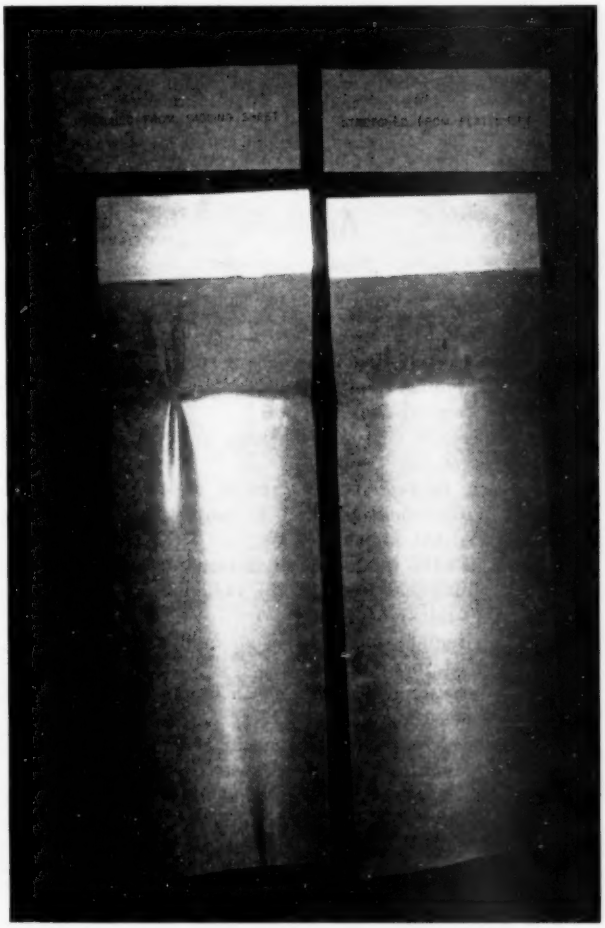

FIG. 16 CONVEX CYLINDRICAL PARTS
(Material, 0.010 24S-T Alclad. Stretched from sagging and flat sheets.)

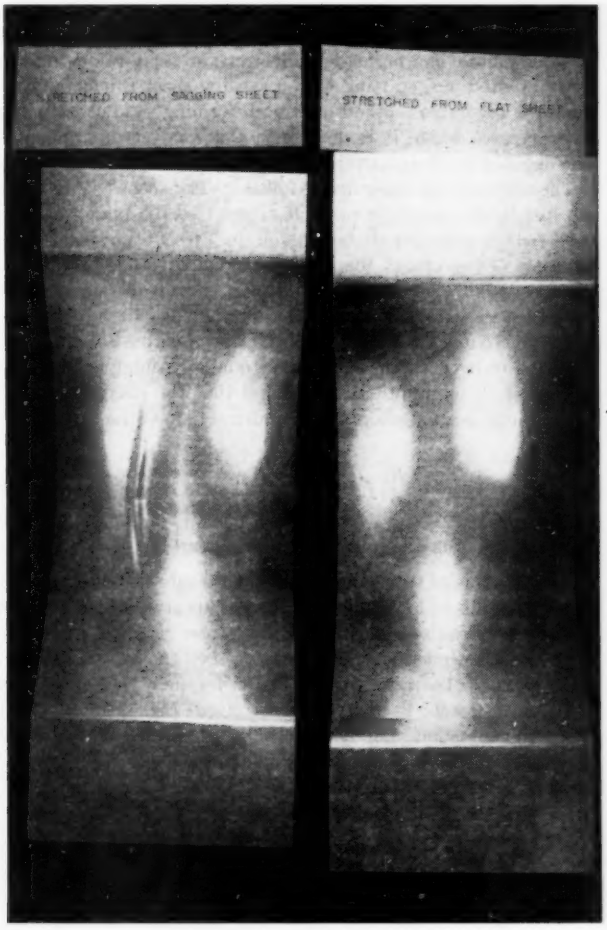

FIG. 17 SADDLEBACK PARTS
(Material, 0.010 24S-T Alclad. Stretched from sagging and flat sheets.)

Because of the fact that the sheet first comes in contact with the part of the punch that has the steepest slope, as indicated by the angle θ in Fig. 10, the transverse compressive stress due to this slope will be predominant over the transverse tension resulting from unequal stretching. This transverse compressive force will tend to push the center of the sheet farther in against the punch, as shown in Fig. 11. This represents buckling of the sheet, but in such a way that the buckle conforms to the transverse curvature of the punch. Additional buckles of smaller wave length (wrinkles) cannot occur before the sheet rests firmly against the center of the punch. Then this firm support of the sheet by the punch will help to prevent such wrinkles as the transverse compressive stress increases to its maximum value.

On the other hand, a slight variation in the method of clamping the sheet will alter considerably the possibility of wrinkles forming. If the sheet is placed in the press in such a way that it is allowed to sag between the clamps so that just before stretching begins it has a shape such as shown in Fig. 12, the case will be entirely different. In this case the sheet will be bent into a cylindrical shape at each end of the punch, as shown in Fig. 12. This longitudinal curvature at each end of the punch will offer a considerable resistance to transverse buckling of the sheet and will also prevent the sheet from bending easily to conform to the curvature of the punch. However, if the transverse compressive forces become large enough to cause buckling, these buckles will be of small wave length and will be likely to remain as permanent wrinkles when the stretching operation is completed. This is illustrated by the aluminum-alloy parts shown in Figs. 16 and 17.

Case 4—Convex-Concave Part (Saddleback). Consider that the part in Case 3 has in addition to the transverse convex curvature a longitudinal concave curvature. This results in a saddleback shape, such as shown in Fig. 1 (*g*). The same reasoning as in Case 3 also applies here regarding the transverse stresses due to uneven stretching and transverse slope of punch. The difference is, however, that in this case the transverse compressive stress is distributed over the entire part of the sheet in contact with the punch instead of being confined to the ends of the punch.

If a flat sheet is used (see Fig. 13), it will have a tendency to conform easily to the transverse curvature of the punch just as in Case 3, and the resulting support by the punch will help to prevent wrinkles as the transverse compressive stress increases. If the sheet is allowed to sag, however, it will conform to the longitudinal curvature of the punch just before stretching begins (see Fig. 14). This cylindrical part of the sheet will offer a considerable resistance to buckling just as for the sagging sheet in Case 3 (see Fig. 12). When buckling finally does occur, however, the resulting short waves are likely to remain in the sheet as wrinkles. It has been found that even a small amount of sag is often enough to cause wrinkling.

Quantitative Analysis of Saddleback Stretch-Forming. If a

saddleback part is stretch-formed from a sagging sheet, an analysis of the transverse compressive stress due to the transverse slope of the die can be made under certain assumptions. As already pointed out, starting with a sagging sheet is generally not the most favorable method of stretch-forming saddleback parts, but for cases where it is necessary, this analysis is applicable. The detailed analysis for this case may be found in the Appendix.

The assumptions made are as follows: The sheet has an initial sag just large enough to make it tangent to the punch near its ends (which corresponds fairly well to present methods); the influence of bending of the sheet is negligible; the width of the sheet does not change during stretching; and, in regions being stretched, the strain is in the plastic range, and hence the stress is approximately constant across the stretched part of the sheet. Also, the transverse stress due to unequal stretching is neglected.

With these assumptions it is found that the maximum transverse compressive stress in the cylindrical part of the sheet would be

$$(f_c)_{max} = \frac{R_1}{R_2} f_p[1 - e^{-\mu\theta}(2\mu \sin\theta + \cos\theta)] \quad [1]$$

in which equation the following notations are used:

R_1 = radius of transverse convex curvature of the part, in.
R_2 = radius of longitudinal concave curvature of the part, in.
f_p = longitudinal plastic tensile stress due to stretching (assumed constant), psi
θ = angle between vertical axis of punch and normal to stretched edge of sheet (see Fig. 14) (assumed constant, but does actually diminish slightly as the stretching progresses), radians
μ = coefficient of friction
e = 2.718, base of natural logarithms

The resistance to transverse buckling of a cylindrical sheet of radius R_2 and thickness t may be given by the following formula (3)

$$f_{cr} = E \frac{0.6\frac{t}{R_2} - 10^{-7}\frac{R_2}{t}}{1 + 0.004\frac{E}{f_{cy}}} \quad [2]$$

In this equation

E = modulus of elasticity in elastic range, psi
f_{cy} = compressive yield stress, psi

If $(f_c)_{max}$ according to Equation [1] is larger than f_{cr} according to Equation [2], buckling of the unstretched cylindrical center part of the sheet is likely to occur.

Conclusions

The conclusions to be drawn from the qualitative analyses and verifying tests made are:

1 There are two distinctly different sources of transverse stress during stretching. One is due to the variation of longitudinal tensile strain across the width of the sheet, and the other is due to the slope of a transverse cross section of the punch. These two effects are often opposed to each other so that if one causes compression, the other causes tension in the transverse direction. If the compressive effect predominates, a tendency to form longitudinal wrinkles will result.

2 The methods of stretch-forming may be so improved that, in some cases, the compressive forces causing wrinkling may be avoided, and in other cases enough support may be given to the sheet to prevent wrinkles even though the compressive forces are present. The only limit to stretch-forming in these cases is then the tearing of the sheet due to excessive elongation.

Nomenclature

The following nomenclature is used in the Appendix:

R_1 = radius of transverse convex curvature of part, in.
R_2 = radius of longitudinal concave curvature of part, in.
f_p = longitudinal plastic tensile stress due to stretching (assumed constant), psi
f_c = transverse compressive stress on cylindrical part of sheet, psi
ϕ = angle between vertical axis of punch and normal to any element in sheet in contact with punch (see Fig. 18), radians
β = value of ϕ for innermost element of sheet in contact with punch (see Fig. 18), radians
t = sheet thickness, in.
dl = longitudinal dimension of an infinitesimal element of sheet, in.
N = normal force of punch on an infinitesimal element of sheet (see Fig. 20), lb
V = vertical resultant of longitudinal tensile forces on an infinitesimal element of sheet (see Fig. 20), lb
F = transverse compressive force on an infinitesimal element of sheet (see Fig. 20), lb
dF = change in F across infinitesimal element of sheet (see Fig. 20), lb
μ = coefficient of friction
e = 2.718, base of natural logarithms
E = modulus of elasticity, psi
f_{cy} = compressive yield stress, psi

Quantitative Analysis of Saddleback Stretch-Forming

Saddleback parts often wrinkle because the transverse curvature causes a transverse compression during the stretch-forming operation. The wrinkles are more apt to occur if the sheet is clamped with an initial sag. A quantitative analysis for the buckling stress in a saddleback part formed from a sheet with an initial sag will be given.

The following assumptions are made:

1 The initial sag in the sheet is enough to make the sheet tangent to the punch near its ends (Fig. 14).
2 The influence of bending is negligible.
3 The width of the sheet does not change during stretching.
4 The strain is in the plastic range, and hence the tensile

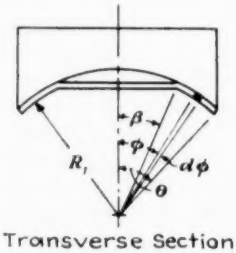

Fig. 18 Forming of Saddleback Part From Sagging Sheet (Condition after stretching begins.)

stress is approximately constant across the stretched part of the sheet.

5 The transverse stress due to unequal stretching is negligible.

Just before stretching begins the sheet has a cylindrical shape with the radius R_2 and touches the punch all along its circular edges, as shown in Fig. 14. After the forming is partially completed, the sheet will be stretched into contact with the punch for some distance in from the edges, and the center portion will still be cylindrical, as shown in Fig. 18.

Consider now an element of the stretched part of the sheet located at an angle ϕ from the vertical axis of the punch, as shown in Fig. 18. The width of this strip is $R_1 d\phi$, and the length is taken as dl as shown in Figs. 19 and 20. Due to the stretching

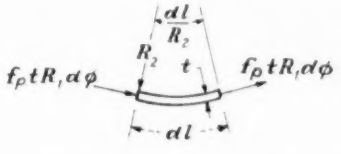

FIG. 19 LONGITUDINAL VIEW OF ELEMENT IN STRETCHED PART OF SHEET

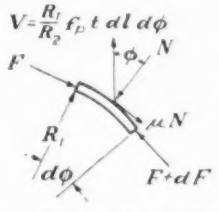

FIG. 20 TRANSVERSE VIEW OF ELEMENT IN STRETCHED PART OF SHEET

stress, the longitudinal forces acting on this strip are $f_p t R_1 d\phi$ (Fig. 19). The vertical resultant V of these forces is then

$$V = 2(f_p t R_1 d\phi) \sin \frac{dl}{2R_2} = \frac{R_1}{R_2} f_p t\, dl\, d\phi$$

which is shown in Fig. 20. Then in the transverse plane, Fig. 20, the condition for equilibrium in the tangential direction is satisfied if

$$\mu N = (F + dF) - F + V \sin \phi$$
$$= dF + \frac{R_1}{R_2} f_p t\, dl\, d\phi \sin \phi \quad \ldots\ldots\ldots\ldots\ldots [3]$$

The condition for equilibrium in the normal direction is satisfied if

$$N = 2F \sin \frac{d\phi}{2} + V \cos \phi$$

Since

$$\lim_{d\phi \to 0} \sin \frac{d\phi}{2} = \frac{d\phi}{2},$$

the foregoing equation becomes

$$N = F d\phi + \frac{R_1}{R_2} f_p t\, dl\, d\phi \cos \phi \quad \ldots\ldots\ldots\ldots [4]$$

Eliminating N from Equations [3] and [4] gives

$$\frac{dF}{d\phi} - \mu F = \frac{R_1}{R_2} f_p t\, dl\, (\mu \cos \phi - \sin \phi) \quad \ldots\ldots\ldots [5]$$

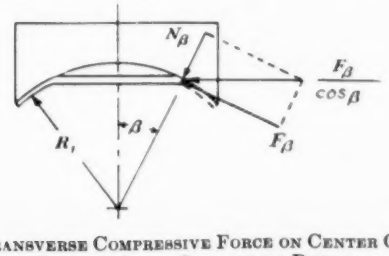

FIG. 21 TRANSVERSE COMPRESSIVE FORCE ON CENTER CYLINDRICAL SECTION AFTER STRETCHING BEGINS

Solving Equation [5] for the boundary condition that $F = 0$ when $\phi = \theta$ gives

$$F = \frac{R_1}{R_2} \cdot \frac{f_p t\, dl}{1 + \mu^2} \left\{ 2\mu \sin \phi + (1 - \mu^2) \cos \phi - e^{-\mu(\theta - \phi)} [2\mu \sin \theta + (1 - \mu^2) \cos \theta] \right\} \quad \ldots\ldots [6]$$

Equation [6] gives the value of F for any angle ϕ between β and θ, but the particular value of interest is F_β, the one for $\phi = \beta$ where the cylindrical part of the sheet meets the punch.

The compressive force on the cylindrical part of the sheet will be $\frac{F_\beta}{\cos \beta}$ as shown in Fig. 21, where N_β is the punch reaction at that point. (The friction force μN_β is neglected here for simplicity.) The compressive stress f_c on the cylindrical part of the sheet is then

$$f_c = \frac{F_\beta}{t\, dl \cos \beta}$$
$$= \frac{R_1}{R_2} \cdot \frac{f_p}{1 + \mu^2} \left\{ 2\mu \tan \beta + (1 - \mu^2) - \frac{e^{-\mu(\theta - \beta)}}{\cos \beta} [2\mu \sin \theta + (1 - \mu^2) \cos \theta] \right\} \quad \ldots\ldots\ldots [7]$$

Since the buckling load of a thin-walled cylinder is independent of its length, it is only the maximum compressive stress $(f_c)_{max}$ that is important in determining whether or not buckling will take place. The value of β at which $(f_c)_{max}$ occurs is found by setting the first derivative of f_c with respect to β equal to zero

$$\frac{df_c}{d\beta} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

By differentiating Equation [7], it is found that

$$\frac{df_c}{d\beta} = \frac{R_1}{R_2} \frac{f_p}{(1 + \mu^2) \cos^2 \beta} \left\{ 2\mu - (\sin \beta + \mu \cos \beta) e^{-\mu(\theta - \beta)} [2\mu \sin \theta + (1 - \mu^2) \cos \theta] \right\}$$

To satisfy the condition of Equation [8], the expression within the braces must be zero

$$2\mu - (\sin \beta' + \mu \cos \beta') e^{-\mu(\theta - \beta')} [2\mu \sin \theta + (1 - \mu^2) \cos \theta] = 0$$

where β' is the particular value of β giving the maximum value of f_c. Placing all terms containing the variable β' on the left gives

$$(\sin \beta' + \mu \cos \beta') e^{-\mu(\theta - \beta')} = \frac{2\mu}{2\mu \sin \theta + (1 - \mu^2) \cos \theta} \quad \ldots [9]$$

This value of β', found from Equation [9] and substituted into Equation [7] for the compressive stress, gives $(f_c)_{max}$. Thus

$$(f_c)_{max} = \frac{R_1}{R_2} \cdot \frac{f_p}{1 + \mu^2} \left\{ 2\mu \tan \beta' + (1 - \mu^2) - \frac{e^{-\mu(\theta - \beta')}}{\cos \beta'} [2\mu \sin \theta + (1 - \mu^2) \cos \theta] \right\} \quad \ldots\ldots [7a]$$

However, no simple explicit expression for β' can be obtained from Equation [9] to substitute into Equation [7a], but the following study of Equation [9] indicates that an accurate approximate formula for $(f_c)_{max}$ can be obtained which does not contain β'.

Take a representative case such as that wherein $\theta = 60$ deg. Solving Equation [9] for β' for this case, it is found that

$$\begin{aligned} \beta' &= 21.6 \text{ deg when } \mu = 0.20 \\ \beta' &= 13.1 \text{ deg when } \mu = 0.10 \\ \beta' &= 1.7 \text{ deg when } \mu = 0.01 \\ \beta' &= 0 \text{ deg when } \mu = 0.00 \end{aligned}$$

Thus, when the coefficient of friction μ is very small, as would be the case for a lubricated punch, the value of β' is also very small, that is, the maximum compressive stress occurs when almost the entire sheet is in contact with the punch. An approximate form of Equation [7*a*] may be obtained for small values of μ and β' by considering that

$$\begin{aligned} \mu^2 &\leqq 0 \\ \mu \tan \beta' &\leqq 0 \\ e^{\mu\beta'} &\leqq 1 \\ \cos \beta' &\leqq 1 \end{aligned}$$

The approximate equation for $(f_c)_{max}$ then becomes

$$(f_c)_{max} \leqq \frac{R_1}{R_2} f_p \left[1 - e^{-\mu\theta}(2\mu \sin \theta + \cos \theta)\right] \quad [7b]$$

This is the equation given as Equation [1] in the main report.

The resistance to transverse buckling of the cylindrical portion of the sheet is given by the following formula (3)

$$f_{cr} = E \frac{0.6 \frac{t}{R_2} - 10^{-7} \frac{R_2}{t}}{1 + 0.004 \frac{E}{f_{cy}}} \quad [10]$$

This is the equation given as Equation [2] of the main report. If $(f_c)_{max}$ according to Equation [7*b*] is larger than f_{cr} according to Equation [10], buckling of the unstretched cylindrical center part of the sheet is likely to occur.

Plastic Plywoods in Aircraft Construction

By R. D. HISCOCKS,[1] OTTAWA, CANADA

Using a typical fuselage fabricated from plastic plywood and veneer as an example, the author indicates the general procedure followed in building wood aircraft. Basic design problems were solved by extensive investigations and tests conducted by the National Research Council. A method is described for fabricating disposable fuel tanks for fighter planes from veneer and plywood, as representing the wide range of possiblities of wood in war and postwar industry.

AT the beginning of the war it was felt in the National Research Council that the possibilities of the wooden airplane were not fully appreciated. It was considered that the factors which govern the speed with which a prototype machine might be developed and placed in full-scale production weighed heavily in favor of wood, especially when the question is examined in the light of Canadian facilities.

As a result, we undertook in the Structures Section to set up a small pilot plant in order to test and develop these ideas and, in particular, with the object of demonstrating that recent advances in materials and techniques can be applied rapidly to produce an airplane which is not merely a metal substitute but a machine of technical merit.

Strength Properties of Wood

Although wood is one of the oldest structural materials in the world there has accumulated surprisingly little information as to its strength properties. Admittedly far from the isotropic ideal dear to the elastician, the elastic properties of the material are specified by at least 12 constants or rather parameters which vary with moisture content, specific gravity, and even from the heartwood to the sapwood of the same tree. Time effects are important and, particularly when shear loads are involved, both deflections and loads at failure will vary with the time the load has been applied.

This may sound like a rather vague proposition for an engineering material but if the experimental data on the external loading condition of an airframe is critically examined, it is apparent that the only logical assessment should be on a statistical basis; and therefore, providing the probable variations fall within reasonable limits, there is no inconsistency in employing a material the strength properties of which are not uniquely determined. Moreover, since the leading dimensions of an airplane are defined chiefly by aerodynamical and operational requirements, few compact structural sections can be employed without an excessive penalty in weight. Stiffness, therefore, rather than ultimate strength considerations usually govern the design. In elastic-stability problems, it can be shown that the ratio of Young's modulus to density, to density squared, or even to density cubed is the figure of merit for any material and that, under such conditions, an expanded material such as wood is supreme. Finally, with the present insistence on perfectly smooth surfaces, it is not difficult to see that contemporary metal construction is considerably handicapped.

Tests on Basic Design Problems

In view of the broad scope of the problem, we felt at the Research Council that useful results could most quickly be obtained by concentrating on one or two design problems, performing such basic tests as from time to time appeared desirable and acquiring in the same process a good deal of useful experience in shop technique.

One cannot proceed very far with the design of shell structures without some basic data, and a few of our early tests were conducted on cylinders in compression, Fig. 1. Some of these

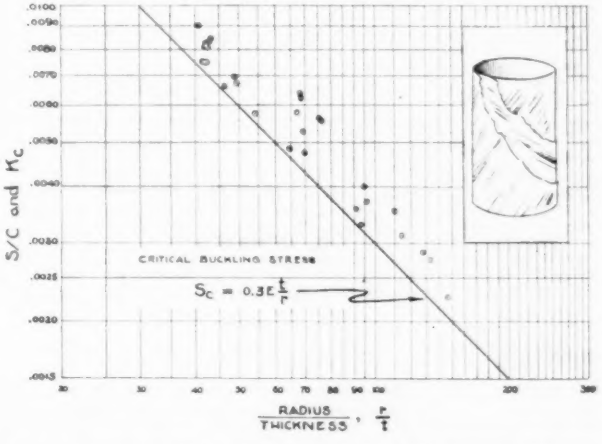

Fig. 1 Buckling Tests on 45-Deg Birch and Spruce Plywood Cylinders

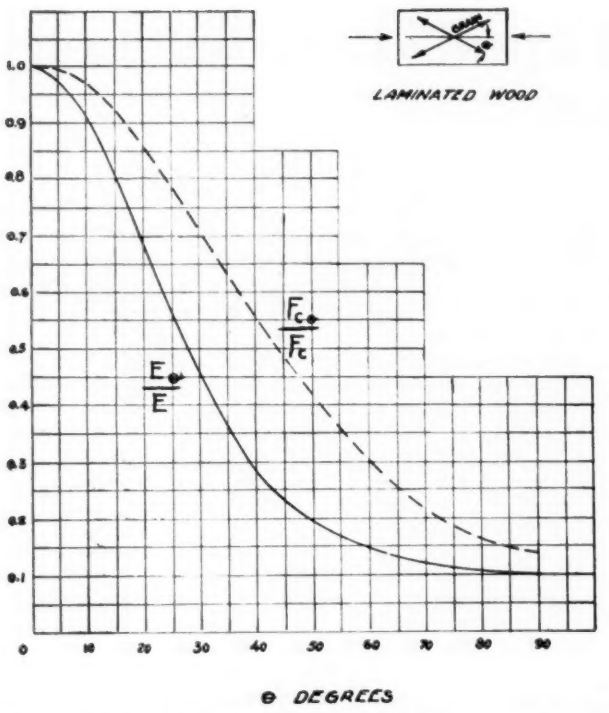
cylinders were hot-press-molded with a rubber bag in the autoclave, others were formed with two-ply veneer and cold-press resin on a wrapping machine. The grain of the wood was in all cases at 45 deg to a generator, with inner and outer plies parallel and the grain of the core plies at right angles. The diameter of the cylinders ranged from 6 to 24 in. We have been able to detect a slight length effect with matched specimens but consider that it is negligible for all practical purposes.

It is interesting to observe that the critical compressive buckling stress can be expressed in the familiar form $F_{crit} = KE\frac{t}{R}$, where K is an experimental constant, E is the modulus of elasticity of the material, in our case parallel to the direction of the load, t is the wall thickness, and R the radius of curvature. A conservative value for design purposes is obtained by taking $K = 0.3$, a value which has enjoyed considerable popularity in the design of metal structures for years.

We have conducted few bending tests on cylinders to date and, in most applications, the problem is complicated by the addition of shear loads. The results of a few pure bending tests indicate that the critical stress again, as in the case of metal cylinders, is some 25 to 40 per cent higher than the critical value in compression.

The curves shown in Fig. 2 are based on the results of a fair number of compression tests on plywood blocks. With compact section, the elastic modulus and ultimate strength vary rapidly with changes in the grain angle.

The low bearing strength of wood perpendicular to the grain



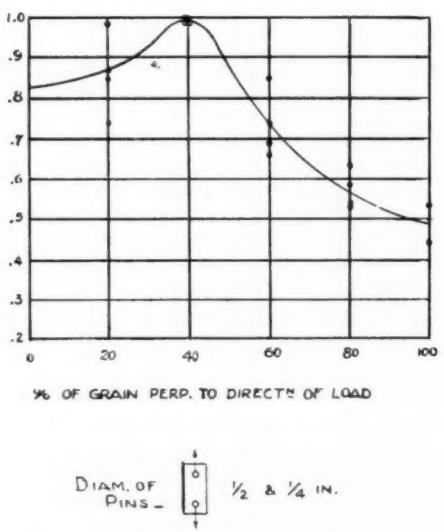


FIG. 2 RELATIVE ULTIMATE COMPRESSIVE STRENGTH AND YOUNG'S MODULUS VERSUS GRAIN ANGLE

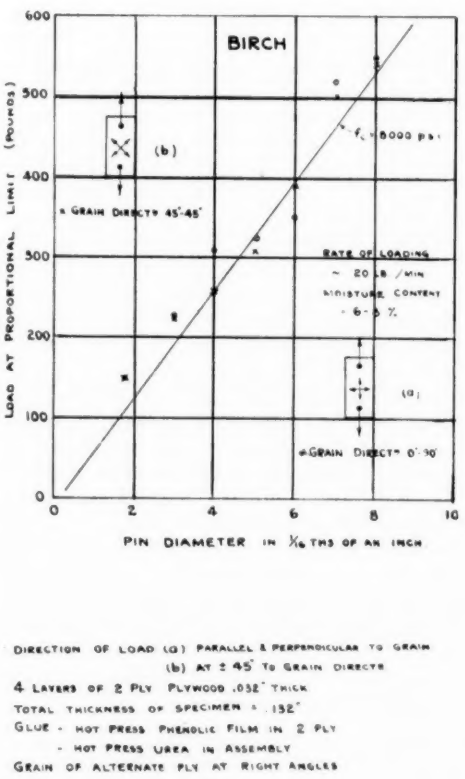
is a shortcoming which can be avoided by the use of plywood. The values given in Fig. 3 have been found useful in the design of joints employing rivets or short bolts. With concentrated loads of any magnitude, the size and number of pins required to transmit the forces directly to the plywood structure usually become formidable, and the need arises for an intermediate material having a high bearing strength, reasonable tensile and shear values, and a moderate density. We have found phenolic-fabric-base laminates satisfactory for this purpose. These are available with a bearing strength of the order of 30,000 psi. Form factors are apt to be unpredictable, however, and it is good practice to conduct a few simple tests in order to determine safe loads for any specific condition.



ADHESIVES AN IMPORTANT FACTOR IN PLYWOOD STRUCTURES

The phenolics usually will bond to wood effectively only with hot-press resins. Since the temperature coefficients of linear expansion for the plastics usually differ substantially from that of wood, it is important to avoid excessive temperature stresses. We consider that the most satisfactory expedient is first to glue a thin layer of veneer to the laminate with hot-press adhesive and then to bond the wood face to the remainder of the structure with a cold-setting adhesive. The same considerations apply in bonding metal to wood.

The problem of diffusing a concentrated load into a shell structure is always troublesome and particular care should be taken with plywood structures because wood has no elastic limit in tension. Highly localized tensile stresses may cause failure even if the average stress in a member is quite moderate, be-

(a)

(b)

FIG. 3 BEARING STRENGTH OF PLYWOOD
(a, Variation with percentage of end grain. b, Variation with pin diameter.)

cause the material cannot yield plastically and distribute the local stresses.

Many of the weathering difficulties which have arisen with wooden airplanes in the past can be attributed to the use of primitive glues, and it is safe to say that recent advances in the art largely are the outcome of improvements which have occurred in glues. Many synthetic-resin adhesives are now available which have a high resistance to water, ample shear strength, and are proof against mold and extremes of temperature. Quite a number will even survive the boiling-water test still cherished by some specifications, although it has never been explained why anyone should want to boil an airplane.

Contrary to popular opinion, high pressures are not required in gluing, and it is quite possible to construct satisfactory joints with a pressure of less than 1 psi if the viscosity of the glue is not excessive. The pressure requirements are determined solely by the forces necessary to obtain a thin glue line and, if the veneers are thin and the pressure uniformly distributed, then the forces required are small. With more rigid sections, high pressures are essential only if the faces of the wood do not match reasonably well. On thin members, nails or screws will provide ample pressure but it should not be assumed that the nails or screws will be effective after the glue has set because large shear deflections, sufficient to cause the glue to fail, are necessary for these elements to assume any load.

It is not unduly difficult to produce a bond with a shear strength equal to that of the wood, but it does not follow that every joint can transmit a load corresponding to the block shear strength of the wood. For example, in the standard three-ply test specimen, the stresses in the joint are far from pure shear, and it is not surprising that the failing load, for a thin specimen and with the grain in the core parallel to the face grain, is of the order of 25 per cent of the strength of the wood in pure shear. A further reduction results when the grain of the intermediate ply is not parallel to the load; at 90 deg, for example, there is a further decrement of 30 to 50 per cent due to the rolling effect of the wood fibers.

The rolling-shear type of failure has always to be guarded against. Fig. 4 is a very convenient spar section which behaved rather badly until we provided sufficient glue area in the flange-web joint. The bond between the parallel fibers in the flange and the web was entirely satisfactory but trouble arose where the veneers crossed at right angles further in the web.

Sometimes failures in box beams are unfairly charged to the glue. A thin web will buckle at very moderate shear stresses and continue to carry the load in diagonal tension. As a result the maximum shear stresses in the flange-web joint are more than double the values calculated from simple shear considerations.

It relieves the load on glued joints considerably if the ends of stiffeners are tapered. In flooring, decking, and the like, where local distortion may be large, we find rivets extremely effective in discouraging peeling in the glue joint.

In gluing it is of the utmost importance to match the moisture content of the pieces which are to be glued together. If a thin strip of veneer is coated with liberal quantities of a water-soluble glue and bonded to a heavier piece which is perfectly dry, it is obvious that the wet member will contract in drying and the result will be a badly warped component. Moreover, wood is a hygroscopic material and no amount of finishing will prevent it from shrinking and swelling with changes in the moisture content of the air. Most of the dimensional change occurs in a direction perpendicular to the grain and, if two pieces of veneer are glued together with the grain at right angles, then at only one value of the relative humidity will the panel remain flat.

For a stable material, it follows that three plies of veneer

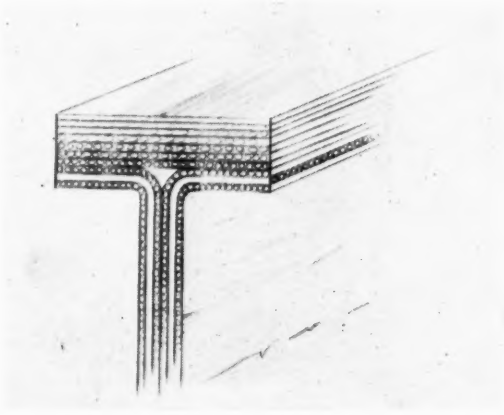


FIG. 4 SPAR SECTION SHOWING CONSTRUCTION TO AVOID ROLLING-SHEAR FAILURE

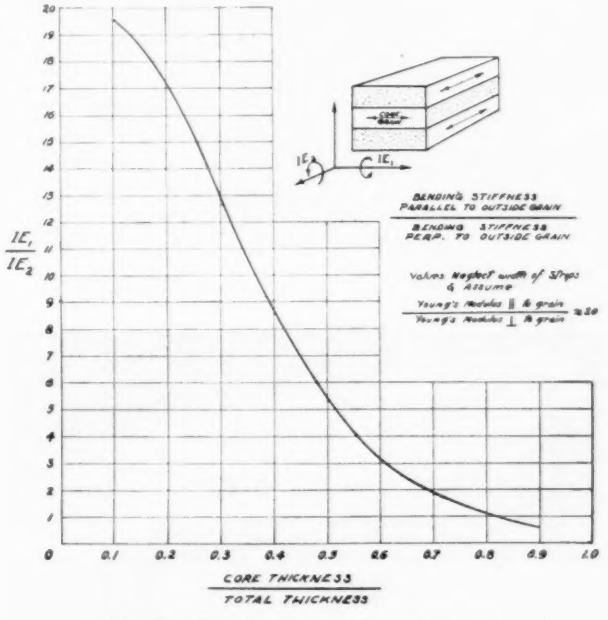

FIG. 5 THREE-PLY PLYWOOD IN FLEXURE

are the minimum. Unfortunately, conventional three-ply is composed of veneers of equal thickness and the bending stiffness parallel to the face grain is some 12 times the stiffness at right angles. Therefore, unless special design considerations demand a much superior strength in one direction, from the standpoint of general stiffness and dimensional stability, it is preferable to employ a construction which gives a more comparable stiffness in both directions (Fig. 5).

TESTS ON MOLDED FUSELAGE

Turning our attention to more ambitious experiments, Fig. 6 indicates the general structure of a rear fuselage which we designed and constructed in molded plywood. It did not appear desirable to redesign the forward portion of the structure because the existing steel-tube framework with detachable side panels permitted access to a large amount of equipment which could not readily be moved. Hence the detail design of this portion was predicated somewhat by the original metal layout, but every attempt has been made to approach the true monocoque form. The skin is sufficiently thick to carry all loads ex-

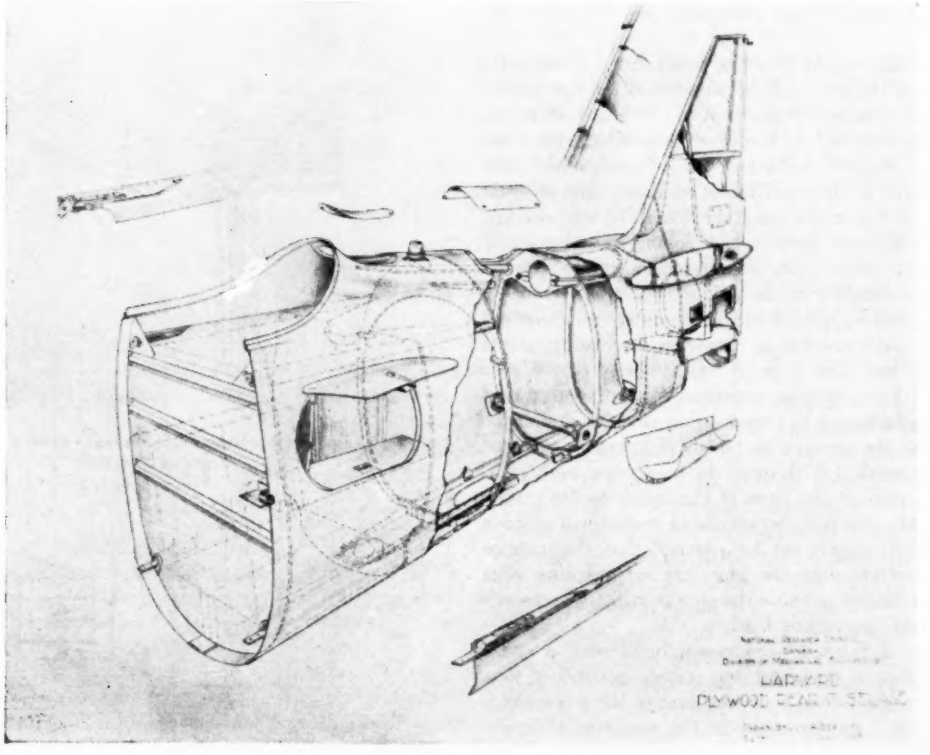

FIG. 6 REAR FUSELAGE STRUCTURE OF MOLDED PLYWOOD

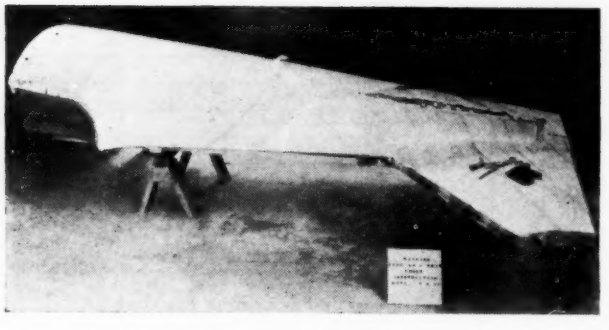

FIG. 7 FOUR LAYERS OF SPRUCE VENEER BONDED WITH THERMOSETTING UREA GLUE FORM THE FUSELAGE SKIN WHICH IS MOLDED IN HALVES

cept in the vicinity of cutouts and in the forward portion where the loads from the four attachment points are distributed by stub longerons. Light wooden frames maintain the correct shape. Plastic pads transmit the axial loads from the attachment fittings to the longerons. It is interesting to note that the problem of stress diffusion is frequently less difficult with a plywood than with a metal structure. With the longerons, for example, we have endeavored to taper the cross-sectional area and to graduate the elastic properties by varying the construction so that the glue joint between the longeron and the skin is uniformly stressed.

The skin, Fig. 7, which is molded in two halves, is composed of four layers of spruce veneer bonded with thermosetting urea glue. The veneers are trimmed to shape and stapled in place on a wooden mold with the inner and outer layers at right angles to the middle layers and at an angle of 45 deg to the fuselage center line. Successive layers are coated with adhesive, the

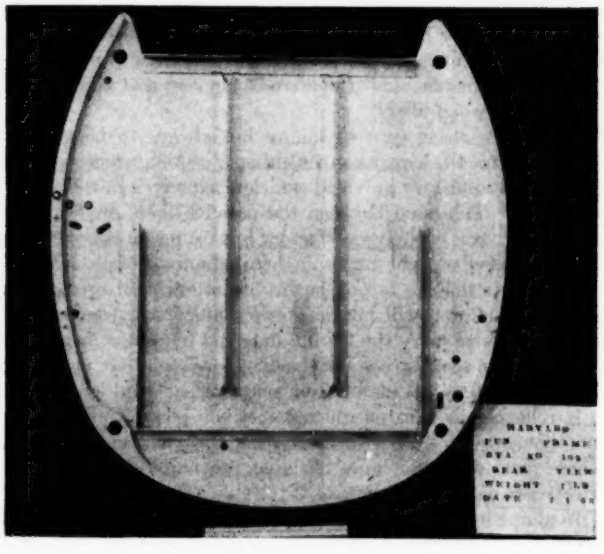

FIG. 8 VIEW OF FRONT BULKHEAD

assembly is sealed in a rubber bag and cooked with steam in the autoclave for about 35 min at a temperature of 240 F and a pressure of 30 psi.

Fig. 8 is a view of the front bulkhead. Plastic pads again transmit shear loads from the fittings to the frame. It will be observed that we have borrowed a leaf from metal practice in using molded top-hat sections to stiffen the flat panels. We prefer to fabricate the frames separately, mounting these in a jig to glue the half-skin to the frames with cold-setting glue. Woodscrews at a liberal pitch are supplemented with webbing

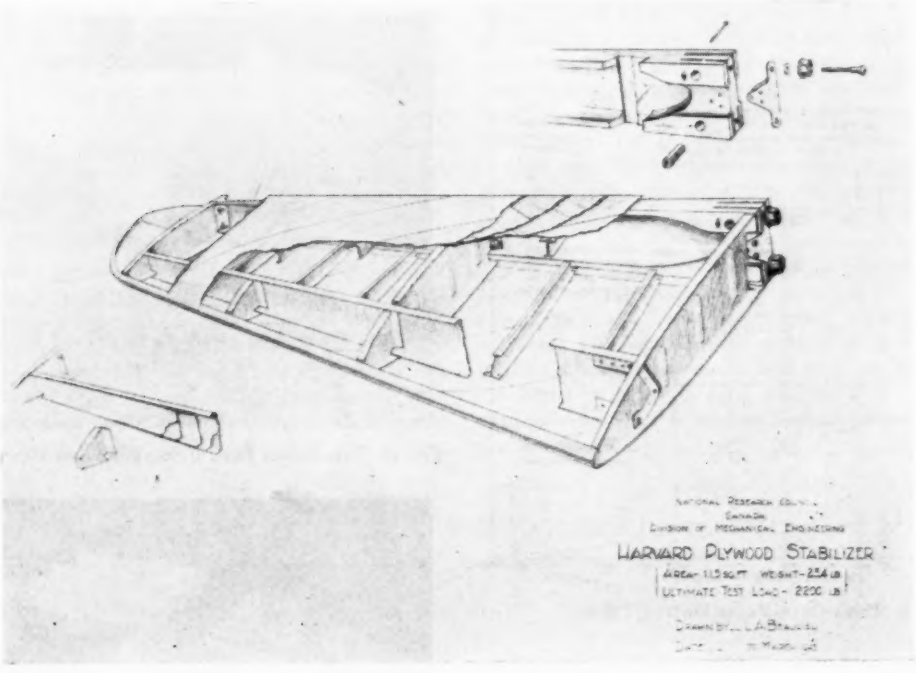

FIG. 10 STABILIZER STRUCTURE

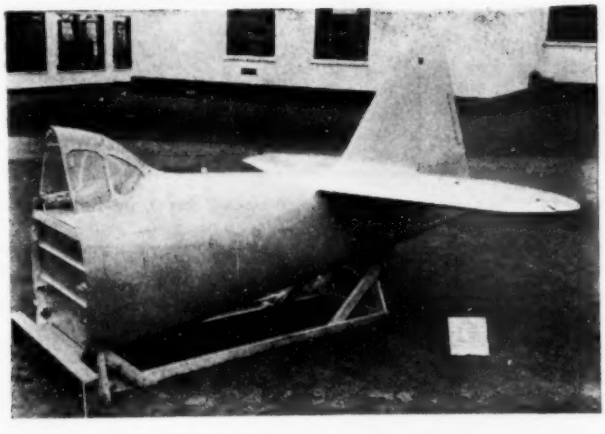

FIG. 9 COMPLETED REAR FUSELAGE

at appropriate sections to apply the pressure and, with the drying accelerated by infrared lamps, the entire operation is completed in less than 1 hr.

The fuselage, Fig. 9, was static-tested in six different flight and landing conditions and proved well up to design requirements. Weighing 154 lb, as tested, it has carried a down load on the tail equal to the design breaking load for a Spitfire fighter aircraft. In the landing attitude it has sustained a tailwheel reaction slightly in excess of 2.5 tons.

Fig. 10 is a view of the stabilizer structure. The skin is hot-press-molded and stiffened with channel-section molded stiffeners. The ribs are also flanged and bonded in a rubber bag. For the rear spar we chose an I-beam section with the grain in the plywood web running diagonally. The root fitting consists of a pair of ball-and-socket joints attached to trunnions. These trunnions transmit the loads to a phenolic laminate inserted in the spar flanges. The total stabilizer weight is 23 lb. On test it carried 2200 lb without evidence of distress.

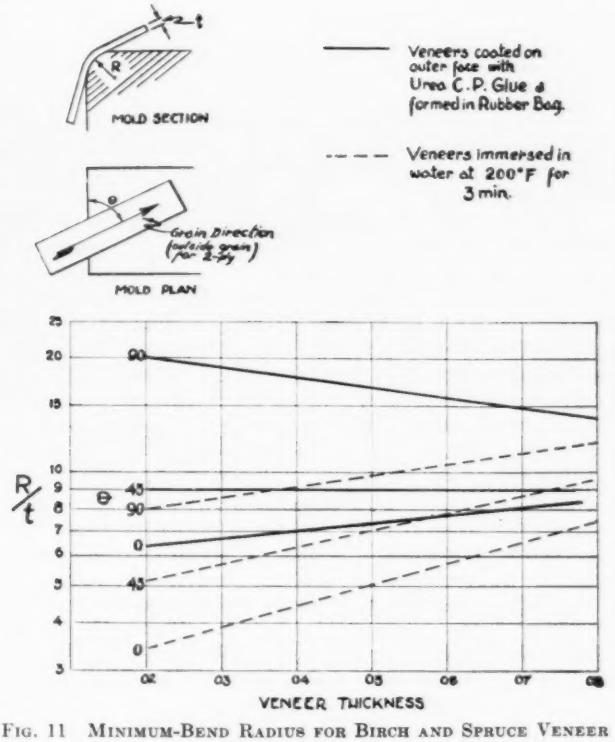

FIG. 11 MINIMUM-BEND RADIUS FOR BIRCH AND SPRUCE VENEER AND TWO-PLY PLYWOOD

The elevator is similar in construction to the stabilizer shown in Fig. 10. The skins and stiffeners are assembled on the bench and then glued to the channel-section spar and end ribs in one operation. Finally the molded leading edge is glued in place. The complete weight less mass balance is 13 lb. The structure failed at a test load of 1040 lb or 140 per cent of the design load.

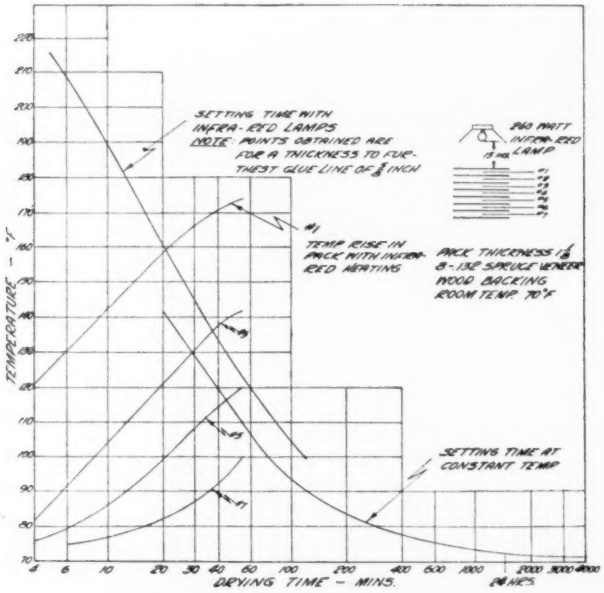

FIG. 12 UREA COLD-PRESS DRYING TIME

With the rudder, as in the foregoing components, we endeavored to make the skin the major structural element. The bottom fairing which is detachable is composed of fabric impregnated with urea-formaldehyde resin, and molded in the autoclave. Weighing 18 lb complete with mass balance, it was tested to 150 per cent of the design load without any evidence of failure.

One of the first things one needs to know in designing these structures is a safe bend radius to use with the various veneer thicknesses. Fig. 11 gives values which we consider to be a practical minimum.

Infrared lamps will greatly accelerate the drying of cold-setting resin adhesives. Fig. 12 indicates the time required to achieve a reasonable shear strength at a constant temperature. The time is very considerable at the temperatures which frequently prevail in workshops. Referring to Fig. 12, the time-temperature curves for a thick pack of veneers exposed to an infrared lamp are given. As a simple example, consider a glue line $^1/_8$ in. below the surface. During the first 8-min interval, the average temperature is roughly 120 F. At that temperature, we see from this curve the total time required would be 40 min for the glue to set. Therefore, in 8 min we obtain 20 per cent of the required cooking. During the next interval, the average temperature is about 145 F, and the total time required would be 20 min. Therefore, in 8 min, we obtain an additional 40 per cent of the required cooking. Adding the percentages to a total of 100 per cent, we obtain the required time with this lamp and distance to set a glue line $^1/_8$ in. below the surface. This curve is based on experimental results with a $^5/_8$-in. panel and shows the considerable time saving which can be realized.

THE TECHNIQUE OF BAG MOLDING

No description of the bag-molding art is necessary, as it has received a good deal of attention in the literature lately. Lockheed employed the fluid-pressure idea 15 years ago to produce a number of extremely refined plywood airplanes, but the production possibilities of the method have only recently received attention. The wooden mold, rubber bag, and autoclave, as currently used, form a convenient arrangement for experimental work but suffer numerous drawbacks for large-scale production.

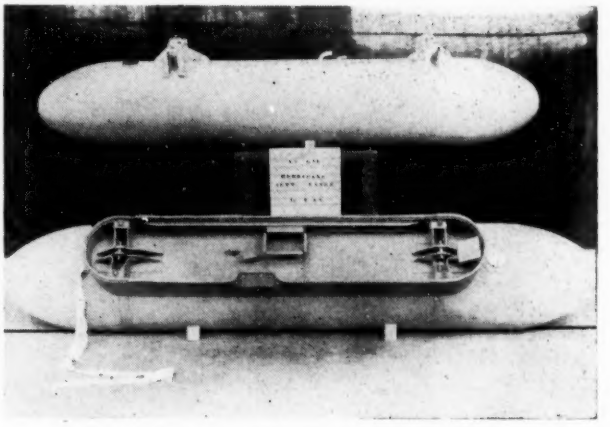

FIG. 13 DISPOSABLE FUEL TANKS FOR LONG-RANGE FIGHTER PLANES

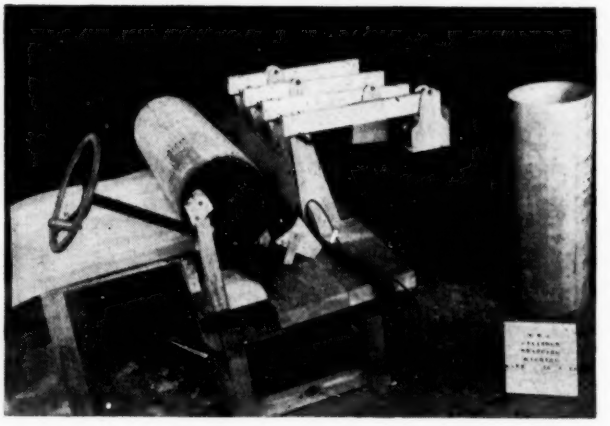

FIG. 14 COLLAPSIBLE DRUM FOR WINDING SHELL OF FUEL TANK

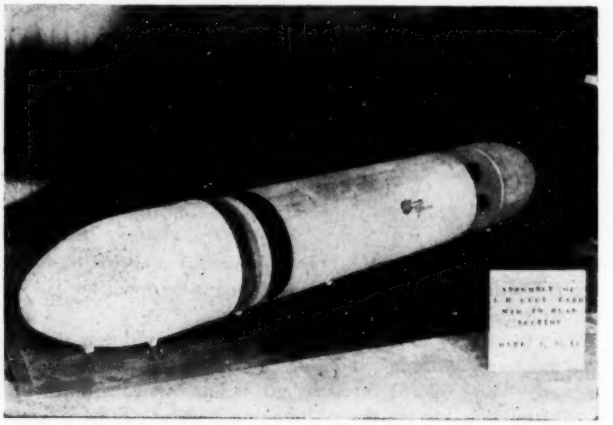

FIG. 15 ASSEMBLY OF CENTER SECTION, DOUBLER RINGS, AND LAMINATED END SECTIONS OF FUEL TANK

Wooden molds are woefully impermanent when subjected to frequent heating and cooling cycles, a great deal of time and heat are wasted in cooking the great bulk of the mold, and its size and general awkwardness present a considerable handling problem not to mention the wear and tear on rubber bags. Alternative methods are in use with varying degrees of success, but we believe that a metal mold in the majority of production applications will quickly pay for itself. The form is metal, and internally

heated, preferably with steam. The veneer-and-glue assembly is placed on the form and stapled to wooden inserts at the edges. Over this assembly is placed a reasonably airtight blanket; it does not need to be rubber and even a few leaks do not matter. Finally a light outer shell is dropped in place and sealed. Compressed air can therefore provide the pressure independently of the temperature. We have performed a number of cookings on a unit of this type; the temperature rise is extremely rapid and the results uniformly satisfactory.

Forming Fuel Tanks to Be Jettisoned

Another plywood enterprise in which we have been engaged is a jettisonable or disposable fuel tank for a long-range fighter aircraft, Fig. 13. The machines carry two of these tanks, one under each wing, and when the fuel is consumed the tanks are dropped. Therefore cheapness and simplicity of construction are essential.

We start with a two-ply veneer which is wound on a collapsible drum, shown in Fig. 14. Metal bands are loaded with a lever weight arrangement to apply pressure. Infrared lamps supply the heat necessary to set the cold-press resin as the two-ply ribbon is wound on the drum. The nose and tail are of the same shape and are composed of 5 layers of two-ply hot-press-molded wood. Laminated rings, which also carry the loads from the attachment fittings, serve as doublers between the ends and the cylindrical portion, Fig. 15. Pipe and attachment fittings are riveted in place first, then the ends are glued on and a fairing added. The tanks are flushed with a gasoline-resistant sealing compound, pressure-tested, and with a coat of paint are ready for service.

We have performed a number of tests on these tanks but none so drastic as that which recently occurred when one laden with 100-octane fuel was accidently released from an aircraft about to land. The tank dropped a distance of 4 or 5 ft and commenced a journey across the field at some 100 mph. Although enveloped in spray, it did not ignite and despite considerable damage was still a complete unit when retrieved by the somewhat shaken ground crew.

Pressure Loss in Elbows and Duct Branches

By ANDREW VAZSONYI,[1] CAMBRIDGE, MASS.

The pressure loss in a duct branch is a function of at least six independent variables, and there is no complete set of data available for correlation. Equations [II] and [III] of this paper are derived on a theoretical and experimental basis. These equations correlate all available data with fair accuracy with the aid of four experimental curves (Figs. 2, 3, and 5). Furthermore, they permit prediction of probable pressure losses for ducts heretofore untested. Similar formulas can be derived for elbows, diffusers, contracting passages, and other configurations, e.g., Equation (1) presents losses for elbows.

Nomenclature

The following nomenclature is used in the paper:

A = area of cross section
d = diameter of pipe
f = friction factor
h = mixing loss = total loss — friction loss (given in Equation [9])
H = total loss = $(p_1 + {}^1/_2 \rho V_1^2) - (p_2 + {}^1/_2 \rho V_2^2)$
l = length of pipe
p = pressure
P = circumference of pipe
Q = mass rate of flow
V = velocity
$\bar{V}$ = mean velocity based on mass rate of flow
α, β, γ = angle of deflection in elbow or branch pipe
α', β', γ' = effective angle of deflection of stream
ρ = density
τ = shear force on wall of duct
λ = new loss coefficient
η = diffuser efficiency
ζ = standard loss coefficient

Introduction

When the practicing engineer is confronted with the problem of predicting pressure losses in ducts, he can find little help from the available literature. There are so many different types of ducts that one could hardly expect to chance upon the one desired. However, it is somehow expected that a duct system can be separated into different types of "elementary" ducts, and one hopes that knowing pressure losses for these elementary ducts, the total pressure loss in a duct system can be predicted by summation. Therefore it is very desirable to know pressure losses for a great variety of ducts, and indeed a vast number of experiments have been run for this purpose. Unfortunately, nothing like a convenient and practical summary of data exists. Furthermore, often the available material is somehow confused, even contradictory.

The subject of this paper is the presentation of losses for duct branches, and so let us examine this configuration in detail. What does the pressure loss depend upon in this duct system? In order to obtain any answer, we have first to specify completely the configuration considered. Let us assume that we have three circular pipes "meeting" at a point. In order to avoid flow disturbances by the entrance and exit, let us assume that all the pipes are very long. Now we have a well-defined elementary duct, and we can ask for the pressure loss in this duct. The pressure loss will obviously depend (at least) upon the following quantities: The diameters of the pipes; the respective fluid velocities; the angles of inclination of the branching pipes; roughness of the wall; and the kinematic viscosity of the fluid—altogether ten variables.

Using the continuity equation and similarity considerations, four of these variables can be eliminated and the remaining six can be listed as follows: Ratios of exit areas to inlet area; ratio of velocities in two of the pipes; the branching angles; friction factor. No more reduction in the number of variables is possible and experiments have shown that all these variables are of major importance. Hence we see that to obtain a complete survey of the losses would necessitate an enormous number of experiments. But even if all these data were known, how could they be put into a useful form for the designing engineer? The situation is somehow similar to that of the friction-factor data at the time when the Reynolds number was not yet used.

Investigators of the Hydraulic Institute of the Technical University of Münich have run extensive tests on duct branches (13, 28, 30, 35).[2] Nine different configurations were selected. In all of them there is a main pipe continuing ahead; the duct branch forms an angle of 30, 45, or 90 deg with the main pipe; the ratio of the diameter of the branch pipe to that of the main pipe is $\frac{15}{43}, \frac{25}{43}, \frac{43}{43}$.

The pressure loss is expressed as a fraction of the kinetic energy (per unit of mass) of the fluid in the main pipe, as is customary for friction-factor data. For the independent variable the ratio $\frac{Q_1}{Q_0}$ is used. We have replotted these curves, using the velocity ratio $\frac{V_1}{V_0}$ for the independent variable, as this appears to suit better the nature of the problem, e.g., Fig. 10 shows losses for three different duct branches, each of them having an angle of deflection of 45 deg. The data lie fairly well on one and the same curve, and so one curve replaces the three different curves given in the original papers. Figs. 11 and 12 show two further curves of the many presented by the German investigators. It can be seen that the pressure-loss coefficient varies between —10 and +45. (Negative pressure-loss coefficients indicate pressure rises.) Similar curves can be found in the original papers for the nine configurations, and also for some slightly different ducts. But let us suppose we do not have a duct with an angle of 30, 45, or 90 deg, or the area ratios do not check with those tested. The coefficients vary so much, that interpolation can be of little help.

The pressure-loss-data presentation as a fraction of the kinetic energy of the main pipe is a fully arbitrary one, and its only justification is that it works well for straight pipes. As it is certainly not satisfactory in the duct-branch case, why not use some combination of the kinetic energies of the different pipes of the duct system? The difficulty now is how to select suitable formulas.

[1] Teaching Fellow in Mechanical Engineering, Graduate School of Engineering, Harvard University.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

In this paper a trial is made in this direction. First of all the pressure loss is divided into two parts, i.e., friction loss and mixing loss. The former can be determined by the knowledge of the friction factor; the latter is supposed to be (approximately) independent of the wall roughness. After some theoretical investigation, formulas are derived for the mixing loss. There are experimental coefficients in these formulas which are determined to fit the available test data. The main results are as follows:

Elbow Losses:

$$2h_{12} = V_1^2 + (2\lambda - 1)V_2^2 - 2\lambda V_1 V_2 \cos \alpha \ldots\ldots [I]$$

where for circular elbow $\lambda = 0.6$, for rectangular elbow $\lambda = 0.75$.

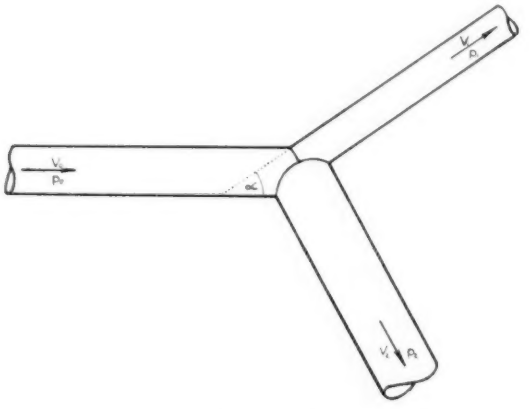

FIG. 1 DUCT BRANCH WITH SEPARATING FLOW

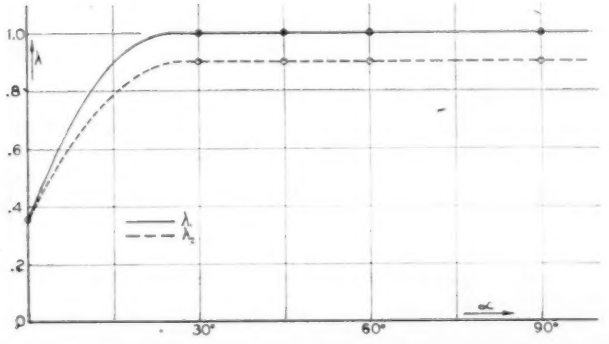

FIG. 2 PRESSURE LOSS IN DUCT BRANCH WITH SEPARATING FLOW
(λ_1 and λ_2 of Equation [II], as functions of angle of deflection α.)

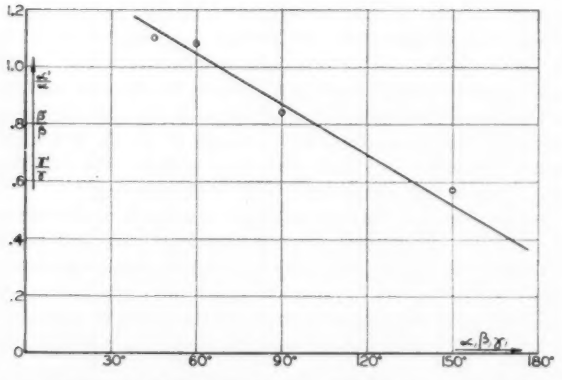

FIG. 3 EFFECTIVE ANGLE OF DEFLECTION AS FUNCTION OF ANGLE OF DEFLECTION; EQUATIONS [II] AND [III]

Straight Pipe Branching Into Two Pipes:

$$2h_{01} = \lambda_1 V_0^2 + (2\lambda_1 - \lambda_2)V_1^2 - 2\lambda_2 V_0 V_1 \cos \alpha' \ldots\ldots [II]$$

where λ_1, λ_2, α' are functions of α given in Figs. 2 and 3.

Two Straight Pipes Discharging Into One Pipe:

$$2h_{10} = \lambda_3 V_1^2 + V_0^2 - 2V_0\left(\frac{V_1 Q_1}{Q_0}\cos\beta' + \frac{V_2 Q_2}{Q_0}\cos\gamma'\right). [III]$$

where λ_3 is a function of β given in Fig. 5, β' and γ' are functions of β and γ in Fig. 3.

THE ENERGY LOSS

Consider some kind of duct system. The law of conservation of energy states that

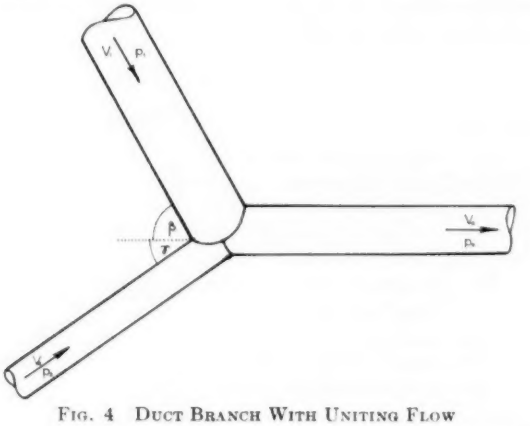

FIG. 4 DUCT BRANCH WITH UNITING FLOW

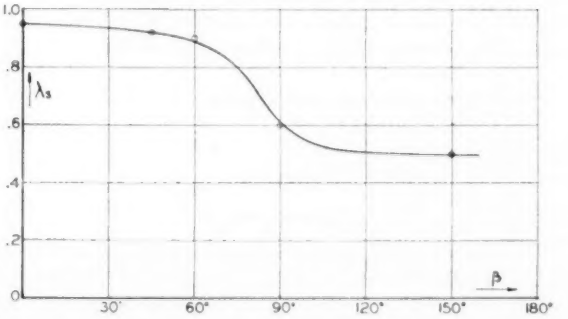

FIG. 5 PRESSURE LOSS IN DUCT BRANCH WITH UNITING FLOW
(λ_3 of Equation [III] as function of β the angle of deflection.)

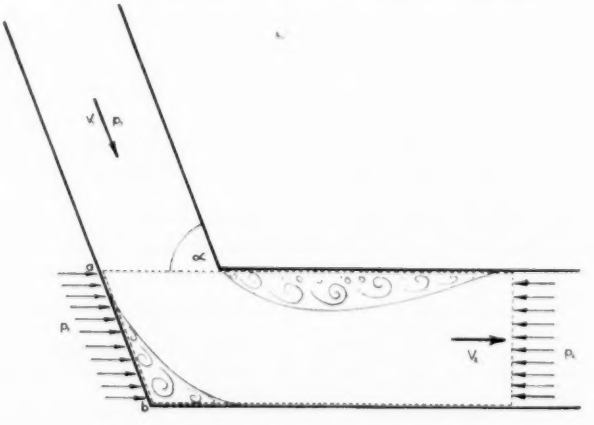

FIG. 6 PRESSURE LOSS IN A MITER ELBOW
(Dotted lines enclose section to which momentum equation is applied.)

$$\int_{A_1}\left(p+\frac{1}{2}\rho V^2\right)VdA = \int_{A_2}\left(p+\frac{1}{2}\rho V^2\right)VdA + \rho HQ \ldots [1]$$

where Q is the mass rate of flow and H is the work done by the fluid per unit of mass flow. By definition, H is the loss through the duct system. In what follows, we will consider only incompressible fluids, and so we can assume that ρ is constant.

Straight Pipe

Consider the case of a straight pipe and assume that p is constant across the pipe. Then Equation [1] can be written in the form

$$\frac{p_1}{\rho}+\frac{1}{Q}\int_{A_1}\frac{1}{2}V^3dA = \frac{p_2}{\rho}+\frac{1}{Q}\int\frac{1}{2}V^3dA + H \ldots [2]$$

Now, if we further assume that we are dealing with a steady-state case, i.e., the velocity profile is everywhere the same, we get

$$\frac{p_1-p_2}{\rho} = H \ldots [3]$$

Writing the momentum equation for the case considered, we get

$$A(p_1-p_2) = Pl\tau \ldots [4]$$

where P is the circumference of the pipe and τ is the shear force on the wall. Introducing the friction factor

$$f = \frac{\tau}{\frac{1}{2}\rho V^2} \ldots [5]$$

we get

$$\frac{p_1-p_2}{\frac{1}{2}\rho V^2} = f\frac{lP}{A} \ldots [6]$$

and for the loss

$$\frac{H}{\frac{1}{2}V^2} = f\frac{lP}{A} \ldots [7]$$

Equations [6] and [7] show that the pressure drop along the pipe measures the energy dissipation. It is important to emphasize that this is true only in the case of a straight pipe, and under the assumption made that the velocity profiles are the same along the pipe.

More General Ducts

Let us now consider Equation [1] in a more general case, e.g., a diffuser or elbow. In order to determine the loss, it is necessary to measure the pressure and the velocity across the entrance and exit areas and to integrate Equation [1]. This is a much too elaborate procedure, and so it is usually assumed that both p and V are constant across the cross sections. This condition is sufficiently well approximated for turbulent flows by inserting a long straight pipe before and after the duct. Then Equation [1] becomes

$$p_1+\frac{1}{2}\rho V_1^2 = p_2+\frac{1}{2}\rho V_2^2 + H \ldots [8]$$

or the loss is given by the difference of the total pressures. It is to be emphasized that Equation [8] holds true only when both p and V are constant across the entrance and exit areas. Some investigators have used the total pressure difference as the loss for cases where these conditions did not hold, and obtained contradic-

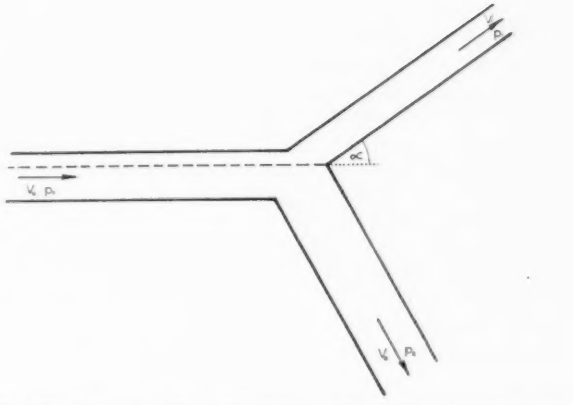

Fig. 7 Duct Branch With Separating Flow Decomposed Into Two Miter Elbows

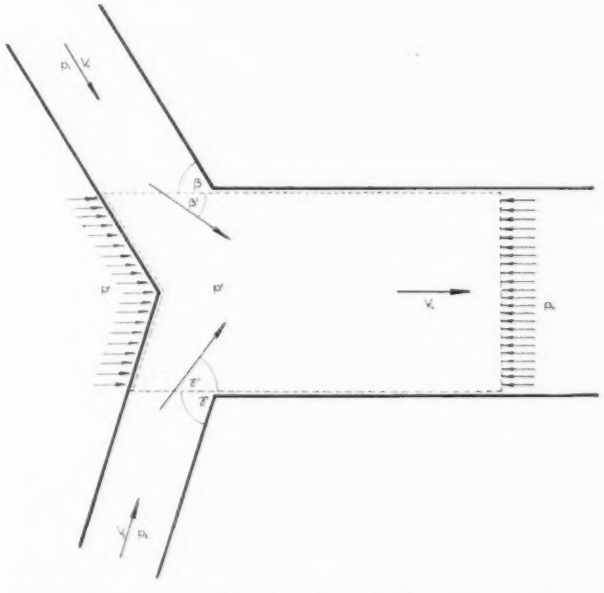

Fig. 8 Pressure Loss in Duct Branch With Uniting Flow
(Dotted lines enclose section to which momentum equation is applied.)

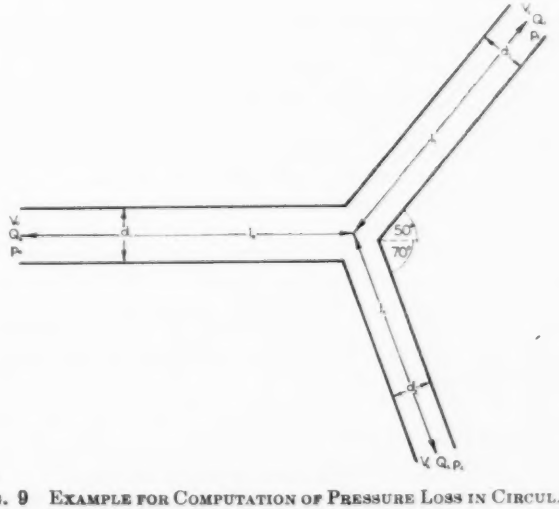

Fig. 9 Example for Computation of Pressure Loss in Circular Duct Branch With Separating Flow

tory loss coefficients. It makes considerable difference whether an elbow discharges into open air or into another pipe. In the latter case there is a recovery in the static pressure, while in the former case the losses are much higher. From now on it will be assumed that we are considering ducts for which Equation [8] can be used.

Obviously, the lengths of the inserted pipes before and after the duct are of extreme importance for the tests. Probably a pipe 50 diam in length is long enough to dissipate disturbances. However, there are examples where disturbances prevail for a distance of over 100 diam. It appears that a rotation of the flow (as for instance after a double elbow) persists for a particularly long distance.

Friction and Mixing Loss

The loss in a duct will obviously depend upon the wall roughness, besides the geometry of the duct, the velocities, etc. How-

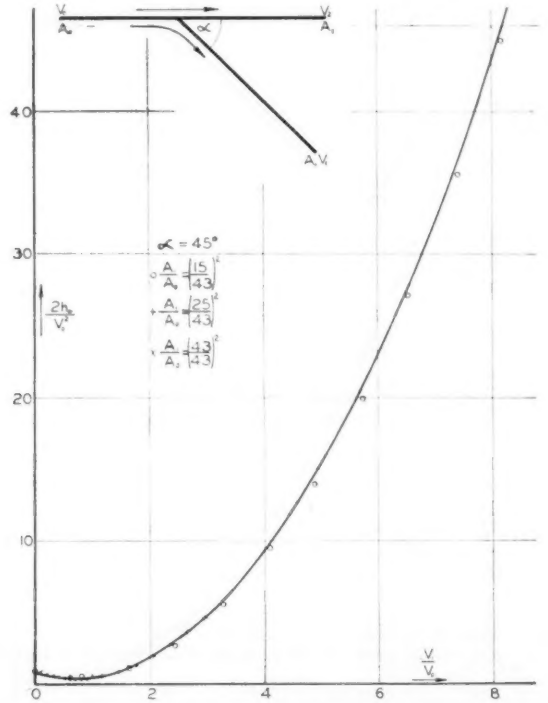

Fig. 10 Pressure Loss in Circular Duct Branch With Separating Flow, Expressed as Fraction of Kinetic Energy of Entering Fluid

(Angle of deflection 45 deg; diameter ratio d_1/d_0 = 15/43, 25/43, 43/43. Data from Bibliography (28), pp. 106, 107, 108.)

ever, it is possible to divide the losses into two groups "the friction loss" and the "mixing loss." Consider the duct "straightened out" in such a way that the center line becomes straight but its length is unchanged. This is a rather indeterminate procedure in general but rather well defined for elbows or a system of long pipes. The loss due to wall friction in the straightened-out duct of the same center-line length is the so-called friction loss of the original duct. The remaining part will be called the mixing loss. Consider, for example, an elbow; then Equation [8] can be written in the form

$$p_1 + \frac{1}{2}\rho V_1^2 = p_2 + \frac{1}{2}\rho V_2^2 + \frac{f_1 l_1 P_1}{A_1} \cdot \frac{1}{2}\rho V_1^2 + \frac{f_2 l_2 P_2}{A_2} \cdot \frac{1}{2}\rho V_2^2 + h\rho \quad \ldots\ldots [9]$$

where h is now the mixing loss by definition. Experiments have shown that h does not vary too much when the wall roughness varies while, obviously, the total loss varies considerably with the roughness, both entrance and exit pipes being necessarily

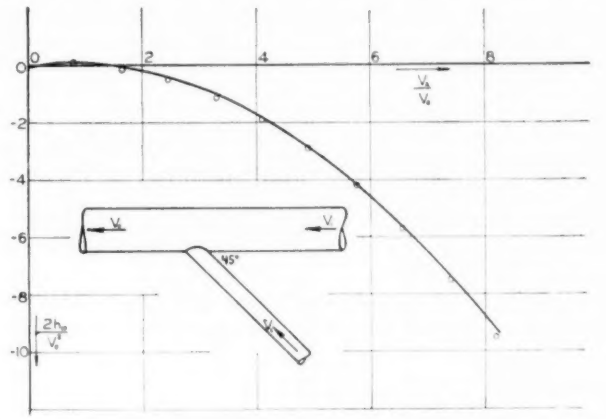

Fig. 11 Pressure Loss in Circular Duct Branch With Uniting Flow Expressed as Fraction of Kinetic Energy of Leaving Fluid

(Angle of deflection 45 deg; diameter ratio d_2/d_0 = 15/43. Data from Bibliography (28), p. 106.)

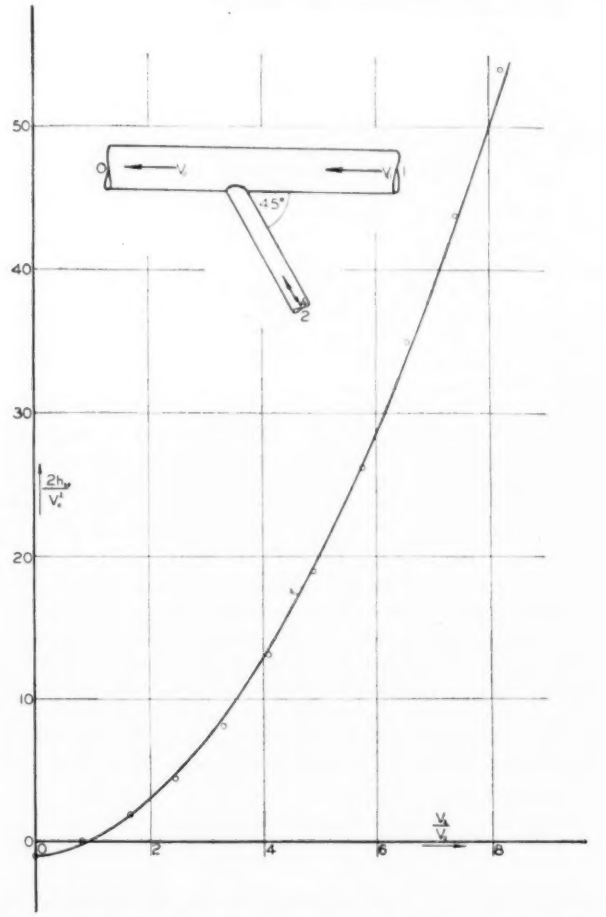

Fig. 12 Pressure Loss in Circular Duct Branch With Uniting Flow, Expressed as Fraction of Kinetic Energy of Leaving Fluid

(Angle of deflection 45 deg; diameter ratio d_2/d_0 = 15/43. Data from Bibliography (28), p. 107.)

long. Furthermore, the total loss depends also upon the lengths of the exit and entrance pipes.

Miter Elbow

In order to develop an appropriate formula for this duct, let us consider first qualitatively what happens to the fluid in this passage.

Let us assume that the angle of deflection is small. The elbow acts as a diffuser and little turbulence occurs in the passage. Diffuser losses have been successfully correlated with the expression

$$2h = (1 - \eta)(V_2^2 - V_1^2) \quad [10]$$

where η is the efficiency of the diffuser, and it might be expected that elbows with a small angle of turn can be correlated with the same formula.

On the other hand, let us consider the case when the angle of turn is large. In this case, considerable turbulence occurs in the fluid and we have a situation similar to that of the suddenly enlarging pipe. But it is known that for this case the so-called Carnot formula, which is based on the momentum equation, works very well (33). So we are going to try to use the momentum equation for an elbow. The pressure in the dead-water region is unknown, and so we write the momentum equation in the direction of the leaving fluid, eliminating thereby this unknown pressure. We assume, furthermore, that the pressure on the wall $a - b$ (Fig. 6) equals p_1, the initial pressure. The momentum equation yields

$$p_1 A_2 + \rho V_1^2 A_1 \cos \alpha = p_2 A_2 + \rho V_2^2 A_2 \quad [11]$$

where it is assumed that the fluid enters under an average angle α and that the effect of wall friction is negligible. Combining

$$p_1 + \frac{1}{2}\rho V_1^2 = p_2 + \frac{1}{2}\rho V_2^2 + h\rho \quad [12]$$

with Equation [11], we get for the mixing loss

$$2h = V_1^2 + V_2^2 - 2V_1 V_2 \cos \alpha \quad [13]$$

This equation is not to be expected to be exact because of our assumptions. So we complete it with an experimental coefficient

$$2h = \xi(V_1^2 + V_2^2 - 2V_1 V_2 \cos \alpha) \quad [14]$$

Now we have two different expressions for the elbow loss, Equations [10] and [14], and we combine the two expressions to get

$$2h = \xi(V_1^2 + V_2^2 - 2V_1 V_2 \cos \alpha) + (1 - \eta)(V_2^2 - V_1^2) \quad [15]$$

or

$$2h = \lambda_4 V_1^2 - 2\lambda V_1 V_2 \cos \alpha + (2\lambda - \lambda_4) V_2^2 \quad [16]$$

Now let us consider an elbow with an extremely narrow inlet pipe, where $V_2 = 0$. Obviously, all the entering kinetic energy will be dissipated and so we get $\lambda_4 = 1$. Hence the final formula is

$$2h_{12} = V_1^2 - 2\lambda V_1 V_2 \cos \alpha + (2\lambda - 1) V_2^2 \quad [17]$$

Fig. 13 shows losses for a circular miter elbow with equal entrance and exit cross sections. Putting $\lambda = 0.6$ in the formula, a curve results which fits the data well. Fig. 14 shows losses for rectangular elbows. The experimental points are too badly scattered to get a reliable estimate of λ. But by considering the limiting case when fluid is discharged from a large container into a pipe, it appears that $\lambda = 0.75$ is a good value.

Pipe Branches With Separating Flow

Consider the branch pipe composed of two elbows, as shown in Fig. 7. Then we can apply our elbow formula, Equation [16], to each of these elbows. We get for the mixing loss in the branch pipe

$$2h_{01} = \lambda_1 V_0^2 + (2\lambda_1 - \lambda_3) V_1^2 - 2\lambda_0 V_0 V_1 \cos \alpha' \quad [18]$$

where we assume that the fluid leaves the branch pipe through opening 1 at an average angle of α'. This angle will be called the effective angle of turn. In order to determine λ_1 we consider experiments when all the fluid is discharged through opening 2. Then $V_1 = 0$ and an experimental curve for λ_1 can be drawn. This curve is plotted in Fig. 2. Then by drawing best fitting

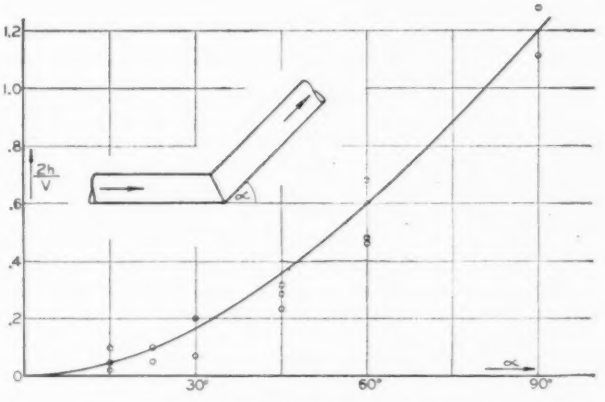

Fig. 13 Pressure Loss in Circular Elbow, Expressed as Fraction of Kinetic Energy of Fluid
(Inlet diameter equals exit diameter. Data from Bibliography (34).)

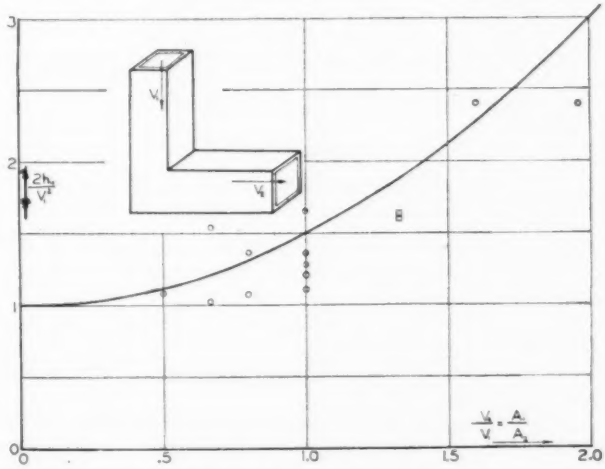

Fig. 14 Pressure Loss in Various Rectangular Elbows With 90-deg Angle of Deflection, Expressed as Fraction of Kinetic Energy of Entering Fluid
(Data from Bibliography (10), (25), (34).)

curves, λ_3 and the effective angle of turn are determined as functions of α (Figs. 2 and 3).

Pipe Branch With Uniting Flow

The derivation of the loss formula for this case will be briefly indicated. Let p' be the "average" pressure in the section of the duct where the two entering fluid streams meet (see Fig. 8). The inlet pipes act as diffusers, and so it is to be expected that the values of p' can be correlated with a formula similar to Equation [10]. This is indeed the case, and the unknown coefficients can be determined from the special experimental cases when $V_1 = 0$ or $V_2 = 0$. After p' has been determined in this fashion,

the momentum equation can be used in the direction of the leaving flow as indicated in Fig. 8. The final result is Equation [III] of the introduction.

Example

Problem. Determine the pressure loss with uniting flow through the duct in Fig. 9, assuming that the rate of flow through pipes 1 and 2 is given as Q_1 and Q_2.

Solution. First we determine the velocities in the pipes

$$V_0 = \frac{4(Q_1 + Q_2)}{\pi {d_0}^2}, \quad V_1 = \frac{4Q_1}{\pi {d_1}^2}, \quad V_2 = \frac{4Q_2}{\pi {d_2}^2} \ldots\ldots [19]$$

Now, knowing the velocities, we can compute the Reynolds number and look up the friction factors corresponding to the given wall roughness, and determine the friction loss as follows

$$\text{Friction loss from 0 to 1} = \frac{4f_0 l_0}{d_0} + \frac{4f_1 l_1}{d_1} \ldots\ldots [20a]$$

$$\text{Friction loss from 0 to 2} = \frac{4f_0 l_0}{d_0} + \frac{4f_2 l_2}{d_2} \ldots\ldots [20b]$$

In order to get the mixing loss, we have to find the effective angle of turn and the λ_1, λ_2 values corresponding to the angles 50 and 70 deg. We find from Figs. 2 and 3

when $\alpha = 50$ deg, then $\alpha' = 55$ deg, $\lambda_1 = 1, \lambda_2 = 0.9, 2\lambda_1 - \lambda_2 = .2$

when $\alpha = 70$ deg, then $\alpha' = 68.5$ deg, $\lambda_1 = 1, \lambda_2 = 0.9, 2\lambda_1 - \lambda_2 = .2$

Putting these values into Equation [II], we get for the mixing loss

$$2h_{01} = V_0^2 + 0.2V_1^2 - 1.8V_0V_1 \cos 55 \text{ deg} \ldots\ldots [21a]$$

$$2h_{02} = V_0^2 + 0.2V_2^2 - 1.8V_0V_2 \cos 68.5 \text{ deg} \ldots\ldots [21b]$$

From Equations [20] and [21], we get the total loss by addition.

Conclusions

The results and methods of this paper are believed useful in the following respects:

1 The formulas presented permit the calculation of losses in many duct branches by reasonably accurate correlation of sparse test data.

2 The number of curves required to present experimental data can be greatly reduced.

3 The method is applicable to many other configurations, including diffusers.

4 The formulas obtained by the method presented point the way to necessary tests in future test programs.

Acknowledgment

The author wishes to expresses his appreciation to Prof. H. W. Emmons of Harvard University for the suggestion of the subject and for his invaluable aid in the work.

Discussion

MAURICE MARTIN.[6] The author should be commended for attempting to correlate the results of previous experiments. One of the outstanding features of previous work in this field has been the divergence of test results. This is due, of course, to the many unknown variables mentioned by the author. The writer has found that the best method for determining losses is to make and test typical duct layouts utilizing workmanship and material available to the engineer in actual construction. If this proves too cumbersome a method, the writer has found remarkable agreements in present literature on the losses in elbows and branches, i.e., "Fan Engineering" of the Buffalo Forge Company.

The writer has found that in Dr. Vazsonyi's attempt to apply the equation developed for elbows to losses in branches, he has failed to take into account the fact that the amount of air that will turn from the main and enter the branch will depend almost entirely on the resistance or back pressure set up by the entire length of branch as compared to the resistance of the remaining portion of main duct. One cannot, therefore, consider an imaginary splitter n the main to take off a definite portion of air. This is especially true in consideration of the two branches at the end of the main.

[6] Assistant Naval Architect, Navy Yard, Brooklyn, N. Y. Jun. A.S.M.E.

Most modern experiments on the subject agree that the losses in both elbows and branches can be expressed best in terms of the velocity or velocity pressure in the duct and, workmanship and other things being equal, for geometrically similar elbows and branches will depend directly on this pressure. When approached from this viewpoint I think that the author will find little disagreement in the more recent experiments.

E. O. BERGMAN.[7] Several tests of branching pipes have been made by the U. S. Bureau of Reclamation to check and extend the work of Professor Thoma. These have been published in Boulder Canyon Projects Final Reports; Part VI, Hydraulic Investigations; Bulletin 2, Model Studies of Penstocks and Outlet Works.

AUTHOR'S CLOSURE

Mr. Martin is right in stating that in certain cases "the amount of air that will turn from the main and enter the branch will depend almost entirely on the resistance or back pressure set up by the entire length of branch, etc." However, Equation [9] of the paper takes care of the resistance of the branch pipe, whereas the "mixing-loss" formulas take care only of the additional "nonfrictional" losses. This is exactly the reason why it was necessary to separate the friction loss from the mixing loss.

Mr. Martin is also right in stating that many experimenters did not pay due attention to the great number of variables and thus received contradictory results. However, it is difficult to see how such experiments could be made satisfactory by introducing new variables.

The reports quoted by Mr. Bergman were not known to the author.

Laboratory and Field Tests on Coal-in-Oil Fuels[1]

By J. F. BARKLEY,[2] A. B. HERSBERGER,[3] and L. R. BURDICK[4]

It has been determined from extensive laboratory and field tests on the stability of coal suspensions in fuel oil that each installation must be given individual consideration if satisfactory results are to be obtained. However, no particular difficulty in devising equipment or operating routine for efficient use need be experienced. A sufficiently stable suspension of coal in oil for practical purposes can be prepared by dispersing 40 per cent coal by weight ground from 98 to 99 per cent through a 230-mesh screen in heavy fuel oil. Careful control of storage and handling temperatures is required for most successful operation. Combustion efficiency is likely to be slightly less than that of fuel oil. The best opportunity for the successful use of coal-in-oil suspension is in the larger plants with better operating personnel and more readily accessible equipment.

Introduction

THE following report covers laboratory studies on the stability of coal suspensions in oil, the mixing of pulverized coal and oil, and field tests on these mixtures in typical oil-burning equipment. This work was undertaken to obtain needed practicable information not found in technical literature, a review of which was given by Schroeder[5] in 1942. The work is the result of a joint effort by the Federal Bureau of Mines and The Atlantic Refining Company of Philadelphia, Pa. The laboratory work and preparation of the fuels were done by The Atlantic Refining Company. The main series of field tests made at The Atlantic Refining Company's Philadelphia Plant and additional tests made at the Cambria Silk Hosiery Company and the National Airoil Burner Company, both in Philadelphia, were conducted by the Bureau of Mines.

Laboratory Studies

In the laboratory, stabilities of coal-in-oil suspensions were studied by measuring the change in the center of gravity of the suspensions by means of a pendulum arrangement. This method was first used by Manning and Taylor.[6] The results are reported as the percentage of the coal settled, based on 100 per cent settled, as determined in an alcohol-water mixture. Other methods were also used to check the results obtained in this manner. Details of the procedures are given in the Appendix.

The majority of the samples were mixed by vigorous stirring under about 10-mm vacuum. This was done to avoid including air in the samples which would eventually interfere with the pendulum readings.

The absolute viscosities, reported in Figs. 1 and 2, were obtained by means of a Brookfield Synchro-lectric viscometer which had been calibrated for average rates of shear and shearing stresses. The coal used in most of the experimental work was

screened to narrow size ranges. The data presented in Figs. 1 to 8, inclusive, are representative of a large number of experiments. The properties of the bituminous coal and the oil used in this particular set of experiments are given in Table 1. The oil was a typical refinery product containing both straight-run and cracked components.

From consideration of elementary formulas, relating settling

TABLE 1 PHYSICAL PROPERTIES OF COALS AND OIL USED IN LABORATORY EXPERIMENTAL STABILITY STUDIES

Coal	No. SC-1	No. SC-2	No. 6 Fuel oil	
Specific gravity at 60 F	1.29	1.34	A.P.I. gravity at 60 F	14.6

Ash, per cent	3.5	4.5	Viscosity at 210 F	86 Saybolt
Moisture, per cent	0.7	0.4		
Fixed carbon, per cent	62.7	73.4		
Sulphur, per cent	0.78	1.19		

velocities to particle size, gravity differential between the particles, and the liquid medium and its viscosity, it was evident that the best results would be obtained by using bituminous coals (low specific gravity), and oils of high specific gravity and high viscosity. It was also evident that suspensions of high coal content would be more stable than those of low content because of hindered settling.

The actual conditions for settling in concentrated suspensions are complex. Such suspensions develop rigidity for high solids content. Coal-in-oil suspensions have been shown to develop this rigidity[7] in the neighborhood of 38 volume per cent of coal.

A number of experiments were run to determine the effect of coal concentration on the viscosity of the coal-in-oil suspension. For finely divided coals in heavy fuel oils, the viscosities of the suspension were found to rise markedly in the region of 40 to 50 per cent of coal by weight, such results being in general agreement with those reported by others. This rapid rise in viscosity in the range of 40 to 50 per cent of coal was found to be relatively independent of the viscosity of the oil and the temperature of the measurement. These suspensions were also found to be non-Newtonian, i.e., the viscosity varied with the rate of shear, this deviation from viscous flow resulting from the development of structure in the suspension. Fig. 1 shows a typical viscosity-per cent coal curve.

If it is assumed that the rigidity in concentrated coal-in-oil suspensions results from the particles touching each other, it would appear that the smaller the diameter of the particle, i.e., the larger the surface area per unit concentration of coal, the greater the interference between particles. This should be evidenced by the effect of particle size on viscosity for concentrated suspensions, other variables being constant. Fig. 2 shows the effect of particle size of the coal on the viscosity of a 40 per cent by weight suspension of coal in oil. It is seen that a rapid increase in viscosity occurs between the coal sizes of 200/230 and 230/325 mesh (U. S. Standard screen). This rapid rise in viscosity and then a flattening out may be regarded as the result of a critical increase in surface area where the interference between particles has become large. The viscosity of these suspensions was measured fresh and after aging. The positions of the two curves show that the suspensions are thixotropic, i.e., the viscosities decrease with agitation. This property is more pronounced with the smaller-size particles.

Determinations of the stability of 40 per cent by weight suspensions of bituminous coal in oil were made in which the particle size of the coal and the temperature were varied. The effect of these variables is shown graphically in Figs. 3 and 4. The suspensions are relatively stable at 77 F when the maximum particle size is not larger than 200 mesh. At 120 F a satisfactory degree of stability is obtained if the maximum particle size does not exceed 230 mesh. Fig. 5 is a plot of percentage settled in 20 days against average particle size.

It is to be noted that the marked improvement in stability occurring with decreasing particle size falls in approximately the same particle-size range as the rapid rise in viscosity occurs, as shown in Fig. 2.

[7] "Laminar Flow of Oil-Coal Suspensions," by F. J. Gradishar, W. L. Faith, and J. E. Hedrick, Trans. American Institute of Chemical Engineers, vol. 39, April 25, 1943, pp. 201–222.

The relation of the stability of the suspension to the coal concentration was determined for minus-230-mesh bituminous coal. These results are shown in Fig. 6. No worth-while degree of stability is obtained until a coal concentration of approximately 40 per cent by weight is used.

The effect of physical properties of the oil and coal on stability of suspensions was also found to be important. Oils with either low viscosity or low specific gravity, in general, gave less stable suspensions. No marked differences in the stability of suspension of bituminous coals of slightly different properties were observed, although the range of bituminous coals studied was narrow. One experiment was run on a sample of anthracite which proved to be considerably less stable than a similar suspension containing a bituminous coal. Data illustrating these facts appear in Table 2.

TABLE 2 EFFECT OF PHYSICAL PROPERTIES OF COAL AND OIL ON STABILITY OF SUSPENSION[a]

Coal			Oil		
Type	Specific gravity at 60 F	Mesh	A.P.I. gravity at 60 F	Furol viscosity at 122 F	Stability, 10 per cent settled at 120 F, days

Bituminous	1.32	99 per cent minus 230	17.5	89	6

[a] Coal by weight, 40 per cent.

TABLE 3 EFFECT OF OVERSIZE PARTICLES ON STABILITY OF 40 PER CENT SUSPENSION OF COAL IN OIL BY WEIGHT

Size of oversize coal	Oversize coal, per cent (based on coal)	Stability 10 per cent settled at 120 F, days
Blank—230/325-mesh bituminous coal in No. 6 fuel oil	..	23
100/140	5	14
6/100	5	5

Laboratory samples were mixed by vigorous stirring under about 10-mm vacuum; other methods of mixing were also tried, such as passing the mixture through a homogenizer and ball-milling. Neither of these methods gave suspensions of better stability than those obtained by vigorous agitation of the mixture.

The coal used in the laboratory experiments was screened to a narrow range of sizes. From a practical point of view the effect of the maximum-size coal particles on the stability of the suspensions is important. The presence of small quantities of oversize particles was found to decrease the stability of the suspensions; data are shown in Table 3.

Figs. 7 and 8 show some stability tests on coal-in-oil suspensions containing stabilizers. Tests were conducted on 140/200 U. S. Standard-mesh coal at 77 F, and on 200/230-mesh coal at 120 F. Lime-resin soap (1 per cent), claimed to be an excellent stabilizer, was found to be very poor. Of all the stabilizers studied, the addition of 1 to 1.5 per cent of sulphuric acid to the coal surfaces before mixing with the oil was found to give the best results. Coal tar when used as 10 per cent of the oil mixture showed a stabilizing action. However, even these two materials, which were considerably better than any others of a large number tried, were not as effective as additional grinding of the coal, say, from minus-200 to minus-230 mesh. Also, both sulphuric acid and 10 per cent coal tar have practical disadvantages—sulphuric acid because of its probable corrosive action and coal tar because of the large quantity required.

If the criteria, from a stability and handling viewpoint, of a satisfactory coal-in-oil fuel are (1) high degree of stability at normal temperature, (2) sufficient stability at elevated temperatures to permit handling in conventional oil-burning equipment and (3) reasonable viscosity, the results of this work point

toward a 40 per cent by weight suspension of minus-230-mesh bituminous coal dispersed in No. 6 fuel oil. For practical purposes, the coal-specification size could be set at 98–99 per cent passing a 230-mesh screen and the limiting oil properties at 12 to 14.8 A.P.I. gravity at 60 F, and 55–70 Furol viscosity at 122 F. The laboratory results also indicate that the coal can be dispersed in the oil by relatively simple methods.

Tests in Typical Oil-Burning Plants

To obtain information on the operating problems involved in handling and burning coal-in-oil mixtures in typical oil-burning plants, tests were made at three different plants. From the laboratory information, it was decided to experiment with fuel of about 40 per cent coal by weight. Four batches of fuel were prepared, one batch having coal of a fineness of about 88 per cent through a 230-mesh A.S.T.M. (U. S.) Standard screen, one of about 95 per cent, and two of about 99 per cent. Coal could be ground to this fineness in present standard commercial equipment. As far as the authors know, no equipment is available at present that will, from a practical standpoint, continuously and satisfactorily produce coal of, say, the extreme fineness of minus 325 mesh. Table 4 gives data on the coal and oil used in the mixtures. In addition, the Appendix gives the distillation results, Bureau of Mines, Hempel method, obtained with the oil used in batch 3.

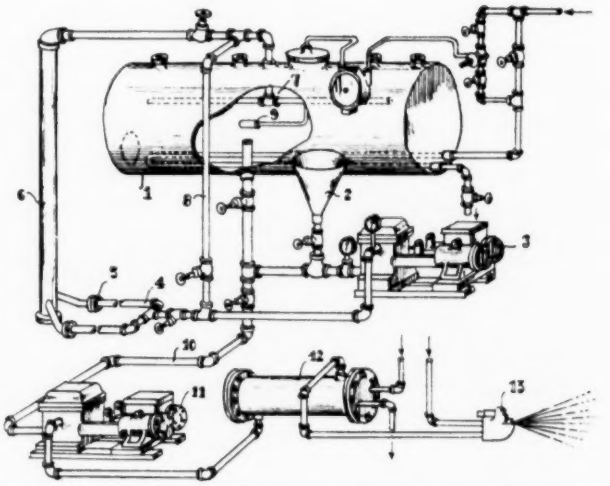

FIG. 9 TEST ASSEMBLY SHOWING GENERAL ARRANGEMENT OF MIXING DEVICE AND OIL-BURNING EQUIPMENT

1 Steam coil
2 Hopper, powdered-coal intake (approx 2.5 ft diam)
3 Duplex double-acting pump: Steam end, 7.5 in. ID Liquid end, 7.5 in. ID Stroke, 10 in.
4 Split flow
5 Knothole mixer (1 in.)
6 Riser
7 Spreader
8 By-pass
9 Temperature controller
10 Feed line to burner system
11 Reciprocating feed pump
12 Preheater
13 Steam-atomizing burner (1/2 in. Best)

As indicated by the laboratory results, it was found in the field that the mixing of the coal and oil needed for the tests did not present much difficulty. A simple batch-mixing device shown in the upper part of Fig. 9 was used. The fuel oil required for a batch, (about 5000 to 7000 gal), was put in the storage tank and then pumped from the tank suction line by an ordinary reciprocating pump. The oil temperatures used varied from about 75 to 120 F, the chosen temperature being maintained by steam coils in the tank. In the suction line, mounted on a tee and valve, was a funnel kept filled with pulverized coal. The coal under hand valve control was allowed to flow slowly into the stream of oil on its way to the pump. The mixture was discharged by the pump through two horizontal pipes, each having an orifice near the end. After passing the orifices, the two streams of fuel met at the base of a vertical pipe and then passed on to the storage tank. The fuel was spilled into the tank from two outlets, one at each end of the tank. The coal was fed into the oil at the rate of about 1500 lb per hr, and the fuel was continually circulated at a rate of about 9000 gph.

After the required amount of coal was fed for the batch, the fuel was circulated for about 12 hr. Laboratory tests of samples of fuel taken at various places throughout the tank showed that the mixture was uniform. No further recirculating of the fuel was done during burning tests, the mixing device being valved off from the suction line.

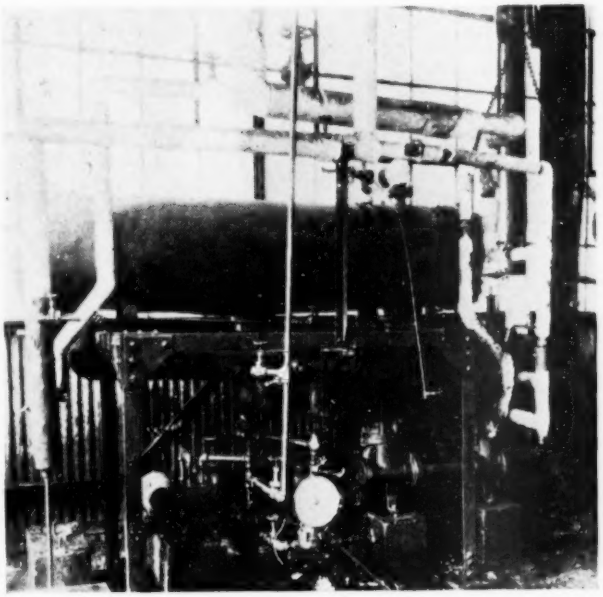

FIG. 10 HEATER-PUMP SET USED

Putting coal into oil produces a fuel having characteristics different from those of oil. The mixture used was about 10 per cent heavier in weight per unit volume than oil; it was about 4 to 8 times as viscous depending upon the temperature; it was much more abrasive; any settling out of the coal resulted in paste-like accumulations in various parts of the equipment, such as tanks, heaters, and valves; the ash from the coal was set free in the furnace.

TESTS AT ATLANTIC REFINING COMPANY BOILER PLANT

The first and main series of tests was made at one of the boiler plants of the Atlantic Refining Company. The boiler-plant equipment was typical of that of many oil-burning plants. The suction line from the outside above-ground oil storage tank ran underground about 100 ft to the heater-pump set. A steam line, that helped maintain fuel temperatures to the pump, paralleled the oil suction line. Fig. 10 shows the heater-pump set. One pump was a reciprocating and the other a rotary. The fuel was heated to about 160 to 200 F at the set and was pumped about 110 ft to the boiler. A standard Best steam-atomizing burner was used, as shown in Fig. 11. The fuel reaches a horizontal slot at the burner tip through the lower pipe; the steam reaches a vertical slot through the upper pipe and sweeps the fuel into the furnace. The fuel and steam were under hand control.

The boiler was a 151-hp, long-drum, straight water-tube Babcock & Wilcox boiler, 8 tubes wide and 9 tubes high. Fig. 12 shows the boiler layout. The boiler was first operated on oil to establish normal operating characteristics. It was then operated continuously on coal-in-oil fuel. Table 5 shows the average results when fuel oil and coal-in-oil fuels were used. These tests were not specially run by test operators but were run as part of the regular plant steam production with the usual company plant operators. As shown in the tabulation, these operators obtained slightly lower boiler efficiencies with the coal-in-oil fuels than with the oil; about 79.5 to 80.5 per cent was obtained with the coal-in-oil fuels against 81.2 per cent with the oil; the difference is small enough to be within test errors. There was a small loss, item 69, of unburned combustible in the fly ash for the coal-in-oil fuels that was measurable.

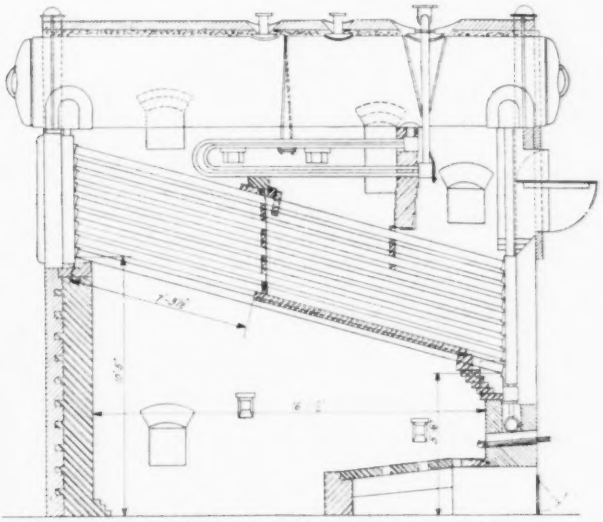

FIG. 12 GENERAL LAYOUT OF BOILER AND FURNACE

No difficulties arose in burning the coal-in-oil fuels in the furnace with the steam-atomizing burner used. The flame responded smoothly to changes of boiler load and to variations of the quantity of air used for combustion. It could be controlled with the same ease as fuel oil. The CO_2 content of the products of combustion could be carried as chosen up to about 16 per cent with no CO. During operation no difficulties were experienced in the production of smoke; smoke could be controlled the same as with oil. However, in starting up a cold furnace with a coal-in-oil fuel, considerable smoke was produced. Fig. 13 shows conditions when starting. The boiler was operated at about rating during most of the testing, this load fitting best into the plant steam requirements from this boilerhouse. However, ratings from about 40 per cent to over 200 per cent were carried for several hours without difficulty.

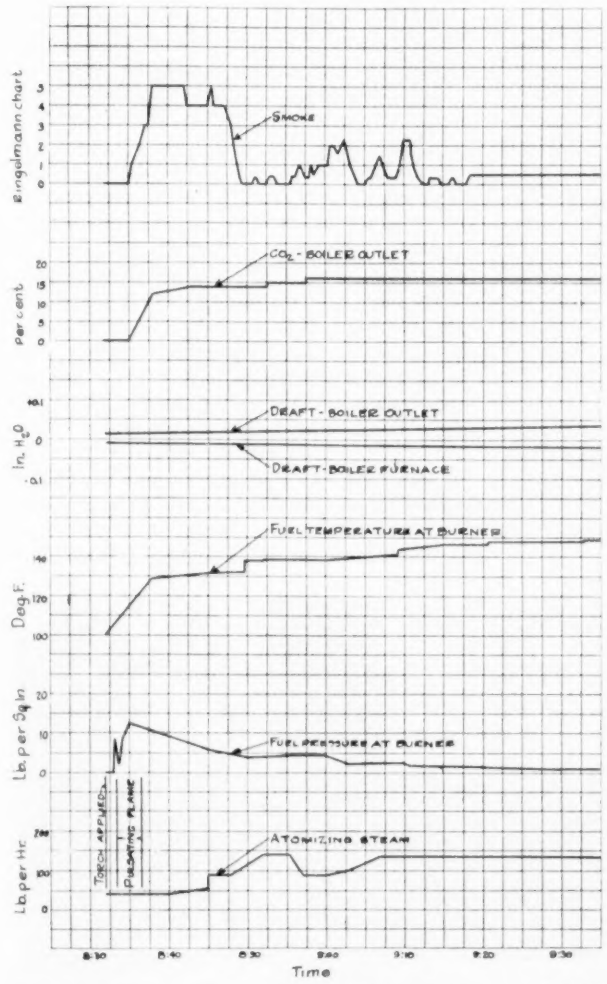

FIG. 13 CURVES SHOWING OPERATING CONDITIONS WHEN STARTING WITH COAL-IN-OIL FUEL IN COLD BOILER FURNACE

As shown in Table 5, about two-thirds more atomizing steam was required for the coal-in-oil fuels than for the oil. Both saturated steam and superheated steam were tried. Essentially the same amount of each was required to produce the same combustion results, as far as could be measured. It was found, however, that superheated steam gave a little less difficulty from pulsations and blowing of flame from the burner when higher amounts of steam per pound of fuel were used.

Troubles from the ash of the coal in the furnace were less than had been anticipated. The use of pulverized coal has supplied a vast amount of information on the action of ash in boiler furnaces and passes. In general, much less ash troubles should be expected with coal-in-oil fuels. It is not desirable to re-explore this field to any great extent in connection with an emergency fuel.

Fig. 14 is a view of the furnace with the ash accumulation after one week of operation. There was no dripping or slagging. The fly ash on the tubes was cleaned without difficulty every 8 hr during the test by the boiler soot blowers. Fig. 15 shows the effects of soot-blowing on the flue-gas temperatures when running at about rating with a CO_2 range from about 14.7 to 15.9 per cent. As shown in Table 5, about 45 per cent of the ash in the fuel accumulated in the furnace and breeching of the boiler.

It was found that with batch No. 1, for which coal had been ground to a fineness of about 88 per cent through a 230-mesh screen, there was considerable sludge accumulation at the bottom of the tank after about 7 days. The average temperature maintained in the tank was 81 F; no movement was given the fuel. With batch No. 2, for which coal had been ground to 95 per cent through a 230-mesh screen, only a small amount of sludge had accumulated at the end of 5 days. The average temperature in this case was 85 F. With batch No. 3, for which coal had been ground to 99 per cent through a 230-mesh screen, no discernible settling occurred after 9 days with the temperature in the tank at about 82 F. When the temperature was raised to 120 F, however, sludge accumulation was definitely discernible at the end of a few days. About 1500 gal of batch No. 4, for which coal had been ground to 99 per cent through a 230-mesh screen, was loaded in a typical delivery tank truck at about 115 F. The truck was then driven on the highway for about 9 hr covering about 150 miles; it was then allowed to stand for 32 hr. No settling occurred. The fuel was allowed to stay in the standing truck about 8 weeks. No settling was found at the end of this period. These field findings check with the laboratory findings.

No settling or clogging was experienced in the pipe lines from tank to pump to burner, although the lines were relatively long and the fuel was at elevated temperatures. For a given temperature, the coal in a coal-in-oil fuel separates much more readily when quiet than when the fuel is in motion.

There was appreciable accumulation of coal-oil paste in the heater when both batch No. 1 and batch No. 2 were used. It was unnecessary, however, to clean the heater during either test run. With the 88 per cent coal, there was an accumulation of 113 lb of paste after about 7 days; with the 95 per cent coal, 84 lb of paste after about 6 days. With the 99 per cent coal, the accumulation after about 9 days was practically negligible, being so

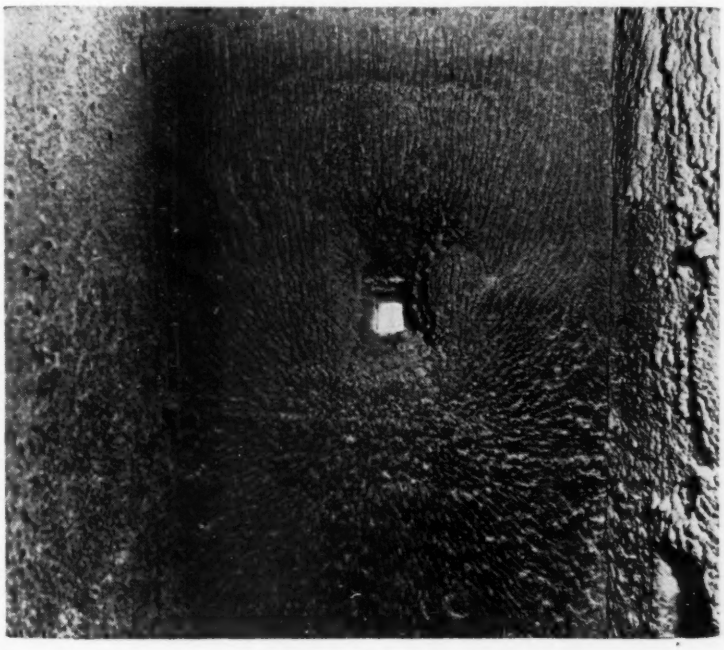

FIG. 14 INTERIOR OF BOILER FURNACE SHOWING ASH ACCUMULATION AFTER ONE WEEK OF OPERATION

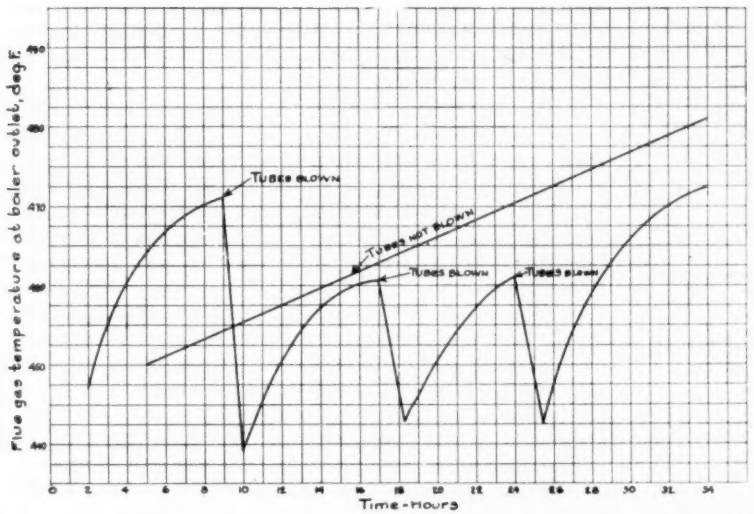

FIG. 15 CURVES SHOWING EFFECT OF USE OF BOILER SOOT BLOWERS ON EXIT TEMPERATURES OF FLUE GASES

somewhat higher amount of steam, which could readily be done when superheated steam was used, appeared to help prevent this trouble.

Coal-in-oil fuels with their higher specific gravity and viscosity present new pumping problems when used in oil equipment. Studies of the flow of oil-coal suspensions have been reported by Gradishar, Faith, and Hedrick;[7] they supply formulas for determining pressure differentials. Table 1 gives viscosity comparisons of the coal-in-oil fuels, and the oil from which they were made.

The main pumping problem was from the storage tank to the pump; after the fuel was heated in the heater it was not so hard to pump. Coal-in-oil suspensions would have to be heated to temperatures of 140 to 170 F to give about the same viscosity as that of oil at about 100 F. These higher temperatures were avoided in the storage tank in order to eliminate settling of coal-oil paste. At The Atlantic Refining Company boiler plant, the storage tank was above ground, and when oil was pumped at about 70

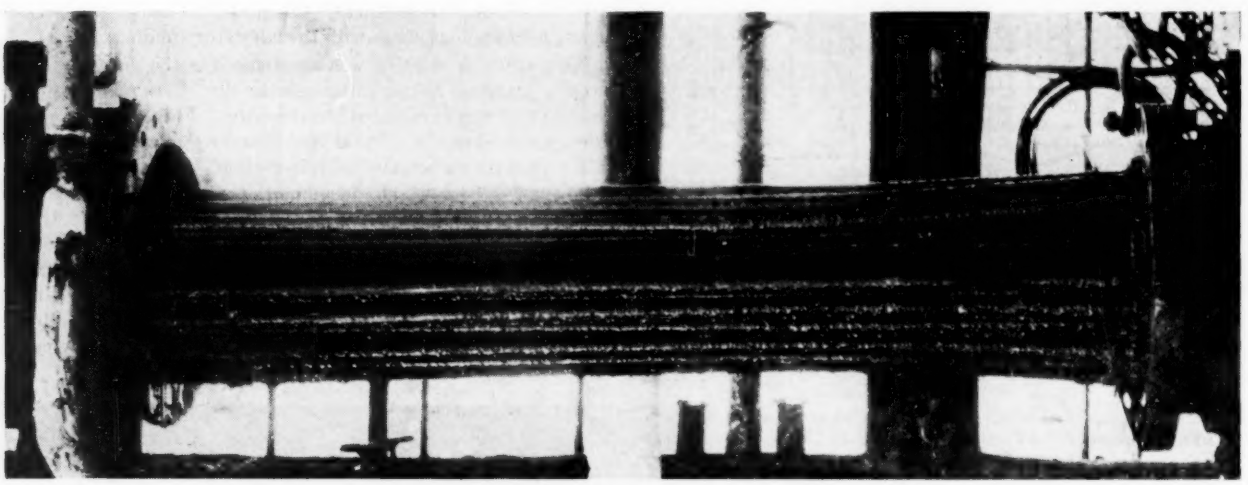

FIG. 16 VIEW OF HEATER COILS AFTER ABOUT 9 DAYS OF USE IN HEATING TO ABOUT 150 TO 170 F COAL-IN-OIL FUEL HAVING 99 PER CENT OF COAL GROUND TO MINUS 230 MESH
(Accumulation was so slight as not to warrant cleaning for the next run.)

slight as not to warrant cleaning the heater. Fig. 16 shows the heater coils after the 99 per cent coal was used. In a steam heater of this type, some of the fuel is heated much hotter than the average temperature shown at the heater outlet. Fuel in contact with the steam coil approaches the temperature of the steam which was of the order of 350 F entering the coil. An offsetting factor, however, is the movement of the fuel which helps keep the coal in suspension. When coal-in-oil fuel is used, it is best not to heat it any hotter than necessary at any point in the system up to the furnace. Operating routine can be arranged to clean the heater when found necessary. If there are two heaters, they could be used alternately.

There was some clogging in the meters and screens with all of the coal-in-oil fuels. By-passes prevented loss of load during cleaning. Occasionally throughout the day the fuel control valve tended to clog, but it could be readily cleared by opening it wide quickly. Control-valve clogging would be apt to create some difficulties under automatic control. The burner tip occasionally clogged a little and had to be blown clear with a shot of steam piped to blow through the oil slot. Carrying continuously a F at the pump the pressure at the oil-pump inlet was about 1.5 psi; when coal-in-oil fuels were pumped at about that temperature the inlet pressure was about 7 in. of vacuum or —3.4 psi. In starting up on coal-in-oil fuel, with no fuel in the lines about 1 hr pumping with the reciprocating pump was required to bring the fuel, at a temperature of about 80 F, from the tank to the burner; the rotary pump was not successful in starting the fuel but was quite satisfactory after the flow was established. When the fuel in the tank was 120 F, about $^1/_4$ hr of pumping was required to start.

About 30 lb pressure was in general maintained ahead of the burner oil-control valve for both oil and coal-in-oil fuels. Table 5 shows the pressures at the burner; much higher relative pressures were required for the coal-in-oil fuels. The electric inputs to pump motors were increased. Under one set of operating conditions this input was about doubled. The increase in motor input depends upon the percentage of the total pump load which comes from moving the fuel itself.

For the rotary pump used the capacity dropped about 20 per cent. No satisfactory measurement was obtained in the loss of capacity of the reciprocating pump. The higher-viscosity fuel

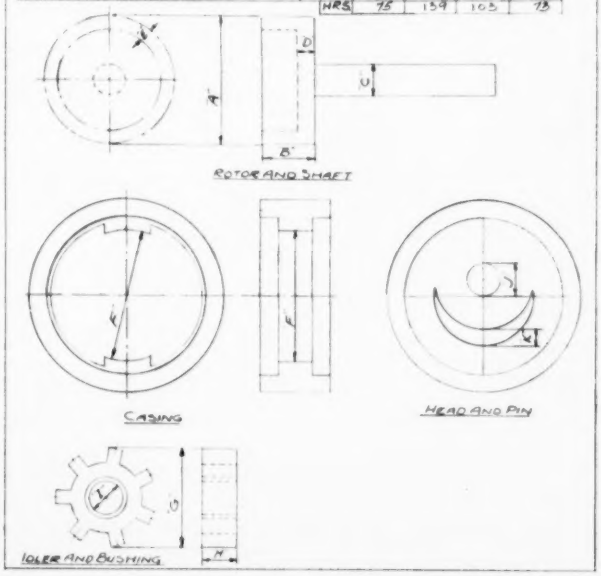

FIG. 17 TABLE AND SKETCH SHOWING WEAR ON ROTARY PUMP FROM PUMPING COAL-IN-OIL FUEL

causes the valves of reciprocating pumps to seat at a slower speed; stiffer valve springs helped to overcome this difficulty.

Coal-in-oil fuel was found to be rather abrasive. It acted something like a lapping powder. Fig. 17 gives a record of the wear on the rotary pump shown in Fig. 18. Appreciable wear occurred at the spindle; no repairing, however, was found necessary during the entire series of tests. There was also some cutting of the burner tip. Fig. 19 shows this erosion at both outer edges of the tiptable. It was unnecessary, however, to change the tip during the tests, good combustion being obtained. It is doubtful if this abrasive characteristic would necessarily be a serious handicap to successful operation. Equipment affected would have to be watched and repaired as found necessary.

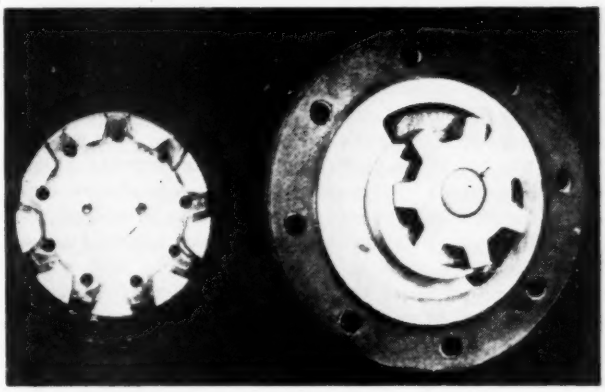

FIG. 18 ROTARY TYPE OF OIL PUMP USED AS PART OF HEATER-PUMP SET
(Most of the wear was at spindle.)

TESTS AT CAMBRIA SILK HOSIERY COMPANY BOILER PLANT

A part of the batch No. 4 coal-in-oil fuel was burned in the boiler plant of the Cambria Silk Hosiery Company, Philadelphia, Pa. This plant was typical of the smaller industrial plant burning No. 6 fuel oil. The boiler used on the trial was a typical brickset 72-in. × 18-ft 150-hp H.R.T. boiler, equipped with one burner. The burner was a standard Johnson type 30-H automatic on-and-off rotary-cup burner having a maximum capacity of about 90 gph of oil. The oil pump, rated at 150 gph, an integral part of the burner assembly, drew oil from an underground storage tank through a 16-wire-mesh strainer and discharged it to a steam heater; from the heater the oil took two paths, one through a manually set relief valve back to the storage tank, and one to a 24-wire-mesh strainer to an electric heater, through a control orifice, and then to the burner cup. Primary air was supplied by a fan on the burner; additional air was dampered through a checkered furnace floor. Automatic ignition was effected by electric spark and gas pilot which were cut off after ignition.

In switching this plant from oil, the coal-in-oil fuel was not put into the underground storage tank. It was supplied to the pump through an auxiliary suction line of the same size as the main suction line direct from the delivery tank truck stationed about over the underground tank. This eliminated the suction lift. With the fuel at about 85 F in the truck, it was found that insufficient fuel could be pumped to maintain an even fire—perhaps

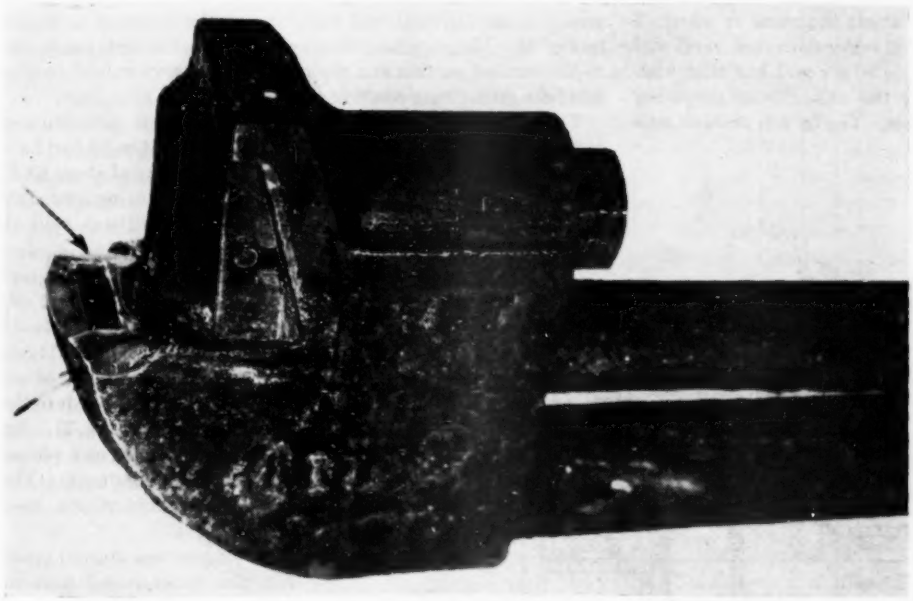

FIG. 19 VIEW SHOWING EROSION AT OUTER EDGES OF THE TIP-TABLE OF STEAM-ATOMIZING BURNER FROM USE OF COAL-IN-OIL FUEL

30 per cent of burner capacity—although 18 in. of vacuum was registered at the strainer just ahead of the pump. Under normal operation with No. 6 fuel oil at about 90 F from the underground tank, only 6 in. vacuum was required. A special heater was installed near the suction outlet in the tank and the relief hot-oil return flow was also piped closer to this outlet. This was done to heat the fuel at the suction outlet, where there was considerable movement; it was considered that the main body of fuel in the tank should be kept cool to avoid settling of coal-oil paste. When the fuel temperature at the suction was increased to about 95 F, the burner could be fired near capacity with a small amount of return oil to the tank. At 120 F very satisfactory pumping conditions resulted, a vacuum of 7 in. being carried.

On the delivery side of the pump it was found necessary to change the size of the orifice from 0.0935 in. diam as regularly used, to a larger orifice 0.161 in. diam to lessen restriction of flow. Under normal operating conditions with oil and with the smaller orifice, an oil pressure of about 15 to 18 lb was carried; with coal-in-oil fuel and with the larger orifice, a pressure of about 20 to 23 lb was required for the same load. The 24-mesh screen ahead of the electric heater became clogged after about 3 hr; a larger-mesh screen would be desirable for coal-in-oil fuels. The final temperature of the fuel to the burner ranged in general from about 140 to 160 F.

When starting with a comparatively cold furnace, it was found that the automatic ignition would not ignite coal-in-oil fuel; a hand torch had to be used. A larger gas pilot was needed. With a hot furnace, however, the automatic ignition operated quite satisfactorily.

The revolving cup of the burner for use with oil fuel was tapered outward somewhat. The flame of the heavier coal-in-oil fuel flared out from the cup more than the flame of the oil. This caused carbon masses to accumulate on the circular brickwork throat of the burner, which had to be cleaned about every 15 min. The tapered cup of the burner was changed to a straight-line cup; the brickwork of the throat was flared out a little farther. These changes resulted in satisfactory operation. The burner was readily adjusted and the CO_2 could be carried as chosen. Somewhat improved operation could be had by heating the fuel to about 160 to 170 F ahead of the burner. The efficiency when coal-in-oil fuel was used was about the same as when oil was used. The maximum load on the boiler with coal-in-oil fuel on this installation was approximately 10 per cent less than with oil. This was caused primarily by the difficulty of supplying enough secondary air in the right spots. The fly-ash problem was of little moment.

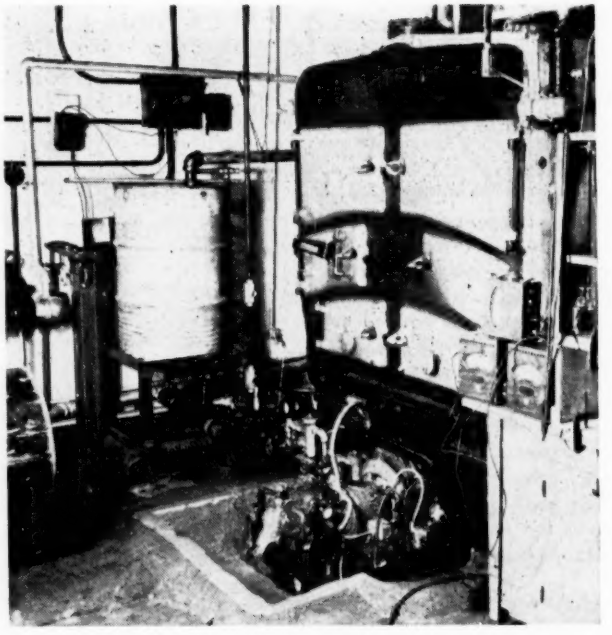

FIG. 21 VIEW OF BOILER FRONT AND BURNER AT HEATING PLANT OF NATIONAL AIROIL BURNER COMPANY

TESTS AT NATIONAL AIROIL BURNER COMPANY HEATING PLANT

In co-operation with the National Airoil Burner Company of Philadelphia, Pa., part of batch No. 4 of coal-in-oil fuel was tried in its office headquarters' heating boiler. This boiler was a cast-iron sectional boiler having an output of about 3,060,000 Btu (approximately 90 hp). It was equipped with a small rotary-cup burner of a capacity of 20 gph of oil. Figs. 20 and 21 show the general layout. This plant was typical of the small heavy-oil-burning heating plant.

Normally the plant uses No. 6 oil pumped from an underground storage tank. Since it was believed that the regular burner setup would not be able to pump coal-in-oil fuel from the underground tank, a 275-gal tank was installed above ground as shown in Fig. 21. The suction and return lines, *A* and *B*, were connected to the existing suction and return piping properly valved so that fuel from either tank could be used.

The oil burner was started with oil, and normal operation was established. The equipment was switched to coal-in-oil fuel having a temperature of about 68 F. The pump suction registered 20 in. of vacuum and was held at this point for 1 hr, but no fuel reached the burner. The equipment was switched back to oil, and the vacuum dropped to 15 in., giving a good oil flow. It was then decided to install a 52-gal tank above and to the side of the burner, as shown in Fig. 21. An electric fuel heater was placed directly under the tank. The usual suction and return lines were installed.

The burner was started on oil from the underground tank at 65 F, and a burner pressure of about 26 lb was used. The pump suction was about 13 in. of

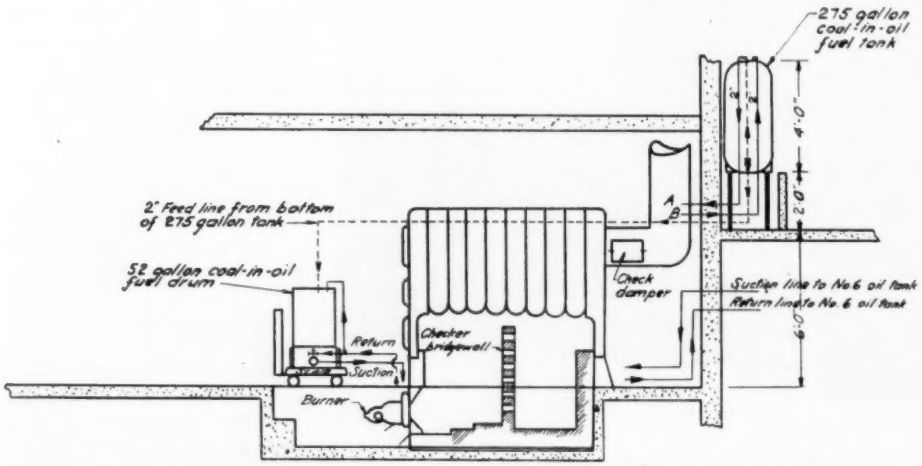

FIG. 20 GENERAL LAYOUT OF TEST SETUP AT HEATING PLANT OF NATIONAL AIROIL BURNER COMPANY

vacuum; the CO_2 ranged from about 11.5 to 13.5 per cent; the stack temperature was about 570 F. The equipment was switched to coal-in-oil fuel ranging in temperature at the tank from about 85 to 110 F. The pump pressure was about 26 lb; the pump suction was about 0; the CO_2 ranged from about 10.5 to 13.5 per cent; the stack temperature was about 625 F. The combustion was not satisfactory, as the flame was smoky at the outer edges. Carbon deposits accumulated on the side walls.

The equipment was shut down and allowed to cool to determine possibilities of cold starting with this type of equipment. After the fuel cooled in the pipe lines, it was very difficult to pump. The burner pressure was raised to about 40 lb to move it. The gas pilot would not ignite it. Ignition was finally obtained with a hand torch, and after furnace and fuel had reached higher temperatures, the flame was fairly well established. The carbon deposits continued to build up on the brickwork around the burner and in front of the cup until the opening was choked and it was necessary to shut down after about 20 min. The wider angle of the flame of the coal-in-oil fuel was the main cause of this difficulty.

Conclusions

Coal-in-oil fuel has its own peculiar characteristics which must be given thorough consideration for each job if satisfaction is to be obtained. However, this fuel does not present a particularly difficult problem in devising equipment and operating routine for efficient use. It appears that in some instances premixing of the fuel might be eliminated. The direct introduction of the coal into the flowing stream of oil to the heater-pump set offers possibilities. The information obtained from this work on bituminous coal-in-oil fuels leads to the following conclusions:

1 A sufficiently stable suspension of coal in oil for practical purposes can be prepared by dispersing 40 per cent coal by weight, ground from 98 to 99 per cent through a 230-mesh screen, in heavy fuel oil. The coal must be ground to this fineness to avoid most of the difficulty arising from unstable suspensions.

2 Mixing the coal into the oil does not present a particularly difficult problem.

3 Careful control of storage and handling temperatures is required for most successful operation.

4 Careful attention must be given the pumping of coal-in-oil-fuels, particularly in cases where underground storage tanks are used.

5 The combustion efficiency of coal-in-oil suspensions is apt to be slightly less than that of oil.

6 The load-carrying flexibilities of oil and coal-in-oil fuels are about the same.

7 The best opportunity for the successful use of coal-in-oil suspension is in the larger plants with the better operating personnel and more readily accessible equipment.

Acknowledgments

Acknowledgment should be given to the following persons for their part in carrying out this work: of The Atlantic Refining Company, C. J. Cutting, W. A. Myers, S. W. Ferris, W. A. Schmidheiser (for his part in getting the first large-scale test under way), J. C. Reid, and K. M. Thompson (the last two for performing most of the laboratory work); of the Bureau of Mines, Dr. W. C. Schroeder, R. Wiggers, and J. G. Mingle (the last two for their general field-testing work).

Appendix

Description of Pendulum Apparatus and Procedure for Its Use in Studying Stability of Coal-in-Oil Suspensions

Since the opacity of the oil used in coal-in-oil suspensions precludes visual observation of settling phenomena, the evaluation of stability presents a problem. A modification of a method, described by Manning and Taylor[6] and again by McMillen, Stutzman, and Hedrick,[8] has proved satisfactory for this study. The apparatus used, Fig. 22, consists of a carriage which is supported on knife-edges and is so designed that a tube containing a suspension of coal in oil may be fitted into it and held rigidly in place. The periods of this system (acting as a compound pendulum, observed first with the tube in its normal position in the carriage, and then with the tube raised through a known distance referred to its support by the insertion of a block of known dimensions), provide a means of calculating the location of the center of gravity of any tube and its contained suspension.

Period T of a compound pendulum may be expressed

$$T^2 = \frac{4\pi^2 I}{Mg\bar{r}}$$

where I is the moment of inertia of the pendulum about the axis of support, M is the mass of the pendulum, g is the acceleration due to gravity and $\bar{r}$ is the radius of the center of gravity. Combining this equation with the theorem of mechanics relating the moment of inertia I about any axis to the moment of inertia I_0 about an axis through the center of gravity

$$I = I_0 + M\bar{r}^2$$

and separating the various parts of the system, the location of the center of gravity of the tube and its contained suspension is given by

$$\bar{r}_t = \frac{\bar{r}_c M_c g T_1^2 + [gdM_t - (\bar{r}_c M_c g + \bar{r}_b M_b g)]\, T_2^2 + 4\pi^2 I_b + 4\pi^2 M_t d^2}{gM_t\,(T_2^2 - T_1^2) + 8\pi^2 M_t d}$$

[8] "A Pendulum Method for Measuring Settling Velocities," by J. H. McMillen, L. F. Stutzman, and J. E. Hedrick, *Industrial and Engineering Chemistry*, Analytical Edition, vol. 13, 1941, pp. 475–478.

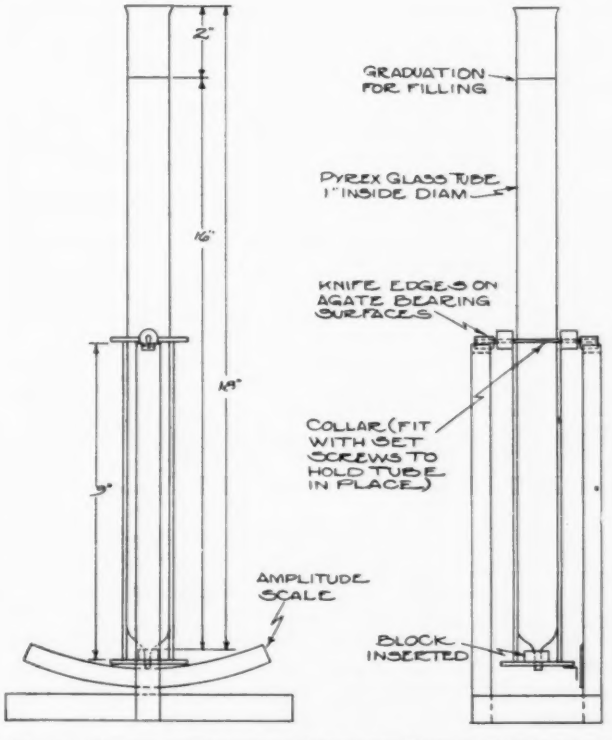

Fig. 22 Sketch of Pendulum Apparatus Used in Determining Settling in Coal-in-Oil Suspensions

where

$\bar{r}_t$ = radius of center of gravity of tube and contained suspension in its initial position, cm
$\bar{r}_c$ = radius of center of gravity of carriage, cm
M_c = mass of carriage, g
g = acceleration due to gravity, cm per sec per sec
d = distance through which tube is raised, cm
M_t = mass of tube and contained suspension, g
$\bar{r}_b$ = radius of center of gravity of inserted block, cm
M_b = mass of inserted block, g
I_b = moment of inertia of inserted block about axis of support, g × cm²
T_1 = period of compound pendulum without block, sec
T_2 = period of compound pendulum with block inserted, sec

Experimental results for the pendulum used in these experiments indicate an average deviation of ±0.025 cm in $\bar{r}_t$ calculated by this equation. For the best accuracy the carriage should be as light as possible and the axis of support should be only a short distance above the center of gravity of the pendulum. Temperature fluctuations affect the accuracy of this work and must be compensated for unless the tests are run at constant temperature. Suitable compensation may be effected by plotting the period against the age of the sample, thereby deriving an average curve from which corrected values may be taken.

The change in the position of the center of gravity may be correlated with the percentage of settling that has occurred. For example, complete settling, determined for a 40 per cent suspension of coal in an ethanol-water solution of the same specific gravity as the oil, results in a net change of 0.48 cm (±0.02 cm) in the position of the center of gravity of a tube and its contained suspension. Assuming that the net effect of the sedimentation is a gradual concentration of the slurry, a linear relationship between the change in the center of gravity and percentage of settling may be used. Thus with the sensitivity of the pendulum method previously noted, a single determination of the percentage settled is accurate to within about 5 per cent. Through the use of the compensation method described, large errors may be detected readily and the accuracy of the determinations considerably improved.

As a check on the pendulum test, samples that had shown no change in the position of the center of gravity on long standing were analyzed top and bottom by quantitative methods. The results obtained showed the same concentration of coal at top and bottom. The stability was checked further by visual examination of beaker mixes; a removable disk was placed at the bottom of the beaker and the material adhering to the disk was examined periodically. Tests in such studies confirmed the findings of the pendulum tests. Visual results were proved by quantitative methods.

Extreme care is required in the preparation of mixes for the evaluation of stability by pendulum test. Air carried into the mixture by the coal is lost very slowly, and by resulting in reduced volume, changes the period of the pendulum in a manner that may easily be misinterpreted as settling. This difficulty may be overcome by heating the mixture to 160 F with hand mixing and then stirring the warm mixture for 15 min at an absolute pressure of 10 mm Hg.

The coal used throughout the laboratory tests was ground in a hammer mill as received. Various sizes were separated carefully by screening. No effort was made to dry the pulverized coal beyond its equilibrium value with the atmosphere.

Discussion

E. G. Bailey.[9] This paper gives some interesting data covering important factors in relation to the burning of mixtures of pulverized coal and oil. The physical factors are one thing, the economic factors quite another.

It is the writer's opinion that with respect to the so-called emergencies we have already had, and those which we may yet expect, it is still better to continue the use of oil in those plants, which are not readily convertible 100 per cent to coal, and make those conversions which should be made to balance the fuel supply, by converting the installations which can readily be operated 100 per cent with coal.

It would seem to take substantially as much pulverizing and special classifying equipment to prepare 40 per cent coal for the mixture, as it would for 100 per cent coal with proper fineness, to be burned in those places where it can be done. Therefore, more oil could be saved with the same equipment or the same saving with less equipment if conversion to 100 per cent coal were the chosen method.

A higher degree of fineness in burning pulverized coal enables its use in many places where it is considered unadaptable with the coarser coals which many people have tried with unsatisfactory results. Many so-called expert opinions on this subject are hand-me-downs from experiences with coarser coal and poor burners of by-gone days, and such opinions and decisions should not prevail over the later experience with finer pulverization and modern equipment.

W. C. Schroeder.[10] The tests reported in this paper give a complete picture of the preparation and burning of colloidal fuel in a relatively small boiler which is typical of a number of oil-burning installations. The authors' work parallels, in several respects, an investigation that has been carried out by W. I. Jones of Powell Duffryn Associated Collieries in Wales.[11] This discussion will show that the results from the two studies are in substantial agreement and will also present additional information available from the work abroad.

Stability of Oil-Coal Suspensions. From the tests which were made in

[9] Vice-President, The Babcock & Wilcox Company, New York, N. Y. Fellow A.S.M.E.

[10] Assistant Chief, Fuels and Explosives Service, Bureau of Mines, Washington, D. C. Mem. A.S.M.E. This discussion is published by permission of the Director, Bureau of Mines, U. S. Department of the Interior.

[11] The information for this discussion was provided by W. Idris Jones, of Powell Duffryn Associated Collieries. The writer is indebted to him for this material and for permission to publish it.

Wales the following statements were made concerning stability:

"This is a relative term and no coal-in-oil suspension is perfectly stable. The stability decreases with a decrease in coal content or fineness and with increasing temperature. Stability also depends on the nature of the oil. Cracked residual fuels of the Bunker C type have adequate inherent stabilising characteristics to yield a stable suspension with 99% through 200-I.M.M. (230-U. S. Standard) mesh, coal in concentrations preferably of 40–45%. Regular laboratory tests and careful inspection of tanks and pipe lines have shown that these suspensions are adequately stable for all normal commercial requirements, provided there is no intense local overheating. In this connection, our storage tank at Aberaman was fitted with hot-water coils instead of steam coils. Coal-in-oil suspensions should not be kept in a static condition in the presence of steam coils more than is strictly necessary to ensure the mobility of the fuel. Turning full steam pressure on the coils is to be avoided unless the fuel is being circulated.

"Reduced stability at elevated temperatures is not accompanied by the precipitation of coal as such. What actually occurs is a gradation in coal concentration increasing from the top layer to a maximum of about 58% in the bottom 20% layer.

"In the case of 40% suspensions of 200-I.M.M. dry steam coal in Bunker C oil numerous stability tests since 1933 have enabled us to draw up the following table (Table 7) which sets out the various times taken to attain a concentration of 45% and 58% of coal in the bottom 20% layer of the "Hurrelled"[12] fuels at various temperatures:

TABLE 7

Temperature,	Deg	Time to reach a coal concentration in the bottom layer of—	
C	F	45%	58%
15	59	More than 150 days	More than 500 days
30	86	Approximately 65–70 days	Approximately 240 days
50	122	Approximately 28 days	Approximately 85–90 days
70	158	Approximately 5 days	Approximately 17 days

"The figures in column 3 show the approximate maximum time for which it is safe to allow a 40% suspension (Hurrell) in Bunker C oil to stand at various temperatures to permit of its direct use from a heated tank. The figures in column 4 indicate the approximate times in which the mixture will break down completely at various temperatures, leaving a top layer of fuel oil.

"Summing up, it may be claimed that if due precautions are taken against overheating, the fuel suspensions containing 40–45% of coal in Bunker C oil are stable enough for all practical commercial requirements and can be handled by the normal oil-handling equipment. The coal, however, must be ground and classified to yield not less than 98.5% through a 200-I.M.M. mesh screen and then thoroughly wetted with the oil, first in a primary mixer and then in a final mixer of the Hurrell Homogeniser type, normally used for making emulsions."

The effect found for temperature, time, coal fineness, and coal concentration on stability are in good agreement with those reported by the authors of this paper. Jones, however, went to somewhat greater length to insure thorough mixing of the finely pulverized coal and oil.

TABLE 8

Coal in mixture, per cent	Viscosity, Saybolt Furol sec. at—			
	100 F	150 F	200 F	250 F
55	...	14000	6000	3000
50	1800	570	250	140
45	660	190	79	37

35	290	88	42	19
30	190	46	17	....

[12] Run through Hurrell homogeniser (G. C. Hurrell, Limited, Old School Works, Woolwich Road, Charlton, England). In all of this work the coal was ground to the desired fineness, mixed with the oil, and then passed through the homogeniser.

Effect of Coal Concentration and Temperature on Viscosity. The data in Table 8 give the results Jones secured for the effect of coal concentration and temperature on viscosity. These data carry the viscosity values to higher temperatures than reported in the paper.

The figures were secured from logarithmic graphs compounded from a very large number of mixtures examined during the course of the work. In general the coal was about 98–99 per cent through 200-I.M.M. (230-U. S. Standard) sieve, while the Bunker C oils showed the following characteristics:

Specific gravity at 60 C	0.98–0.99
Flash point, deg C	156–208
Viscosity, Saybolt Furol, sec	
122 F	99–499
175 F	27–33
225 F	14–17
Pour point (A.S.T.M.), deg F	10–15

Combustion Tests. Jones carried out over 150 combustion tests with colloidal fuel on a boiler having the following characteristics:

Type	3 drum
Heating surface, sq ft	3947
Working pressure, psi	175
Furnace volume, cu ft	795
Evaporation rate, lb per hr	18000–20000
Preheated air, deg F (mean)	335
Air pressure at burners, in.	2–3
Fuel pressure at burners, psi, avg	120
Fuel temperatures at burners, deg F	260–280

He reported as a result of this work that the boiler furnace, when using coal-in-oil suspensions, even when viewed by a skilled observer, was not different in appearance from the oil-fired furnace. The efficiency depended upon the fineness of the coal, the volatile content of the coal, the nature of the oil, and the type of burner used.

Tests were run with coals containing 12 to 40 per cent volatile matter. The mixtures containing high-volatile coal gave a somewhat higher efficiency than those containing low-volatile coal. Under the worst conditions, efficiencies dropped about 5 per cent below those for oil alone. Under the best they were within 1 per cent of oil.

Jones states, "One of the most pleasing features of the boiler tests was the almost complete freedom from burner stoppages. Ignition was hardly ever lost in the tests due to the burners going out. In fact, the whole equipment, comprising pumps, filters, heaters, and atomizers, gave a performance which was quite indistinguishable from that obtained when using fuel oil in the same plant." This seems in essential agreement with the work reported in the paper.

Jones ran his tests with a variety of pressure, pressure and air, or pressure and steam burners and he states, "The Babcock and Wilcox pressure oil burners were adopted for convenience for most of the tests, but other burners of this type would be equally suitable."

Manufacturing. During the period in which this work was carried out in Wales, a small plant was erected to make about 0.75 ton per hr of oil-coal suspension. From this pilot plant, estimates were made of capital and manufacturing costs. On this basis, the writer has estimated that the cost of preparing 60 per cent oil - 40 per cent coal suspensions in the United States today would be about $0.80 to $1 per ton for a plant of about 100 tons per day.

This does not, of course, include the cost of the coal or oil but it does include all preparation costs, i.e., services, power, manage-

ment and supervision, labor, maintenance, rent, interest on investment, taxes, depreciation at 10 per cent, and insurance. It must be recognized, however, that there is considerable chance for error in translating costs in one country to another, which could not be avoided with the data available.

Summary. From the work done in this country and abroad, sufficient technical information is now available to contemplate the erection of colloidal-fuel plants of considerable size with reasonable assurance that the product could be used in certain oil-burning installations with little modification of existing equipment. This procedure provides a means for saving oil without the large equipment alterations necessary to convert plants and furnaces completely from oil to coal. It might therefore be of value during the war period with the prevailing critical equipment shortages. In general, the Bureau of Mines has not looked on the oil-coal mixtures as having a permanent place as an industrial fuel. Under normal conditions, with the necessary equipment available for handling any fuel, a plant will use oil or solid fuel alone, according to the dictates of cost, convenience, or other demands of a particular installation. From the long-range point of view, it is difficult to visualize a large field for colloidal fuel.

During the period in which this work was carried out, even the short-range viewpoint has altered greatly. The shortage of coal in both the United States and Great Britain becomes steadily more acute, and the saving of oil at the expense of coal looks much less attractive than it did a year ago. Unless this situation changes, it is doubtful if there will be any extensive use of colloidal fuel during this war.

C. C. WRIGHT.[13] The authors are to be congratulated for their presentation of a timely and much needed clarification of the technical factors concerning the production and use of coal-in oil fuels. From the viewpoint of the fuel technologist, a small amount of additional data on specific gravities would be most helpful in settling questions regarding the volume of fuel produced upon admixture of coal and oil. Specifically, the writer would like to see data included on the specific gravity of the coal-in-oil fuels reported in Table 2 of the paper, the specific gravity of the coal used in the preparation of the fuels reported in Table 4; also whether or not any change in specific gravity of the coal-in-oil fuel was observed with aging.

[13] Professor of Fuel Technology, The Pennsylvania State College, State College, Pa.

AUTHORS' CLOSURE

The authors agree thoroughly with the statement in Mr. Bailey's discussion that "the physical factors are one thing, the economic factors quite another." In this paper, attempt was made to supply new and needed information of a physical nature; such facts are required before economic factors can be soundly considered. Economic studies have been made both by The Atlantic Refining Company and the Bureau of Mines. Publication of these studies has not been made but they are available.

Dr. Schroeder supplies interesting information from unpublished work recently done in England which adds to the value of the paper.

In answer to Mr. Wright's inquiries, the following is submitted:

The specific gravities of the coal-in-oil fuels of Table 2 were not determined. The specific gravity of the coal of batches 1 and 2 of Table 4 was 1.30 and of batch 3 and 4, 1.32.

The following table gives typical specific gravities and viscosities of a coal-in-oil fuel over a period of eight days; other stable suspensions examined for gravity after much longer periods of storage showed no significant changes in gravity as the result of storage:

Wear-Resisting Materials for Lathe Construction

By R. W. DAYTON,[1] C. H. LORIG,[1] AND R. E. ADAMS,[1] COLUMBUS, OHIO

It was found, from tests of all the materials now in general use as the bearing surfaces of lathes, that the combination of hardened steel and alloy cast iron was far more wear-resistant than others and was adequately scoring-resistant.

A process referred to as "flame refining" was developed for improving the wear resistance of cast iron. An iron treated by this process and used with hardened steel formed the best combination tested, having greatly improved wear resistance and scoring resistance.

A wear test in simulated lathe service confirmed the earlier work and also showed that for minimum wear of a combination containing cast iron and hardened steel, the steel should form the carriage surface and the cast iron the bed surface.

GENERAL-purpose machine tools change but little in design from year to year and would remain useful almost indefinitely if they retained their initial accuracy. However, they do not, largely because of wear on the friction surfaces of the bed and the carriage which causes a gradual but eventually fatal loss of accuracy.

Machine tools vary in ability to resist deterioration of their ways. The ways of grinders, for example, remain true for many years because the conditions of service and the possibilities of design are such that the causes of wear are avoided. Thus materials of great wear resistance are not essential, so the original and most readily used material for machine-tool construction, plain cast iron, is still in use for all rubbing surfaces.

Other types of machine tools such as lathes operate under adverse, almost abusive, conditions. Since design can do little to make these conditions tolerable, wear-resistant materials must be used if the lathe is to have a long useful life. Accordingly, plain cast iron is being used less, and hardened steel and cast iron more, for the beds and carriages of lathes.

The number of materials which can be used for lathe-bed and carriage construction is limited. The body of both bed and carriage must be made of cast iron for economic reasons, so if different types of bearing surfaces are desired, they must be applied on the surfaces. Two methods of altering the bearing surfaces are now in use, flame-hardening the cast iron itself or fastening hardened-steel strips to the surface.

One other limitation in the choice of materials must be observed, namely, that either the carriage or the bed must be soft enough to be scraped to a fit by hand, for machine tools cannot economically machine the bed and carriage surfaces to a satisfactory fit. This prevents the use of fully hardened surfaces on both bed and carriage, a combination which might be the most wear-resistant of all.

As a result of the limitations of choice, only four combinations of materials for the wearing surfaces of lathe beds and carriages are in general use. These are the following:

1 Cast-iron bed, cast-iron carriage
2 Flame-hardened cast-iron bed, cast-iron carriage
3 Hardened-steel-faced bed, cast-iron carriage
4 Cast-iron bed, hardened-steel-faced carriage.

The manufacturing advantages and disadvantages of each of these types of construction are thoroughly understood, but the serviceability of each is not. The purpose of the study being reported was to appraise the serviceability of each of the combinations and then, if possible, to develop one better than any. The problem proved so complex that nearly four years of study were required to achieve the desired result.

Testing Methods

Lathe beds and carriages may experience two distinctly different types of damage. Either they may wear, losing material gradually from their rubbing surfaces until the accuracy of the lathe is lost, or they may gall, material being torn out of one surface in small pieces and welding to the other causing deep gouging and scratching. It can be expected that proper materials for the ways of lathes will not gall and will wear only slowly.

Wear of lathes is generally due to either abrasive or lack of lubrication. With adequate lubrication and abrasive-free conditions, no wear occurs as shown both by laboratory tests and by long-time running of a full-sized lathe under these conditions. If lubrication is lacking because of carelessness, very rapid wear will occur; so unlubricated wear was studied. However, since only a minute amount of oil suffices to prevent unlubricated wear, and since the necessary amount is likely to be present on the bed in all but rare instances, the results for unlubricated wear are considered less significant than those for abrasive wear.

Practically all lathe-bed wear is abrasive in character. If abrasive could be prevented from working between the rubbing surfaces, lathe beds would be as long-lived as grinder beds. Unfortunately, design considerations do not permit adequate protection of beds as long as those of some lathes.

Two types of abrasive cause most lathe-bed wear; scale from heat-treated steel and dust from cast iron. Both of these are brittle enough to crush small particles that get trapped between the rubbing surfaces, and hard enough to cause wear. Tests for abrasive wear were made in both of these abrasives. Some description of the wear tests is given in the caption of Fig. 1.

The galling, or scoring, which infrequently occurs between bed and carriage, is an acute form of failure. It is induced by "short-stroke" work in which the carriage moves back and forth many times over a short distance on the bed. The action appears somewhat similar to the wringing together of gage blocks, the continued slight reciprocation bringing the surfaces closer and closer together until molecular attraction causes welding. The only certain method of resisting this form of failure is to lift the surfaces out of contact at intervals, as by an oiling system which forces oil between the surfaces periodically.

No metals seem capable of resisting this type of failure indefinitely, even at minute loads, when the stroke is short. However, metals vary in their ability to resist scoring for a longer

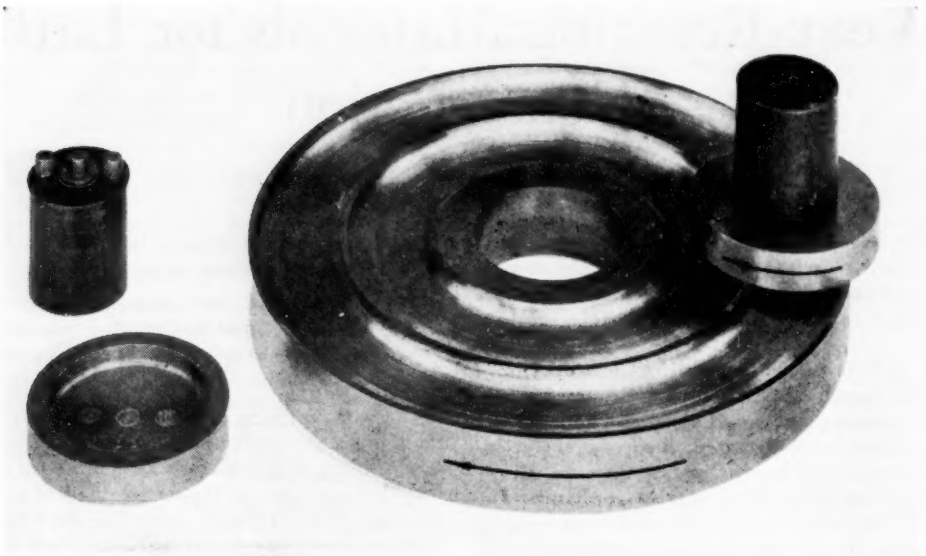

FIG. 1 THE WEAR-TEST SPECIMENS USED IN THE EARLY INVESTIGATION

(The large plate is made of one of the materials under test; the two small specimens like the one inverted in the lower left hand of the photograph are made of the other. The holder behind the small specimen centers and drives it, allowing rocking for alignment. During a test, both small specimens rest on the plate, one in the position shown, the other diametrically opposite. All three specimens are driven at the same angular speed in the direction indicated by the arrows. Unlubricated tests were made in both dry and humid air, for humidity was found to affect wear. The conditions under which each type of test listed in Table 1 is run are as follows:

Scale. The specimens are submerged in an agitated mixture of 25 per cent of —200 mesh heat-treating scale and oil. They are run at 148 ft per min and 210 psi of pressure. Three successive two-hour tests are run and an average taken.

Modified Scale. This test is used to distinguish between slow-wearing combinations. The conditions are the same as for the test in scale, except that the three two-hour tests are preceded by a 16-hour wearing-in period, during which the specimens are roughened and charged with abrasive so that rapid wear occurs.

Cast Iron. The same as the test in scale, except that the specimens are submerged in a mixture of 25 per cent of —200-mesh cast-iron dust and oil.

Dry Air. The specimens are surrounded with thoroughly dried air and run unlubricated, at a speed of 16 ft per min and a load of 75 psi. Four two-hour tests are run.

Moist Air. The same conditions as the test in dry air, except that the air is brought to about 100 per cent humidity and the load is 510 psi.)

stroke, and it is desirable that the best be selected for lathe-bed service. For sorting out the various materials, a scoring test was used which oscillated two specimens together, as discussed in the caption of Fig. 2.

PRELIMINARY TEST RESULTS

The results of the preliminary wear and scoring tests are summarized in Table 1. Each of the values reported is an average of three or more tests of each sample, generally of at least three samples and occasionally of seven or eight. In the cases where only a single material of a type was tested, the hardness is listed as a single number instead of a range.

A "relative-wear index" appears in next to the last column of Table 1. It was introduced to facilitate rough comparisons between the various combinations. The index was obtained by taking a weighted average of all the tests which were first reduced to a ratio, using combination IV-*a* as standard. A relative weight of 4 was assigned to the abrasive tests and of 1 to the unlubricated tests. This weighting takes cognizance of the fact that most lathe-bed wear is of the abrasive type and assumes that four times as much wear results from abrasive as from lack of lubrication.

Groups I, II, III-*a*, and IV-*a* of Table 1 are the combinations of materials in use in lathes at the present time. A study of the data for these four combinations shows that the two combinations in which cast-iron forms, both rubbing surfaces wear far faster, particularly in abrasive, than the two combinations in which fully hardened steel is one component. This is attributed to the fact that a cast-iron surface embeds abrasive in its pores which causes wear of the opposing surface. When both surfaces are cast iron, both will wear rapidly because the hardness of the abrasives exceeds even that of flame-hardened cast iron. When fully hardened steel is one component, there is little wear because it does not embed abrasive to wear the opposing cast-iron surface and is too hard to be worn much by the abrasive embedded in the cast iron. Thus if cast iron were run against softer steel, which could be worn by the abrasive embedded in the cast iron, rapid wear, particularly of the steel, would be expected to occur. The data for groups IV-*c* and IV-*d* show that this does happen.

The unlubricated wear of the two cast iron - cast iron combinations was also appreciably higher than that of the two hardened steel - cast iron combinations, though this fact is considered less serious.

The scoring resistance of the flame-hardened cast iron - plain cast iron combination was the highest. It was not, however, so

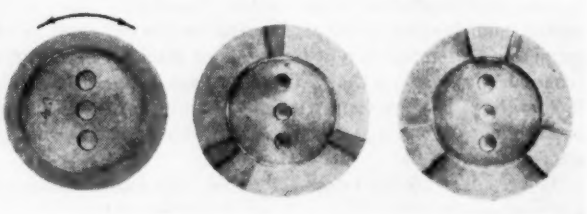

FIG. 2 THE SPECIMENS USED IN THE SCORING TESTS

(The one on the left oscillates as indicated by the arrow, with the annular face in contact with the three narrow (10 deg and 30 deg) raised segments of either of the two specimens on the right. The bearing faces are lapped optically flat for test. For the tests reported in Table 1, the angular motion was 25 deg, and the segmental specimen was like the one on the right with three 30-deg segments. Tests were run in an oil bath at 100 F for 15 min at 570 cycles per min. No scoring starts after this time.)

FIG. 3 THE TYPICAL MICROSTRUCTURE OF A CHILLED-CAST-IRON BED; ×100
(The matrix is fully pearlitic and the graphite is in spidery clusters. This iron is neither as wear-resistant nor as scoring-resistant as the alloy iron in Fig. 4.)

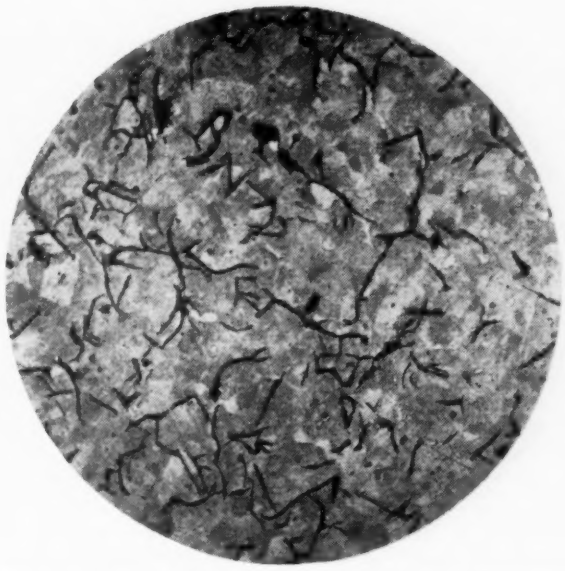

FIG. 4 THE TYPICAL STRUCTURE OF AN ALLOY-CAST-IRON BED
(The graphite is in small flakes randomly distributed. This iron is quite wear- and scoring-resistant.)

much higher than the scoring load of combination IV-*a* as the data would indicate at first glance, for the plain-cast-iron sample tested against all the flame-hardened irons was highly scoring-resistant, and when it was tested against hardened steel, scored at the highest load of all the iron tested in combination IV-*a*, 360 lb. Thus it seems that the combination of flame-hardened cast iron and plain cast iron is inherently only about 50 per cent

TABLE 1 AVERAGE RESULTS OF WEAR AND SCORING TESTS ON VARIOUS LATHE BED-CARRIAGE COMBINATIONS

			Average wear rate —0.001″ per hour

* Fifty per cent higher scoring load than the same piece of plain cast iron against hardened steel.
** Each of the hardened irons scored at a 50 per cent higher load than the same iron not flame-treated.

more resistant to scoring than hardened steel and plain cast iron, instead of 100 per cent better as the data of Table 1 would indicate.

These results indicated that combinations of hardened steel and cast iron were inherently more wear-resistant than combinations of cast iron and cast iron, so the former were investigated more thoroughly. A comparison was made between two types of beds, chilled and alloy iron, being made for the manufacturer sponsoring this work. The former is an iron containing approximately 3.3 per cent carbon, 0.40 per cent chromium, and up to 0.50 per cent copper cast against chills on the wearing surface to produce a fine-grained iron; the latter contains approximately 3.0 per cent carbon, 0.20 per cent chromium, 0.75 per cent copper, and 0.30 per cent molybdenum, cast without chills but just as fine-grained as the chilled iron because of its composition. The photomicrographs of Figs. 3 and 4 show that there is far more difference in microstructure than the slight composition differences would indicate. The chilled iron has what is called a "modified" graphite flake, the alloy iron a normal graphite flake.

Wear and scoring tests showed that chilled beds wore faster and scored at lower loads than unchilled beds. Chilled beds have another disadvantage in that foundries making chilled beds are more likely to produce an occasional ferritic bed than a foundry making alloy-iron beds, and as a comparison of combinations III-*b* and IV-*b* with III-*a* and IV-*a* will show, ferritic irons are extremely poor bearing surfaces. The manufacturer discontinued the use of chilled beds when this information was available and has obtained the indicated improvement in performance.

Investigation of the effect of composition of the cast iron on the performance of combination IV-*a* showed that the composition given was as good as any. Increase of the carbon content or small changes in the alloy content do not greatly change the rate of wear or the scoring load, so long as the iron is fully pearlitic. Ferritic irons like combinations III-*b* or IV-*b* must be avoided or rapid wear and scoring will be experienced. Low-carbon irons too must be avoided, for one fully pearlitic iron with only 2.53 per cent carbon scored at an extremely low load, 140 lb. High-alloy irons, containing considerable amounts of free carbide, wore a little more slowly and scored at somewhat higher loads, but they were expensive and extremely difficult to scrape because the many carbide particles dulled scrapers with extreme rapidity.

Effects of Heat-Treatment

The results of the composition study provided little hope that any considerable improvements could be obtained from modifications of composition alone. Heat-treatment was then tried as a means of obtaining the desired improvement. From furnace heat-treating experiments, it was found that better results were

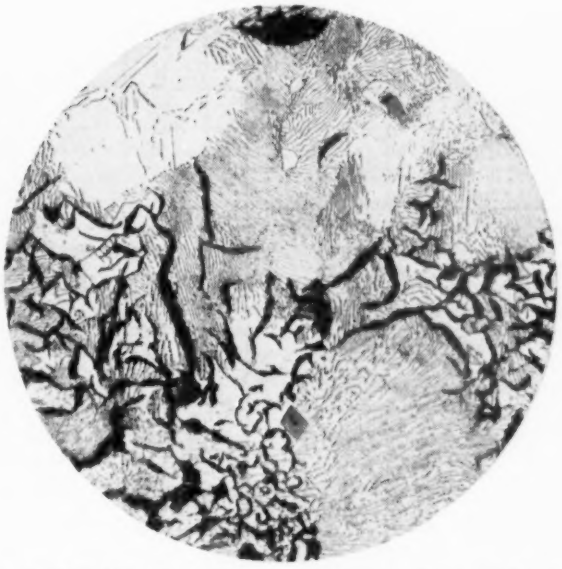

FIG. 8 THE MICROSTRUCTURE OF A MODIFIED FERRITIC TYPE OF IRON; ×500

(The white patches of free ferrite in dispersed grains and between the clusters of graphite flakes form approximately 25 per cent of the structure. This type of iron scores readily and wears rapidly.)

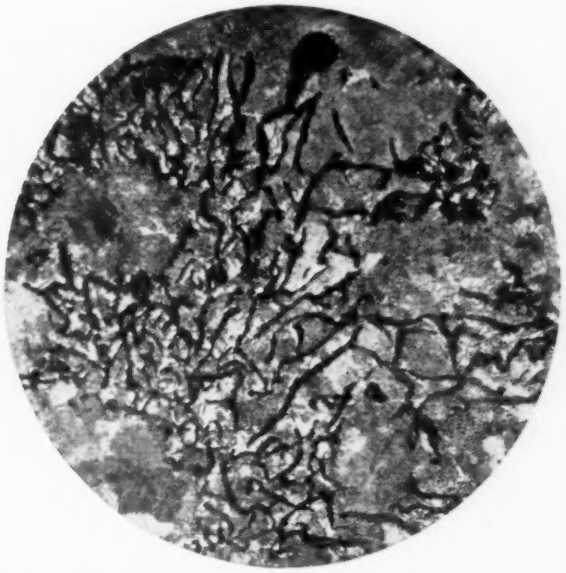

FIG. 9 THE SAME IRON AS IN FIG. 8 AFTER FLAME-REFINING; ×500

(The ferrite has been almost entirely converted to pearlite, and the pearlite has a finer grain size. The hardness of the iron has been increased from 180 to 225 Brinell. The wear and scoring resistance is almost as good as for a flame-refined originally pearlitic iron.)

obtained by cooling comparatively rapidly from above the critical temperature, to produce an extremely fine pearlitic structure, than by quenching and drawing to the same hardness to produce a sorbitic structure.

The experiments were extended to sections of beds, and it was found that the desired structure and wear resistance could be obtained by heating the surface with a flame-hardening torch to above the critical temperature and depending on the heat drain from the cooler interior of the bed to produce the proper rate of cooling. It was found that the temperatures of the underlying bed must be somewhat elevated, by making a preheating run with the torches, to prevent too rapid cooling and excessive hardness. This process is called "flame refining"[2] to distinguish it from flame hardening where a quench is essential and full hardness is desired. By experiment, it was found that these heat-treated irons could be scraped at hardnesses up to 30–35 Rockwell C if carbide-tipped scrapers were used. The structure of an iron before and after treatment is shown in Figs. 6 and 7 where it is evident that the pearlite is greatly refined by the process. The depth of hardening is apparent in the cross section illustrated in Fig. 5.

Wear and scoring tests of these heat-treated irons showed that wear in abrasive was only 70 per cent as great as that of the same irons before heat-treatment, and that the scoring load was 50 per cent greater than for the same irons not hardened. The data for the tests are given under combination V-*a* in Table 1. The heat-treating process performs even more strikingly on ferritic irons, as a comparison of the data for combination V-*b* with III-*b* and IV-*b* shows. It is to be expected that the flame-refining process would have such an effect, for it eliminates free ferrite from the structure, as a comparison of Figs. 8 and 9 shows.

SIMULATED SERVICE TESTS

The results up to this point indicated that a combination of fully hardened steel and flame-refined cast iron was the most wear-

[2] Patent applied for.

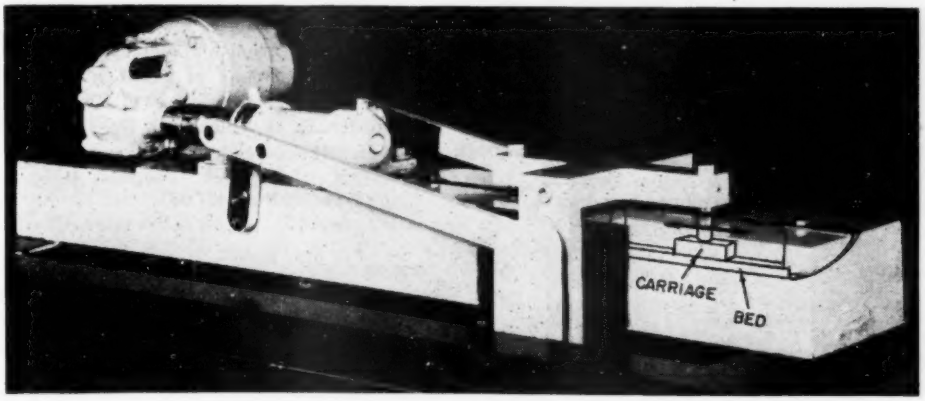

FIG. 10 A RECIPROCATING WEAR-TESTING MACHINE USED FOR SIMULATED LATHE-BED SERVICE WEAR TESTS

(The form of the specimens is shown in phantom outline. The specimens were run in the same slurry of heat-treating scale as the preliminary wear tests. The machine operated at 11½ cycles per min with a 4-in. stroke. The bearing load was 15 psi.)

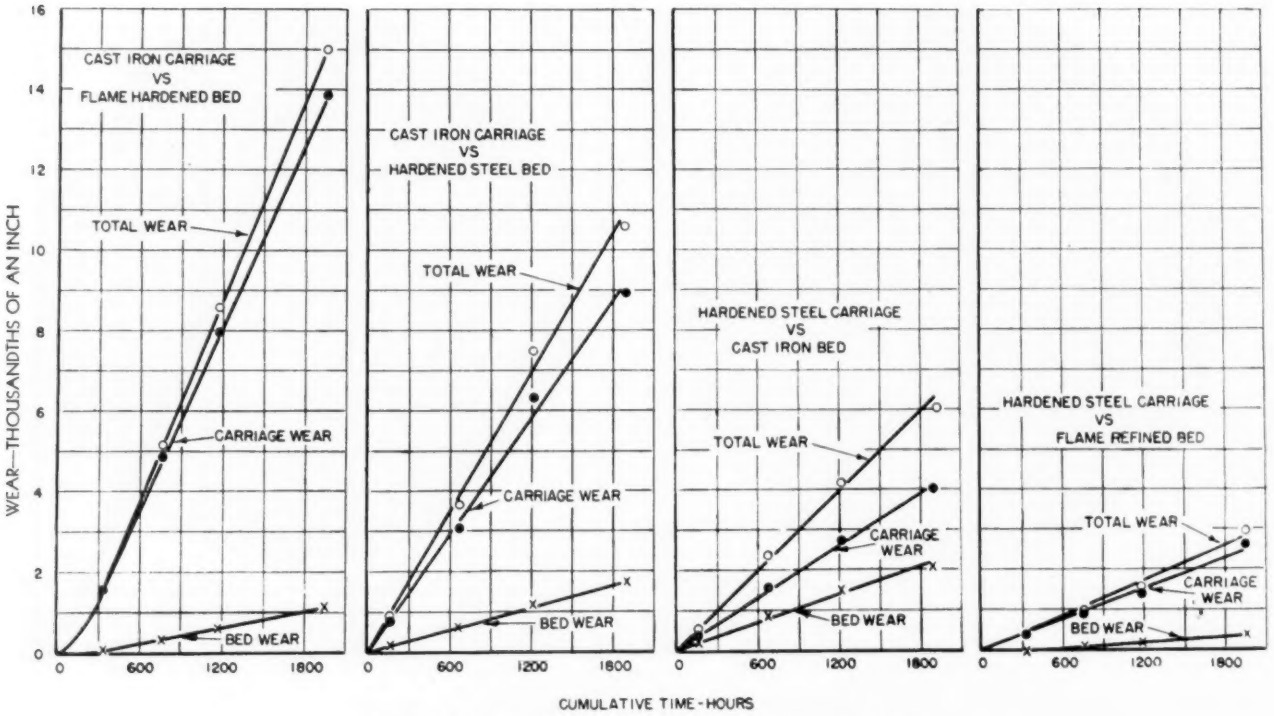

FIG. 11 WEAR OF MATERIALS IN SIMULATED SERVICE TESTS

resistant, but did not show which of the two materials should be the carriage and which the bed. To determine this, as well as to obtain additional confirmation of the results up to this point, long-time abrasive wear tests were made in an apparatus which simulated the wearing action of a lathe. The apparatus is illustrated and described in Fig. 10. The results for four combinations of materials are given in Fig. 11. The materials used in this test were those which had been proved by the earlier work to be the best of their types.

The first combination of a cast-iron carriage and a flame-hardened bed shows little wear of the bed, but relatively enormous wear of the carriage. After test, the originally square ends of the carriage were rounded off, indicating that they had acted as wedges, permitting a great deal of abrasive to work between the surfaces.

The second combination, again of a cast-iron carriage but with a fully-hardened-steel bed, showed slightly more bed wear but considerably less carriage wear. However, the carriage wore at the ends the same as against a flame-hardened bed.

The third combination of an alloy-cast-iron bed and a fully-hardened-steel carriage showed slightly more wear of the bed but far less wear of the carriage than the other two. The carriage remained square at the ends.

The fourth combination of a flame-refined cast-iron bed and a fully-hardened-steel carriage was superior in every respect. Carriage wear was only 60 per cent as great, bed wear only 25 per cent as great, and total wear only 45 per cent as great as on the best of the other combinations in these individual respects.

CONCLUSIONS

The results indicate that the combination of a carriage faced with fully-hardened-steel strips[3] and a cast-iron bed flame-refined to the maximum allowable hardness for scraping will wear far less than any other combination. The combination appears to be about as scoring-resistant as any other, and 50 per cent better than unhardened cast iron against hardened steel. Since service records show no scoring difficulties with this latter combination, except for infrequent ferritic beds, the scoring resistance appears more than adequate.

ACKNOWLEDGMENT

This investigation was made for the Lodge and Shipley Machine Tool Company of Cincinnati, Ohio. The assistance of Mr. W. L. Dolle and Mr. Fred Schoeffler of that organization, and of Dr. H. W. Gillett and Dr. H. W. Russell of Battelle has been greatly appreciated.

Porous Chromium in Engine Cylinders

By RUSSELL PYLES,[1] OLEAN, N. Y.

In recent years it has been possible to deposit thick coatings of chromium electrolytically on machined parts, where lubrication is a vital factor. Diesel-engine cylinders and piston rings may be included among the most critical engine parts from a wear standpoint, and in this application, porous chromium has demonstrated its ability to increase the life span of an engine. The author outlines the properties inherent in porous chromium which contribute to its low wear rate in engine cylinders, i.e., hardness, exceeding that of any other cylinder-lining material; high thermal conductivity; low friction coefficient, and low affinity for other metals; corrosion resistance, preventing surface deterioration.

THE element chromium was discovered in 1798, but not until 1859 was it isolated by F. Wohler who obtained small quantities by reduction of the trichloride. As early as 1848–1854 (1)[2] efforts were being made to electrodeposit chromium. Decorative chromium as thin coatings of 0.00001–0.00002 in. became a commercial fact about 1924 (2). It is interesting to note, too, that the metallurgical advantage of chromium as a steel-alloying agent was put to use in 1870, when Midvale produced 2400 tons of 1 per cent chrome steel for the Eads Bridge over the Mississippi River at St. Louis (3).

Only in the last few years, however, have thick coatings of porous chromium been developed for machine applications where lubrication is a vital factor (4). Cylinders and piston rings are among the most critical engine parts from a wear standpoint. Here porous chromium has demonstrated that it will increase the life span of an engine.

Properties of Electrodeposited Chromium

Hardness. Hardness alone is not accepted as being a criterion for low wear but it is true, that for the same material, wear is lessened when hardness is increased. This has been indicated by many tests on cast-iron engine cylinders and heat-treated steels. Hardness, though, may be a dominant factor where erosion is a problem. Chromium is hard but some variations in hardness are obtainable by control of plating factors, such as bath composition, current density, and temperature. However, within the usual limits of these plating factors the hardness variation is slight.

TABLE 1 HARDNESS TABLE

	Brinell hardness (load 3000 kg; 10-mm ball) or equivalent
Chromium	800–1000
Cast-iron cylinder compositions	150–275
Cast-iron cylinder compositions, heat-treated	Max 400
Steel 4140 heat-treated	250–375
Steel, carburized	625
Nitralloy in cylinders after removal of surface stock	650–750

Chromium is harder than any other of the metals in general use for engine cylinders, and this hardness is maintained throughout the thickness of the case while the hardness of nitralloy or carburized steels decreases with depth. The hardness of the base metal under the chromium is not such an important factor in cylinders, although it may be in other special applications. Crushing loads, due to piston-ring and gas pressures, are relatively light in engine cylinders and porous chromium performs just as well on soft steels and cast irons as it does on nitralloy. Thus, the engine designer may choose his basic cylinder material without any regard for its wear characteristics. Alloy irons are not necessary, except as determined by structural-strength requirements. Cylinders may be of low-carbon steel for good welding where the cylinder assemblies are fabricated for lightness. These economic features are important in normal times and even more so now, when alloys are so difficult to obtain.

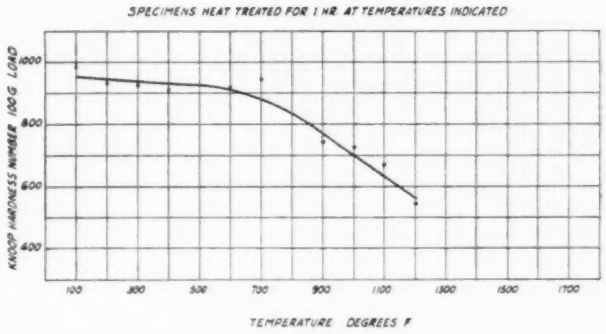

FIG. 1 KNOOP HARDNESS, POROUS-CHROME CYLINDER
(0.0045 in. chromium on cast iron.)

The hardness numbers in Table 1 are given for comparison in Brinell numbers, but it should be noted that the Brinell test is not used for the higher hardnesses and particularly for determining hardness of thin coatings. Because usual hardness tests, such as Rockwell, Shore, and Brinell, cover relatively large areas and are influenced by an appreciable depth of the underlying metal, they do not give a true picture where thin hard coatings are to be tested. The Knoop indentor (5) overcomes this difficulty by using a small diamond pyramid with shallow indentation. This machine is well adapted to use on porous chrome because the short length of the impression (approximately 0.004 in.) readily fits into the plane areas between the pores.

Contrary to many metals, chromium maintains its hardness very well within the range of cylinder-wall operating temperatures, Fig. 1.

TABLE 2 EXPANSION COEFFICIENTS AND THERMAL CONDUCTIVITY

Metal	Linear thermal expansion at 68 F × 10^{-6}	Thermal conductivity, cal/cm²/cm/deg C/sec at 20 C	Melting point, deg F
Chromium, electrolytic	4.5	0.165	3325+
Cast iron	6.6	0.12	2500
Steels	6.2–6.6	0.11	2700–2800
Aluminum	12–13	0.52	1216
Copper	9.1	0.92	1981

The linear-expansion coefficient of chromium is lower than that of cast iron or steel, yet no cases of bond failure due to this have been noted. The surface temperature in a cylinder is higher than that of the underlying metal, there being a steep

Presented at the National Meeting of the Oil and Gas Power Division, Baltimore, Md., June 14–16, 1943, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

temperature gradient through the cylinder wall. This condition, for minimum heat stresses, theoretically calls for an expansion coefficient varying from a lower value at the inner wall to a higher value at the outer cylinder wall. An inside layer of chromium partially fulfills this ideal requirement. Chromium has been plated on the aluminum piston crown of a Lauson engine $1^3/_4$ in. bore $\times$ $1^7/_8$ in. stroke and run for 54 hr without any signs of bond failure or change in surface appearance under the microscope. Many cases of record in high-output air-cooled airplane engines, with 700 to 1000 hr, show no tendency of the chromium to loosen due to differential expansion between the chromium and the steel. These engines are running with cylinder-wall temperatures much higher than those encountered in stationary-engine service. This evidence indicates that the low expansion of chromium may be a desirable feature for cylinder walls.

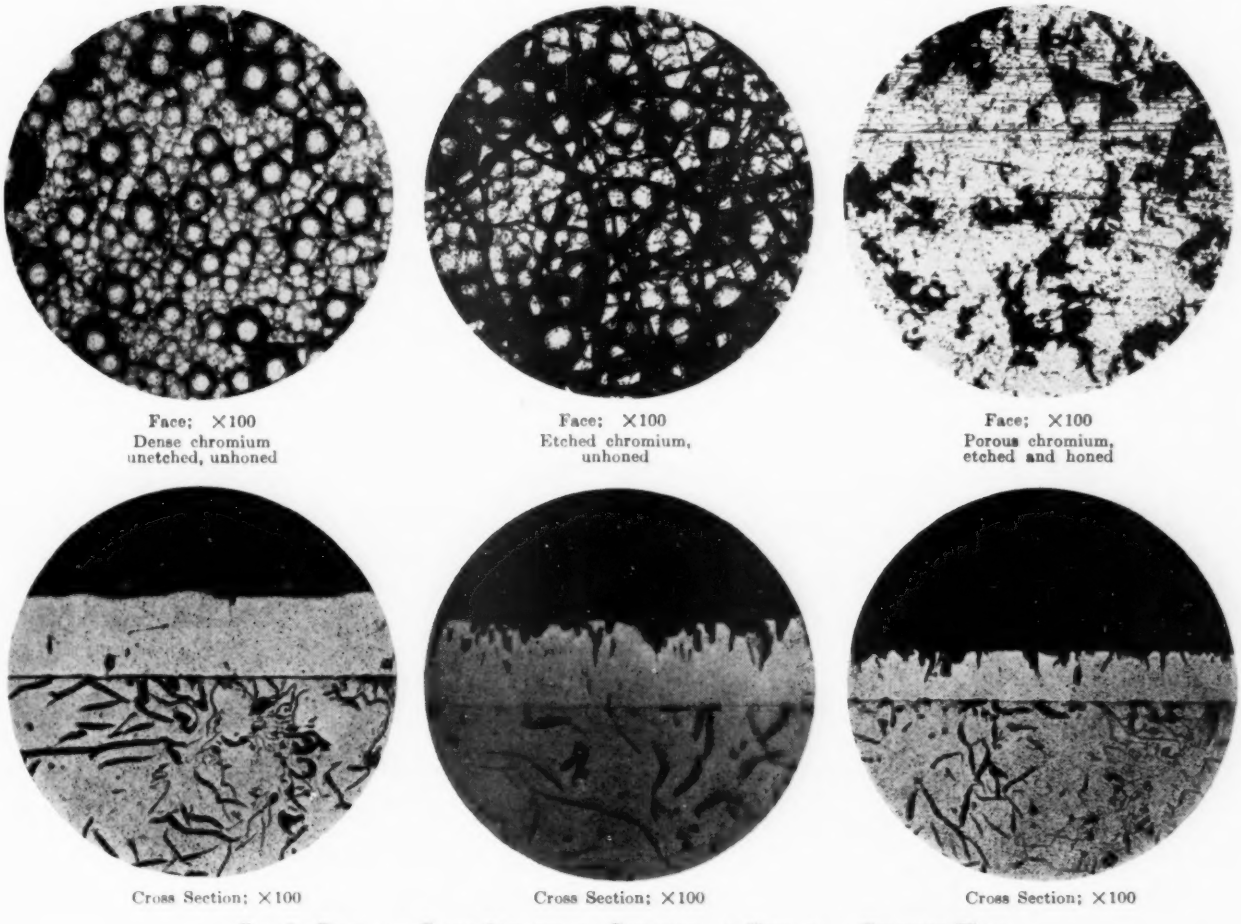
It should be noted that the thermal conductivity of chromium is approximately 40 per cent higher than for steel or cast iron. Maximum metal temperatures of the cylinder are at the inner cylinder surface particularly in the combustion zone. Any improvement in heat transfer results in a lower wall temperature and will improve piston and ring lubrication. Heat actually gets away faster through chromium. Tests on air-cooled porous-chrome cylinders have shown that more heat passes to the barrel fins because a greater quantity of cooling air on the barrel is required to maintain a standard thermocouple temperature. Other tests have shown a higher than normal temperature at the cylinder flange, indicating greater heat transfer to the barrel. Specific fuel consumption was normal so there is no reason to believe that there was any increase in total heat loss. This additional cylinder heat then must have been subtracted from heat loss to the cylinder head, piston, and lubricating oil. It is a fact that in some engine types the bottleneck for heat dissipation lies in the cylinder head. The heat distribution for an air-cooled airplane-cylinder assembly is of the order of 60 per cent to the head and 40 per cent to the barrel. Any diversion of heat to the barrel is evidently very desirable and chromium seems to accomplish this.

The question naturally arises concerning heat transfer through the bond where two dissimilar metals are joined. Inspection of photomicrographs of porous chromium applied directly to iron or steel shows no space or void between the two metals. Of course, the basic metal must be absolutely clean before plating but this is readily accomplished by a short electrolytic etch, which, at the same time, produces some mechanical keying and interlocking on the basic-metal surface.

In some plating the metal is transferred from the anode to the cathode, but in chromium plating, the chromium comes directly out of the bath solution which is essentially chromic acid (CrO_3 H_2O). It is deposited as molecular chromium on the cathode, the molecules being of insignificant size dimensionally. Thus the chromium fills in the smallest irregularities of the surface being plated and a bond approaching fusion such as in welding is obtained. Chromium under the microscope even at high magnification exhibits no crystalline structure such as we see in steels, but the crystalline structure has been indicated by X-ray diffraction. Because of the fineness and intimacy of this bonding good heat transfer results. Mechanical failure at the bond is the least of our worries, calling only for meticulous care in the cleaning of the basic-metal surface.

Friction. Chromium is conceded to have the lowest coefficient of friction of any of the generally used structural metals. The value of the sliding coefficient for chromium on chromium has been given as 0.12 and for chromium on steel as 0.16, while steel on steel is 0.20 (6). It should be pointed out here that our experience with chromium running on chromium under boundary lubrication has been unsatisfactory.

For rotating shafts chromium was found to have the lowest friction of any of the metals tested (7). Friction in an engine cylinder can hardly be estimated from any simple friction tests, and no actual engine tests have yet been run by the author's company to check comparative friction losses with porous-chrome cylinders.



Corrosion Resistance. The corrosion resistance of chromium is high and is an important contributor to its low wear rate in engines. Sulphur is always present to some degree in Diesel fuels ranging from $^1/_2$ to 3 per cent by weight. At the high temperature and pressure existing in the cylinder, sulphur may combine with oxygen to form sulphur trioxide (SO_3) which, with water as a product of combustion, forms dilute sulphuric acid. Chromium is only very slightly attacked by sulphuric acid but ferrous metals are quickly and vigorously attacked. Another sulphur compound, hydrogen sulphide, may be encountered as a corrosive agent, particularly in gas engines running on sour gas.

A steel rod plated over a part of its length was subjected to moist hydrogen sulphide at temperatures ranging from 120 F to 220 F for 252 hr. After this exposure the unplated portion of the rod was blackened and badly corroded, but the chromium-covered portion was unattacked. This resistance to hydrogen-sulphide corrosion has been confirmed in service by excellent performance in gas engines operating on natural gas with an H_2S content as high as 1 per cent by volume. In spite of the resistance of chromium to corrosion from sulphur compounds they should always, in so far as possible, be removed from gaseous fuels because their tendency to increase fuel knock adversely affects combustion. Chromium is unaffected by nitric acid and saturated solutions of ammonia, but it is dissolved by hydrochloric and bromic acid.

Chromium resistance to atmospheric corrosion is well recognized. Porous-chrome cylinders may be stored indefinitely with little or no protection to the chromium surface and no detrimental effect results.

Having mentioned some of the good characteristics of chromium, it is well to note also some of the deficiencies so that its limitations may be recognized. Its tensile strength seems to be negligible. We have made rather crude tests for tensile strength of electrodeposited chromium and obtained a value of around 2000 psi. Chromium was deposited on a copper strip to a thickness of 0.005 in. and the copper was then dissolved by nitric acid, leaving 0.005 in. of chromium. This was very fragile and brittle but with care was clamped and pulled. Search of existing literature fails to reveal any values for tensile, shear, or compressive strength, yet this information is desirable when chromium is used as an engine material. However, chromium, in common with other brittle materials such as cast iron, must have appreciable compressive and shear strength as evidenced by its performance in engine cylinders and on piston rings.

Porous Chromium. Porous chromium has all of the characteristics peculiar to chromium but differs principally in its surface condition. This is responsible for its ease of lubrication and ability to carry high bearing loads. Fig. 2 shows face and cross sections of chromium as used on a cylinder wall. When chromium is electrodeposited to a thickness of 0.004 to 0.015 in., it becomes nodular and exhibits a network of cracks. Thin deposits of the order of 0.00001 to 0.00005 in., as used in decorative work also invariably show checking, except that they may be smeared over by cold working in buffing or polishing operations. These cracks are due to tensile stresses beyond the ultimate tensile strength of the chromium. They are shrinkage cracks probably resulting from the evolution of hydrogen (8). In the plating process, hydrogen is generated at the cathode (cylinder wall), and the chromium as deposited may contain large volumes of occluded hydrogen.

FIG. 2 FACE AND CROSS SECTIONS OF CHROMIUM AS USED ON A CYLINDER WALL

When this hydrogen diffuses out, a change in volume occurs, the result being, for analogy, a condition similar to dried mud from which water has evaporated. These cracks are not the grain boundaries as commonly seen in etched steel. Because tensile failure has occurred along these lines it cannot be assumed that the chromium is stress-relieved. Appreciable stresses still exist throughout the plate, but they are below the ultimate strength. Electrolytic action preferentially attacks along stress lines or planes and the current-reversing process, which is the treatment for producing porous chromium, does exactly this (9). As the reversing process proceeds, the existing cracks become wider and deeper at the same time they tree or sprout branches until the whole surface is completely cut up, appearing under the microscope like a coal pile. Fig. 3 shows well the effect of progressive electrolytic etching or reversal. This porosity treatment effects a great reduction in residual stresses and may be responsible for the slight reduction in endurance limit found on porous-chrome-plated steel specimens (10–15 per cent, while dense unetched chromium may show a reduction of as much as 50 per cent).

Strips of 0.005-in-thick shim stock were plated with the results shown in Fig. 4. Upon plating the strip (*a*) on one side only, it assumed the curvature shown at (*b*), yet the chromium surface on microscopic inspection showed no cracks. Shrinkage of the chromium occurred, but due to the thinness of the steel base strip, it conformed, and the stresses in the chromium did not exceed its ultimate strength. However, the application of reverse current (*c*) produced a reduction in curvature and also many surface cracks, demonstrating that residual stresses were relieved. Strip (*d*) was plated on both sides with the same thickness of chromium. It remained substantially straight, but the chromium surface on each side was cracked exhibiting tensile surface failures because the stresses of deposition were not relieved by conformation or current reversal.

The current-reversing process may be carried to the point of complete removal or stripping of all of the deposited chromium, but in the production of cylinders it is stopped short of any appreciable dimensional change in the bore diameter. Honing of the bore then results in a smooth surface containing microscopic indentations, recesses, or pits.

Wettability. The term "wettability" has been applied to surfaces and oils to define that property of either which affects the rate of oil dispersion. It is a function of both the oil and the surface. Oils vary in wetting characteristics. Surface geometry and profile also play a major part. The porous-chromium surface after honing, with its flats dotted with microscopic pits, depressions, or crevices is readily wetted with oil, which spreads quickly and covers. It has the further advantage of oil retention. Oil may be scraped from the flat surfaces but some remains in the pores, and this will creep up and rewet.

The mechanism of wettability, which has been ably discussed by J. T. Burwell (10), is such that an oil drop on a plane smooth surface will reach a state of equilibrium, where it will neither spread nor recede. At this condition the dome-shaped drop makes a definite contact angle with the plane surface, this contact angle depending upon inherent characteristics of the oil.

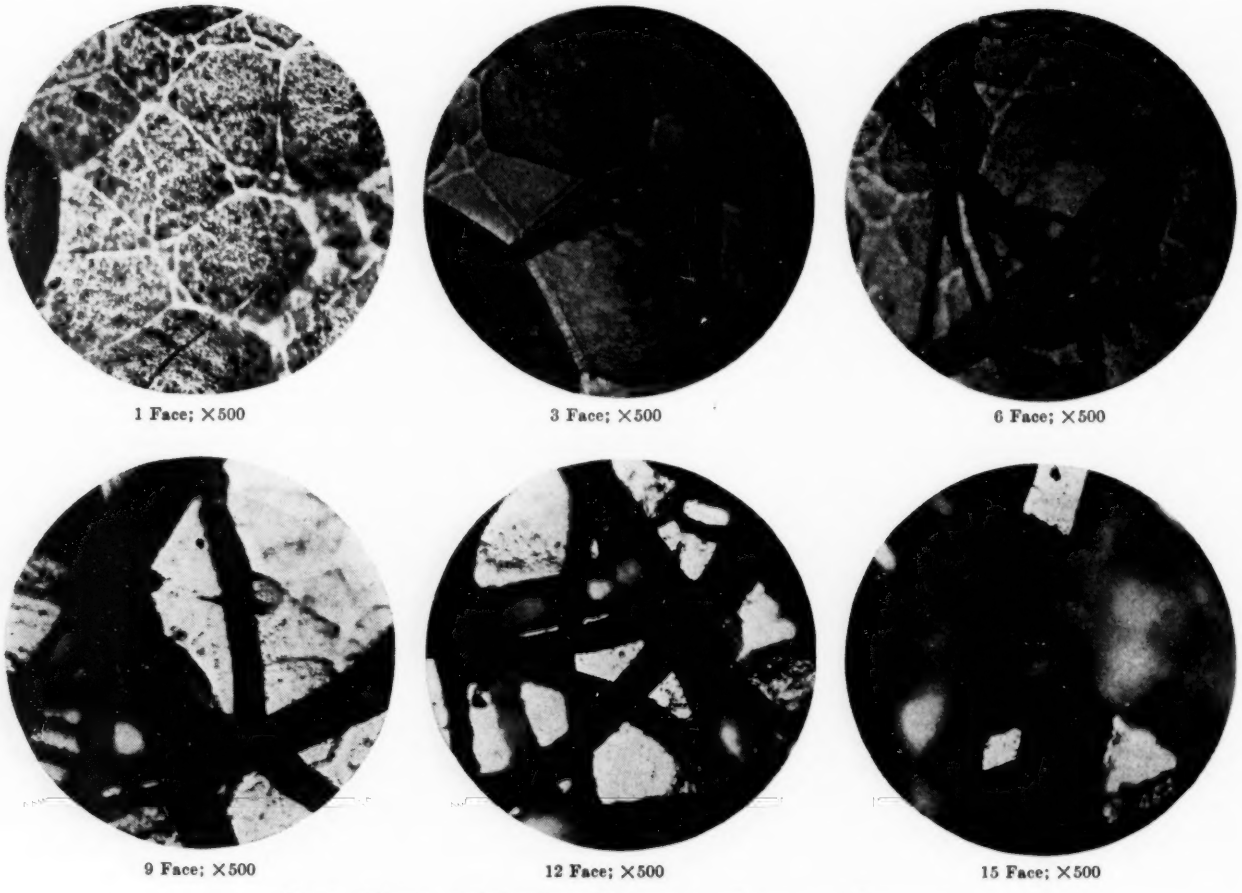

FIG. 3 EFFECT OF PROGRESSIVE ELECTROLYTIC ETCHING ON CHROMIUM

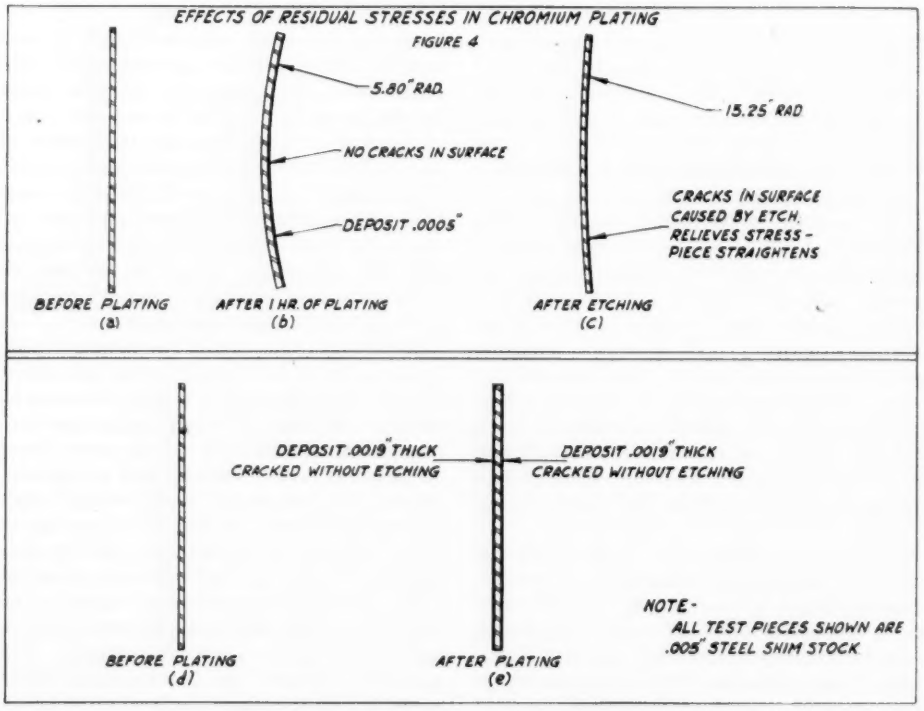

FIG. 4 EFFECTS OF RESIDUAL STRESSES IN CHROMIUM PLATING

itself. The energy of adhesion of the oil W is given by $W = \alpha (1 + \cos \theta)$ (10), where α is the surface tension and $\cos \theta$ is the contact angle.

A $^1/_4$-in-diam area on porous chromium may contain fifty to several hundred pores or crevices depending upon the "porosity." Taking a section through the diameter of such a surface with an oil drop on it, we will find the edge of the drop may be on a flat surface and at this point it will stop spreading when the equilibrium contact angle is reached. However, there is an infinite number of diameters that may be taken through the oil drop and every one will show a different geometrical condition of the porous-chrome surface at the edge of the drop. Circumscribing a circle on a photomicrograph of the porous-chrome surface, it will cut through flats, the downslope of pores, and the upsloping sides. As a result, the condition at the periphery of drop is unstable, because the contact angle of equilibrium can never be reached at all points. The oil thus proceeds to execute enveloping tactics around the flat areas, and to spread over the whole surface.

Our experience indicates that on any metal surface which has roughness, for instance, scratches running in all directions, oil will spread faster than when the surface is smooth. On a specimen polished in one direction, the oil will also spread faster in the direction of the polish scratches than it will at 90 deg to them. In this case the drop becomes elliptical, the major axis being in line with the scratches. This action is explainable by the variation of the contact angle at the edge of the oil drop.

Load Capacity of Porous Surfaces

With full oil-film lubrication the capacity of a bearing is a function of bearing area if other factors such as viscosity and speed are constant. Crankshaft bearings operate, at least during a large part of the cycle, under conditions approaching full film lubrication. An increase of bearing area here results in an increase in load capacity generally. Under conditions of boundary-layer lubrication such as exists between piston rings, piston, and cylinder wall, the case is reversed and load capacity increases with a decrease in bearing area. This is entirely at variance with accepted theories of hydrodynamic lubrication, but this type of lubrication cannot be maintained on cylinder walls. Oil control requires removal of oil from the cylinder wall, what remains being subjected to high temperature and combustion flame as well as dilution from fuel or condensation of combustion products. The dynamic factor of velocity is a requisite for hydrodynamic oil-film maintenance, yet at the top center position of the piston, where all of the adverse conditions accumulate, the piston-ring velocity is zero. Boundary-layer lubrication is the best that can be expected in the upper ring travel.

Notable investigations of boundary-layer conditions have been made by F. P. Bowden (11) and collaborators. Macy O. Teetor (12) has analyzed and experimented on these conditions for the specific case of piston rings and cylinders. The results are startling and establish some novel concepts of factors involved in boundary-layer lubrication. Evidence seems to indicate that scuffing or scoring results when the surface temperatures of the metals in contact reach the melting points, then fusion or welding occurs. These surface temperatures, even under conditions of smooth running and low friction, have been found to exceed 1100 F, yet the body of the test specimen remained at room temperature (11 *b*).

That these temperatures can sometimes exceed the melting point of cast iron is evidenced by inspection of seized cast-iron pistons where we may find some of the cylinder-wall material welded on the piston or the reverse condition of piston surface welded on the cylinder wall. The factors producing heat at the surface are speed, load, and frictional characteristics of the metals in contact, but friction depends to a large degree upon the surface geometry (rough or smooth), and the actual net area of contact. The larger the contact area the greater will be the amount of heat generated. Cooling of the surface is accomplished partially by oil but mainly by heat transfer into the base material. Teetor's work (12) demonstrates that reducing contact area by interrupting the surface results in a smaller amount of generated heat because by so doing he was able to carry higher bearing loads. The low limit for contact area may be dependent upon the physical characteristics of the contacting metals, particularly their shear and compressive strength at operating temperature. The amount of heat that can be carried away from the surface depends upon the thermal conductivity, and the limiting operating surface temperature is fixed by the melting points of the contacting materials. Briefly, the following steps are indicated for increasing load capacity under boundary-lubrication conditions:

1 Reduce the net actual contact area.
2 Choose materials with high thermal conductivity.
3 Choose materials with high melting points.

It is interesting to note how porous chromium fits into these requirements:

1 Inspection of face and cross sections of Fig. 2 shows that contact area is reduced by the pores or crevices. This we call porosity and have come to speak of it on a percentage basis; thus 30 per cent porosity signifies 30 per cent of the total area in depressions and 70 per cent of the area as flats, plateaus, or contact surface. This percentage porosity is to some extent controllable in the electrolytic processing and in the finish-honing.

2 The thermal conductivity of chromium is 40 per cent higher than steel or cast iron, permitting rapid heat flow for the maintenance of lower surface temperature.

3 The melting point of electrolytic chromium is approximately 800 F higher than cast iron and 500 F higher than steel, thus raising the limit for operating-surface temperature.

The exceptional performance of porous-chromium cylinders and piston rings in severe service is a fact and lends credence to these explanations of why it works.

Processing. Before applying porous chromium to a cylinder it should be ground or bored oversize and then honed to a smooth finish of 10 μ in. rms or less. A fine finish is desirable for the following reasons:

1 It gives a more definite calculable actual surface area for plating. Control must be maintained over the thickness of deposited chromium and with a given plating solution this depends upon area, current density, and time. The latter two are controllable but the actual net area is inherent in the part to be plated.

2 Deposition of chromium tends to exaggerate initial surface irregularities; a rough surface becomes rougher as the thickness of deposition builds up. As a finished cylinder must always come within both dimensional and surface-finish tolerances, it is desirable to have a uniform thickness of chromium throughout the bore.

Cracks, inclusions, and spongy spots in the cylinder wall are accentuated by plating; in fact the process displaces the necessity for magnaflux checking. Cracks which are invisible to the eye are clearly shown up after plating.

The cylinders are then assembled in fixtures with accurately centered anodes, given a short anodic treatment, immersed in a plating tank, and plated with the required thickness of chromium. The fixture-and-cylinder assembly is then removed as a unit to an etch tank where it receives a porosity treatment. Upon

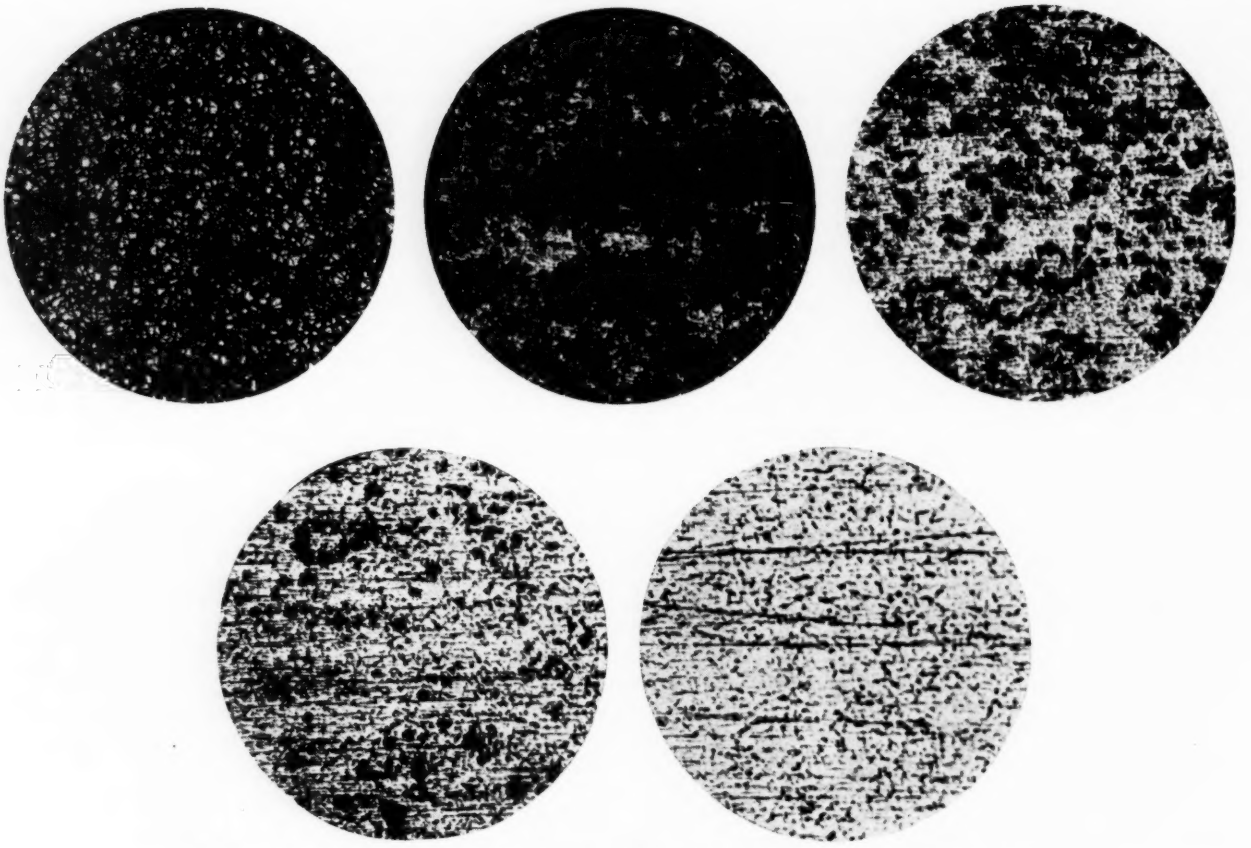

FIG. 5 EFFECT OF PROGRESSIVE REMOVAL OF METAL ON THE POROSITY OF CHROMIUM; ×50
(No. 0 emery paper used.)

disassembly the cylinders are ready for finishing. The porous chromium is readily honed with proper abrasives, but here finishing differs from the usual procedure of honing to a bore dimension only. Surface finish or porosity must also come within limits, because porosity has an influence on oil wettability. Fig. 5 shows the influence of surface stock removal on porosity. The factors affecting the finished cylinder bore are as follows:

1 Initial bore dimensions: the bore should be straight and round, as the ideal plating can do no better than deposit chromium to a uniform thickness throughout the cylinder.

2 Plating control of solution, composition, and temperature, current density, and time to obtain exactly the desired thickness of chromium.

3 Removal of correct amount of stock in finishing to obtain the desired surface finish.

Because of these additional requirements final dimensional tolerances on cylinder bores must be wider than those usually held where the only limiting factor is diameter.

For some time the profilometer was used as an inspection instrument in checking porous chromium for surface finish. However, the profilometer fails to give a true indication of surface condition in this case. Fig. 6 shows clearly that the standard profilometer needle does not trace the surface of porous chromium. Engine tests have subsequently established that surface porosity is an important characteristic and accordingly this property is considered in final inspection. While there is a reasonable correlation between the μ in. reading rms and percentage porosity, Fig. 7, it has been found more accurate and expedient to check porosity directly by microscopic inspection. Photomicrographs of various degrees of surface finishing have been planimetered to determine the percentage of flat and below-surface areas. Inspectors using a 50-power right-angle microscope can then search the bore and by comparison with the calibrated photomicrographs, make a reasonably accurate estimate of porosity.

In order to speed up inspection and minimize human errors of judgment we are now adapting the photoelectric cell to this work. The pores, depressions, or pits in the surface will reflect very little light with vertical illumination, while the smooth flats will have high reflectivity. Thus with a constant light source a photoelectric cell can be made to measure reflected light quantity. This, with a properly calibrated meter, can be a measure of the percentage of flat area or, inversely, of porosity. Such a "porosity meter" is shown diagrammatically in Fig. 8. Experiments to date indicate that this may be a satisfactory shop-inspection instrument, but more actual experience with it will be necessary to establish its utility definitely.

A wealth of experience under service conditions is being accumulated with porous-chrome cylinders on all types of engines, but for military reasons no details can now be given. However, other test data of interest are available, particularly accelerated wear tests on $^3/_4$-hp Lauson engines. This is a $1^3/_4$-in. bore × $1^7/_8$-in. stroke air-cooled 4-cycle gasoline engine. Two engines were run for 9 hr under load, one with the standard cast-iron cylinder and one with a porous-chrome cylinder. Allis-Chalmers type B dust (86 per cent below 5 microns, 100 per cent below 15 microns) was added to the initial charge of crankcase oil, the proportion of dust being 8.6 per cent by weight to accelerate wear. Tables 3 and 4, and Fig. 9, show the cylinder, piston, and ring wear.

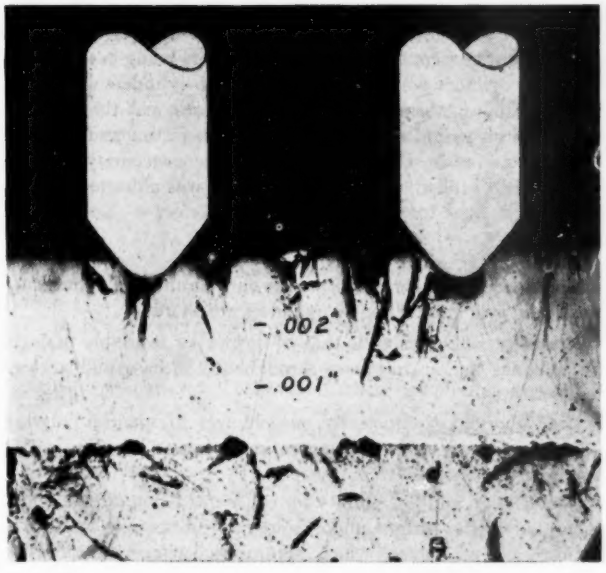

FIG. 6 SHOWING RELATION OF STANDARD 0.0005-IN-RADIUS PROFILOMETER NEEDLE TO PORES
(Honed porous chromium; ×500.)

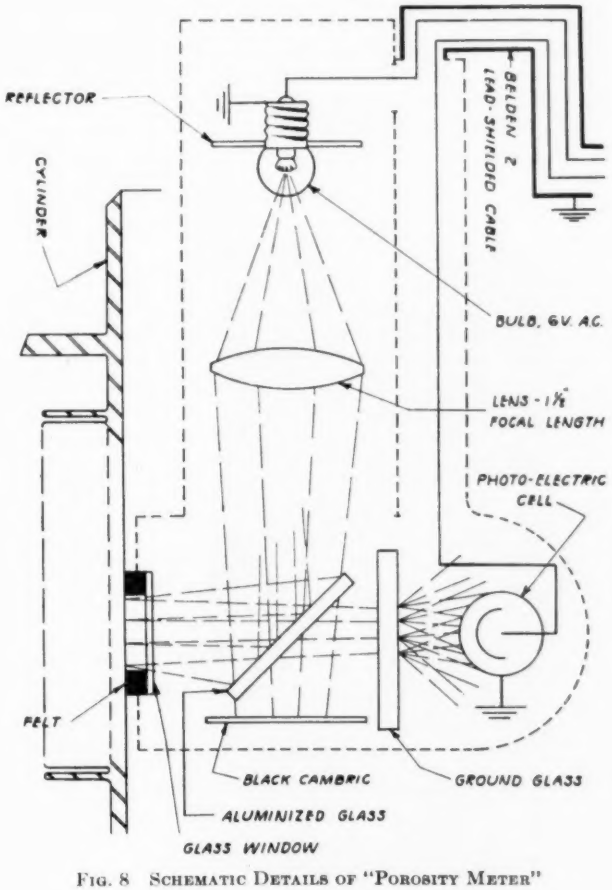

FIG. 8 SCHEMATIC DETAILS OF "POROSITY METER"

The relative wear of the rings is illustrated graphically in Fig. 10 which shows the sections of the worn rings compared with new rings. This test under such severe abrasive conditions, while not quantitatively applicable to full-scale engines,

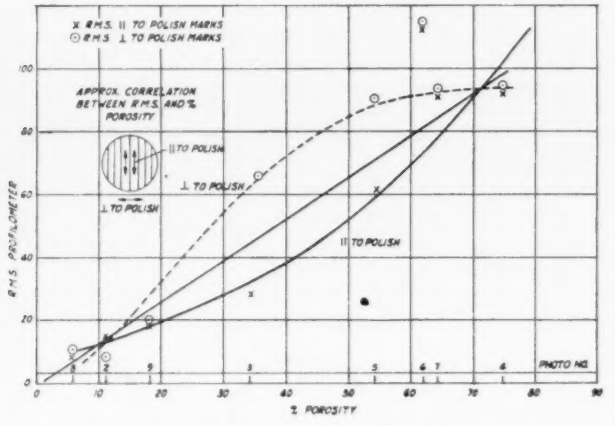

FIG. 7 APPROXIMATE CORRELATION BETWEEN RMS AND PERCENTAGE OF POROSITY

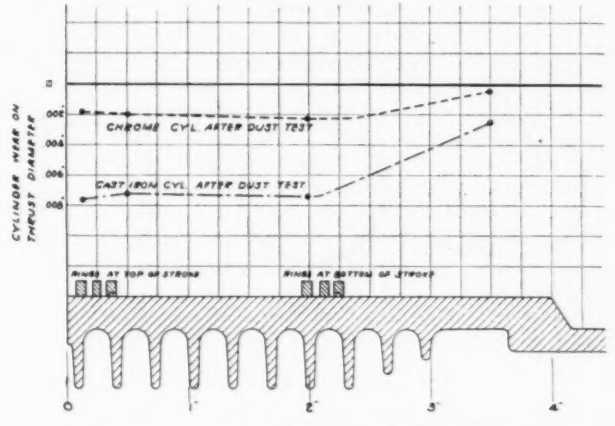

FIG. 9 CYLINDER WEAR ON CHROME AND CAST-IRON CYLINDERS

does indicate greatly lower cylinder wear with porous chromium and at the same time a great reduction in ring wear. Both results have been confirmed in service engines where records have been established of $^1/_{24}$ normal cylinder wear and $^1/_8$ normal

TABLE 3 CYLINDER WEAR

Location	Diametral wear, in. Cast-iron cylinder	Porous-chrome cylinder	Wear ratio, cast-iron cyl., porous-chrome cyl.
$^1/_8$ in. below head end....	0.0077	0.0018	4.3–1
$^1/_2$ in. below head end....	0.0071	0.0021	3.4–1
2 in. below head end.....	0.0083	0.0022	3.8–1

TABLE 4 PISTON AND RING WEAR

	In cast-iron cylinder		In porous chrome cylinder		
	Grams	Per cent of original weight	Grams	Per cent of original weight	Wear ratio, cast-iron cyl., porous-chrome cyl.

ring wear. Of course engines differ, and the improvement resulting from the use of porous chromium will vary with the particular engine.

Another manner in which porous chromium in cylinders immediately shows up to advantage is in the initial test or green

run of an engine. Because of its relative immunity to scuffing and ability to take abuse, ring scuffing and piston seizure are eliminated, and engine production is accelerated. Fig. 11 illustrates two identical pistons from a 10-in. × 12-in. two-cylinder gas test engine, one of the cylinders being cast iron and the other cylinder porous chromium. Both cylinders were carrying the same load and exhaust temperatures, yet the piston in the cast-iron cylinder seized, ruining both piston and cylinder. The piston in the porous-chrome cylinder was only polished where it had rubbed hard and the cylinder was unharmed.

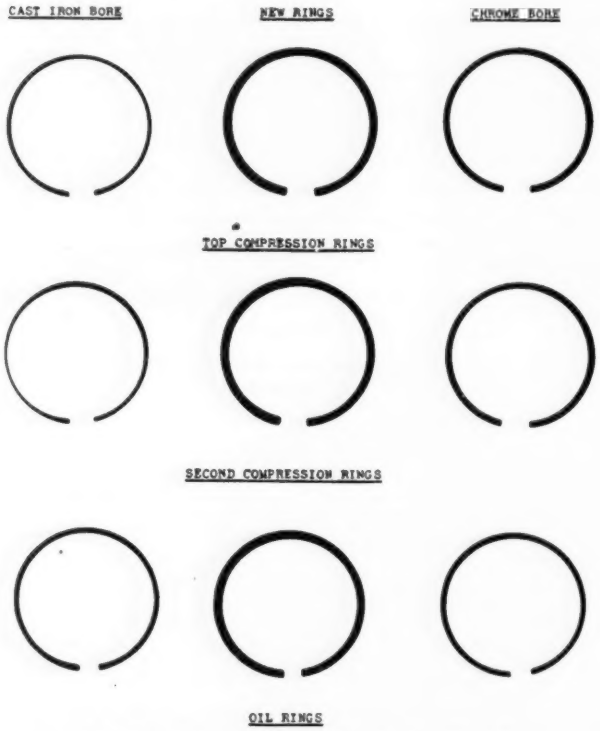

FIG. 10 COMPARISON OF WORN RINGS WITH NEW RINGS

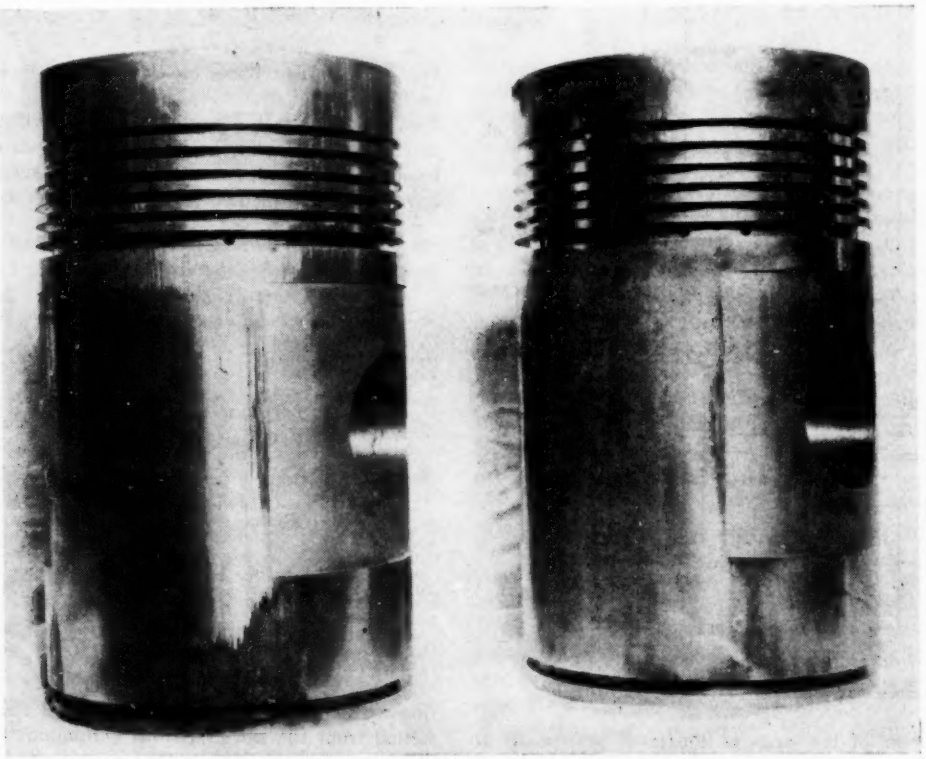
SUMMARY

The inherent properties of porous chromium which contribute to its low wear rate in engine cylinders are as follows:

Hardness, which exceeds that of any other available material for cylinder liners; hardness throughout the case and at high temperatures.

High thermal conductivity, which aids in maintaining low internal cylinder-surface temperatures, improving lubrication and heat transfer.



Low friction and low affinity for other metals, minimizing heat generated at the surface under boundary-lubrication conditions.

Corrosion resistance, which eliminates surface deterioration from action of the products of combustion.

In the light of recent theories concerning boundary lubrication an attempt has been made to explain how and why the peculiar surface geometry of porous chromium fits into the theories resulting in high load capacity and wettability.

The processing, finishing, and inspection procedures have been briefly described. The most important factors here are control of solutions, current density, temperature, and time, as well as a final surface finish.

Much has yet to be learned, but the need for intensive re-

(a) (b)

FIG. 11 RESULTS OF SEIZURE TESTS ON PISTONS IN CAST-IRON CYLINDER (*a*), AND IN POROUS-CHROME CYLINDER (*b*)

search on the potential possibilities of porous chromium is recognized and such a program is under way.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Mr. H. Van der Horst for the continuous assistance and encouragement he has given to this work. Thanks are also due the author's co-workers, particularly Messrs. A. Baum, R. H. Howard, and F. M. McNall for their help in the preparation of data.

Discussion

K. W. SCHWARTZ.[3] Our laboratory measurements on the hardness of chromium indicate that all bright chromium deposits from a chromic-acid bath have about the same hardness, and that holds regardless of the bath composition, temperature, current density, or other plating conditions. However, if the deposit obtained is dull in appearance, the hardness is considerably lower than that of a bright deposit. Our figures indicate a hardness of about 1000 Bhn for bright chromium and a hardness of about 650 Bhn for dull chromium. So-called "milky" chromium has a hardness intermediate between these values, that is, about 800.

As to methods of determining hardness, we have found that practically all of the methods referred to in the literature involve crushing of the chromium deposit to get a reading. This may not be entirely reliable, particularly when the indentation that is made might be influenced by the hardness of the underlying base.

We experimented some years ago with methods of determining so-called hardness of chromium and found that we could get quite consistent results by means of a scratch hardness test. The apparatus which we used was a Bierbaum microcharacter, and the principle on which the apparatus functioned was quite simple. It merely uses a diamond point of definite shape, to which is applied a given weight. The diamond point is drawn across the surface of the chromium to be tested at a regulated speed. The width of the scratch is then measured under the microscope at a magnification of 1000. The results obtained are quite consistent and reproducible. We found that by means of this method the hardness measurements made on chromium deposits, even as thin as 0.001 in., were entirely independent of the base metal on which the chromium was plated.

In connection with comments on the plating operations, it should be stated that pure chromic acid alone, when dissolved in water, will not give a plating bath. The current can be passed through such a solution indefinitely, but no metallic chromium will be plated out. It is quite interesting, and rather unique as an electrochemical phenomenon, that by adding a catalyst to the chromic-acid solution a plating bath results. The catalysts that can achieve this result, interestingly enough, are acid radicals and, as we electrochemists refer to them, they are anions. They have a negative charge and are attracted to the anode, yet they perform their function at the cathode where the metal is deposited.

It is essential that any chromic-acid solution have present in it a certain amount of acid-radical catalyst to enable it to plate; commercially that acid radical is usually sulphate. Whether we add it as sulphuric acid, sodium sulphate, or any other soluble sulphate makes no difference. The point is that the sulphate radical or an equivalent radical must be present in the solution to enable it to plate.

The author states that chromium fills in the smallest irregularities of the surface being plated. From experience, we have found that chromium deposits tend to follow the irregularities in the underlying surface and to reproduce them. For example, let us take the surface of a cylinder liner that had been honed. The reader will be familiar with the honing marks or scratches that are present on the surface. A thickness of chromium as high as 0.008 in. on the radius can be deposited, for example, and the honing marks will tend to be reproduced in the deposit. Furthermore, and this is quite an important precaution, pits in the base metal do not tend to be bridged over by the chromium deposits. Such other things as nonmetallic inclusions in the base metal will not be covered by the chromium deposit, because quite obviously they are not conductors of current, and as such do not take the deposit. Therefore it is quite important that the surface on which we plate the chromium be as free from nonmetallic inclusions as possible.

Incidentally, any uncombined carbon or graphite in cast iron should be kept at the lowest possible minimum, because the con-

[3] United Chromium, Incorporated, New York, N. Y.

ductivity of carbon is very much lower than that of iron, and that will tend to produce undesirable irregularities in the plate.

In connection with chromium deposits on the bore of cylinders, in addition to the degree of porosity, that is to say, the relationship between the so-called table tops or plateaus and depressions, the depth of these depressions is quite important. While we know that electrodeposited chromium is extremely hard and that it functions very well on the bores of liners, it nevertheless does wear after long service. In order to get the maximum serviceable life out of the chromium deposit, these depressions or pores should be as deep as it is practicable to make them. In plating so-called "porous" or oil-retaining deposits of chromium, careful control of the plating conditions and final finishing operations is necessary. This should be performed so that the plated liner when ready to install in the engine has a maximum depth of porosity in addition to the other properties required for satisfactory results.

HANS BOHUSLAV.[4] We have made a few applications of chrome-plated steel liners in high-speed gasoline engines, and one of the drawbacks has been the length of time of break-in of such liners. In our first tests, it took 25 to 30 hr break-in time which, on engines of this type, is too long for efficient production. Even after that, our oil consumption was erratic. So we tried different methods such as match-lapping and individual honing, and found that apparently it was not practical at least on steel liners. Recently we have had some hope of overcoming the difficulty by using taper-face rings. We have found that such rings allow for more irregularities in the liner, at least in plain-steel liners. To try this, we used some of the liners which had been tested some months previously and which had been somewhat misused. Despite the fact that these liners were quite irregular, having been put in a new block which did not allow the same position for the surfaces, the oil consumption came down very rapidly. In about 2 hr running, we were within the normal oil consumption; in another 2 hr, we were considerably below our average.

The author's comments on the following questions would be appreciated: With all the cracks and porosity in the plating, it is the writer's understanding that considerable honing is done after the plating. What happens to the fine particles left during and after the honing operation?

The second question relates to the control of the areas of the metal so they will not fall out. In other words, if two cracks are too close together, or are not exactly perpendicular to the surface, there would normally be some areas in which the cracks finally merged on the steel or on the base surface.

H. VAN DER HORST.[5] It has been shown by tests on porous-chromium cylinders, conducted at the Naval Experiment Station at Annapolis, that the use of chromium plating in a well-known high-speed high-output Diesel engine which had been run for 6000 hr resulted in a reduction in wear of 1 to 14. That is a large figure, and what is more surprising, a reduction of ring wear to 22 per cent was made, which means only 22 per cent of what is known to occur when running-in cast-iron cylinders.

AUTHOR'S CLOSURE

The catalytic effect of the sulphate radical in chromium deposition is known to all concerned in plating, but the author did not wish to burden mechanical engineers with the electrochemical phase of the work. It is true, in general, that chromium deposition tends to follow the base-metal surface. However, the author has observed photomicrographs of edge sections where the base metal has been selectively etched, and the chromium has deposited into the pits and recesses.

Concerning Mr. Bohuslav's question about excessive oil consumption, the only comment is that every engine is a separate personality and often requires some special treatment of its own. As he says, very fortunately now, the taper-faced rings have done the job. The abrasives in the finishing or honing operation, of course, are washed down to some extent by the copious flow of coolant in the honing. It is easily conceivable that some abrasive may lodge in the pores and crevices. However, in the normal procedure, these are thoroughly washed before they ever go into service, and it is doubtful if there has ever been any failure which could be attributed to retaining the abrasive from the honing operation itself.

Regarding the cracks and their proximity, it may be explained by the fact that edge sections through the porous chromium show the table top and the sides coming down from the table top at an angle. The table top has a good firm base. It is not as though it were undercut and standing up like a column. It is rather a truncated cone, if we want to think of it that way, so that the structure is pretty well cantilevered. We have had no breakage or failure of the chromium due to the geometry of the metal structure.

High-Pressure Pipe-Line Research

By F. W. LAVERTY and F. M. McNALL,[1] OLEAN, N. Y.

In estimating gas-pipe-line costs prior to undertaking the detailed design, it has been the practice generally to utilize graphical determinations of such variables as pipe-line diameter, compressor-station spacing, operating pressures, and the like. The graphical method is a time-consuming process, however, entailing the preparation and consideration of a large number of curves. The purpose of this paper is to show the derivation of an empirical equation containing all of the design variables, to which the methods of the differential calculus may be applied to yield a general series of expressions for the most economical design of any pipe line.

Nomenclature

The following nomenclature is used in the paper:

a = compressor brake horsepower per million cubic feet per day of gas compressed, 18.5 for curve data
A = cross-sectional area of pipe, sq ft
avg = average condition
B = fixed charge on pipe, fraction of investment (taken as 0.12 for curve data)
$C = \left(1 - \frac{1}{C_r^2}\right)$
C_I = total investment, dollars per mile
Cy = total yearly cost, dollars per year per mile
Cf = fuel cost, dollars per 1000 standard cu ft (taken as 0.10 for curve data)
Cr = compression ratio
d = inside diameter of pipe, ft
D = inside diameter of pipe, in.
E = experience or efficiency factor for flow equation
f = friction factor, defined by Fanning's equation
F = friction, feet of gas; load factor expressed as a decimal
g = acceleration due to gravity, fpsps (taken as 32.2 for illustrative data)
G = constant in pipe-laying cost, dollars per ton per mile, 12 in data for curves
H = constant in pipe-laying cost, dollars per mile, 3000 in data for curves
K = constant = $(\alpha X + 86.4Cf + 6.79)$ = 19.43 for curves
K_1 = constant = $(B)\ (Y + G)\ (28.2)$ = 328.3 for curves
K_2 = constant = $\frac{80.8}{\rho_0 \mu^{0.0814}} \left[\frac{M}{T}\right]^{0.541}$ = 765.3 for curves
l = distance, interval of pipe between compressor stations, ft
L = distance interval of pipe between stations, miles
m, n = coefficients of optimum diameter equation
M = molecular weight, lb (16 for methane)
N = constant in pipe-laying cost, dollars per in. of diam per mile (270 for illustrative data)
P = absolute pressure, psi
p = absolute pressure, psf
P_0 = base pressure, absolute
P_1 = compressor discharge pressure, psia
P_2 = compression suction pressure, psia
q = quantity of gas transported, cfs, measured at P_0 and T_0
Q = quantity of gas transported, cu ft per day, measured at P_0 and T_0
R = gas constant = 1546 for illustrative data
S = allowable hoop stress, psi (20,000 psi for illustrative data)
T = flowing temperature deg R (520-deg R for illustrative data)
T_0 = base temperature, deg R
t = thickness of pipe wall, in.
u = linear velocity, fps
V = specific volume, cu ft per lb
W = weight of pipe, tons per mile
X = cost of compressors, dollars per bhp, installed (80 for illustrative data)
Y = cost of pipe, dollars per ton (85 for illustrative data)
Z = constant in gas equation, "supercompressibility," dimensionless
α = fixed charge on compressors, fraction (0.05 for illustrative data)
ρ_0 = density of gas, lb per cu ft at T_0 and P_0 (0.0422 for illustrative data)
ρ = density of gas, lb per cu ft at T and P
μ = absolute viscosity of gas, lb per ft-sec (7×10^{-6} for methane)
d = symbol for differential, e.g. ($\bar{d}p$ differential of pressure)

General Considerations for Pipe-Line Cost Estimates

The detailed design of a gas pipe line is so laborious and time-consuming that it is generally desirable first to estimate rather closely the optimum values of the design variables for the case at hand. In general, these include pipe-line diameter, compressor-station spacing and operating pressures as functions of material cost, labor cost, and the character and quantity of gas to be handled.

Previous methods for estimations of this type (1, 3, 4, 6, 7)[2] have for the most part been graphical in nature, entailing the preparation and consideration of a large number of curves. In addition, the effects of deviations from the perfect-gas laws have been in some cases neglected.

If the total cost of a gas pipe line can be represented by an empirical equation containing all of the design variables, the methods of the differential calculus may be applied to yield a general series of expressions for the most economical design of any pipe line.

The first requirement for the development of a generalized cost equation is a gas-flow equation which will be dependable over a wide pressure and composition range. An equation which corresponds fairly well with known pipe-line conditions may be developed from Bernoulli's theorem combined with the Fanning equation. Based on the assumption that the flow is isothermal and at constant elevation, the differential form of Bernoulli's theorem

$$-V\bar{d}p = \frac{\mu}{g}\bar{d}u + \bar{d}F \qquad [1]$$

---

[1] Clark Brothers Company.

Contributed by the Petroleum Division and presented at the Semi-Annual Meeting, Los Angeles, Calif., June 14–17, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

may be combined with the differential form of the Fanning equation

$$\bar{d}F = 2f\left(\frac{\mu^2}{g}\right)\frac{dl}{d} \quad \ldots\ldots [2]$$

to yield the expression

$$-V\bar{d}p = \frac{\mu}{g}\bar{d}u + 2f\left(\frac{\mu^2}{g}\right)\frac{dl}{d} \quad \ldots\ldots [3]$$

Now

$$u = \frac{q\rho_0 V}{A} \quad \ldots\ldots [4]$$

and

$$V = \frac{ZRT}{pM} \quad \ldots\ldots [5]$$

hence the differential form of the flow equation becomes

$$\frac{-M}{ZRT}p\bar{d}p = \frac{q^2\rho^2}{gA^2}\left(2f\frac{\bar{d}l}{d} - \frac{\bar{d}p}{p}\right) \quad \ldots\ldots [6]$$

Integrating between limits leads to

$$q = \frac{A}{\rho_0}\left[\frac{\frac{gM}{2Z_{avg}RT}(P_1^2 - P_2^2)}{\frac{2fl}{d} + \ln p_1/p_2}\right]^{1/2} \quad \ldots\ldots [7]$$

and neglecting ($\ln p_1/p_2$) in comparison to $\frac{2fl}{d}$, it simplifies to

$$q = \frac{A}{\rho_0}\left[\frac{gMd(p_1^2 - p_2^2)}{4flZ_{avg}RT}\right]^{1/2} \quad \ldots\ldots [8]$$

For the Reynolds numbers between 5×10^4 and 5×10^7, which covers practically all gas-transmission practice, an average straight line can be drawn through the logarithmic plot of the Drew and Genereaux data (2)

$$f = 0.03015\left(\frac{du\rho}{\mu}\right)^{-0.1505} \quad \ldots\ldots [9]$$

Substituting the value of f in Equation [9] in Equation [8], and replacing A by $\pi d^2/4$

$$q = \frac{2.467}{\rho_0}\left[\frac{d^{4.85}gM(p_1^2 - p_2^2)}{lZ_{avg}RT\mu^{0.1505}}\right]^{0.541} \quad \ldots\ldots [10]$$

Using the common engineering units and introducing the necessary conversion constants, Equation [10] takes the form

$$Q = \frac{(2.467)(144)^{1.081}(24)(3600)(32.2)^{0.541}}{(12)^{2.622}(5280)^{0.541}(1546)^{0.541}} \frac{1}{\rho_0}\left[\frac{D^{4.85}M(P_1^2 - P_2^2)}{LZ_{avg}T\mu^{0.1505}}\right]^{0.541} \quad \ldots\ldots [11]$$

$$Q = \frac{80.8}{\rho_0\mu^{0.0814}}\left[\frac{D^{4.85}M(P_1^2 - P_2^2)}{LZ_{avg}T}\right]^{0.541}E \quad \ldots\ldots [12]$$

where E is an experience factor ordinarily having a value of from 1 to 1.03 for natural gas.

For simplicity, let

$$K_2 = \frac{80.8}{\rho_0\mu^{0.0814}}\left[\frac{M}{T}\right]^{0.541}E \quad \ldots\ldots [13]$$

a constant for any particular case, then

$$Q = K_2\left[\frac{D^{4.85}(P_1^2 - P_2^2)}{LZ_{avg}}\right]^{0.541} \quad \ldots\ldots [14]$$

Cost on a Minimum Yearly Basis

One of the possible cost bases for pipe-line computation is minimum yearly cost, or that which gives the most economical gas transportation. The total yearly cost may be divided into fixed charges and operating expense.

Compressor Cost. The fixed charges on gas compressors may be formulated as follows: The initial installed cost of compressors is X dollars per horsepower. To pump Q cubic feet of gas per day for a distance of L miles requires aZ_2 brake horsepower per million cubic feet per day, where Z_2 is the deviation of the gas from the perfect-gas laws at the suction pressure, and a is the reference brake horsepower per million cubic feet of gas per day, dependent only upon the nature of the gas and the ratio of compression. The investment in compressors is then

$$X\left(\frac{Q_0Z_2}{L10^6}\right) \text{ dollars per mile}$$

The fixed charge on the compressors α includes interest on the capital investment, depreciation, taxes, insurance, etc. The yearly fixed charge on the compressors is then

$$\left(\frac{\alpha XQ_0Z_2}{L10^6}\right) \text{ dollars per year-mile}$$

Pipe Cost. The fixed charges on the pipe may be found from the pipe cost, Y dollars per ton, and the necessary W tons of pipe per mile. For steel pipe, $W = 28.2\,(D + t)t$, where D is the inside diameter of the pipe in inches, and t is the pipe-wall thickness in inches. The Barlow expression for wall thickness of pipe in terms of maximum pressure P, pounds per square inch, and maximum allowable stress, S pounds per square inch, is $t = \frac{P_1D}{2(S - P_1)}$. The direct pipe investment is then

$$YW = Y28.2\left[D + \frac{P_1D}{2(S - P_1)}\right]\left[\frac{P_1D}{2(S - P_1)}\right] \quad \ldots\ldots [15]$$

dollars per mile.

According to the A. O. Smith report (4), a good division of pipe-laying cost is H dollars per mile for right of way, surveying, clearing, supervision engineering, undistributed costs, and a part of ditching, painting, and cleaning expenses; G dollars per ton-mile for unloading, hauling, aligning, placing, and welding or coupling; and N dollars per mile per inch of diameter for ditching, painting, backfilling, and laying equipment.

The total pipe cost is then ($YW + H + GW + ND$) dollars per mile. At $B \times 100$ per cent fixed charges on the installed pipe (depreciation, taxes, insurance, interest on capital, salaries of pipe-line personnel, and all operating expenses chargeable to line maintenance), the fixed yearly charges on the installed pipe are

$$B(Y + G)(28.2)\left[D + \frac{P_1D}{2(S - P_1)}\right]\left[\frac{P_1D}{2(S - P_1)}\right] + BND + BH \quad \ldots\ldots [16]$$

Operating Expenses

The pipe-line operating expenses may be expressed as functions of the amount of gas transported, if average values of the individual items are considered. Labor, supervision, salaries, etc. amount to about $1750 per month for a 4000-hp compressor

station. Assuming direct proportionality for other stations of approximately the same size, this expense is

$$\frac{1750 \times 12}{4000}\left(\frac{QaZ^2}{L10^6}\right) = 5.25\left(\frac{QaZ_2}{L10^6}\right) \text{ dollars per year per mile.}$$

The average value of maintenance is \$0.50 per hp per year; lift water approximately \$0.20 per hp per year; and oil about \$0.84 per hp per year. The yearly cost of these items is then \$1.54 per hp per year per mile. About 10 standard cu ft of 1000 Btu fuel gas per bhp-hr are required by the gas compressors at a cost of Cf dollars per 1000 standard cu ft. The yearly fuel cost is then

$$\frac{10 \times 24 \times 360}{1000} Cf \frac{QaZ_2}{L10^6}$$

or

$$86.4\, Cf \frac{QaZ_2}{L10^6} \text{ dollars per year per mile.}$$

An allowance for gas lost from the pipe line may also be made, and for present purposes it will be taken as \$100 per year per mile. Taken in this manner, the loss figure has no effect on the design variables.

Upon adding all of the fixed and operating costs, the total yearly cost per mile

$$Cy = (\alpha X + 86.4Cf + 6.79)\frac{QaZ_2}{L10^6} + B(Y + G)(28.2)D^2 \left[\frac{P_1}{2(S - P_1)} + \frac{P_1^2}{4(S - P_1)^2}\right] + BND + BH + 100 \quad [17]$$

For convenience in manipulating any specific problem, let

$$K = (\alpha X + 86.4Cf + 6.79) \quad [18]$$

and

$$K_1 = 28.2B(Y + G) \quad [19]$$

Then

$$Cy = \frac{KQaZ_2}{L10^6} + K_1D^2\left[\frac{P_1}{2(S - P_1)} + \frac{P_1^2}{4(S - P_1)^2}\right] + BND + BH + 100 \quad [20]$$

A set of values of compressor suction pressure P_2, compressor discharge pressure P_1, pipe diameter D, and compressor-station spacing L, which makes the total yearly cost a minimum, must satisfy the requirement that the partial derivatives of the total yearly cost with respect to each of these variables must simultaneously equal zero. Proof that a set of values so found corresponds to minimum-cost conditions may be found by substitution of the set in the cost equation, comparing the total yearly cost with that resulting from any other set.

The term L may be eliminated from the yearly cost equation on replacing it by its value determined from the flow Equation [14]

$$\left(\frac{K_2}{Q}\right)^{1.85}\frac{D^{4.85}(P_1^2 - P_2^2)}{Z_{avg}} = L \quad [21]$$

The yearly cost equation then becomes

$$Cy = \frac{KQ^{2.85}Z_2aZ_{avg}}{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)} + K_1D^2\left[\frac{P_1}{2(S - P_1)} + \frac{P_1^2}{4(S - P_1)^2}\right] + BND + BH + 100 \quad [22]$$

The partial derivatives of Cy with respect to D, P_2, and P_1 are

$$\frac{\partial Cy}{\partial D} = \frac{-KQ^{2.85}Z_2aZ_{avg}\,4.85}{10^6K_2^{1.85}D^{5.85}(P_1^2 - P_2^2)} + 2K_1D\left[\frac{P_1}{2(S - P_1)} + \frac{P_1^2}{2(S - P_1)^2}\right] + BN \quad [23]$$

$$\frac{\partial Cy}{\partial P_2} = \frac{2KQ^{2.85}Z_2aZ_{avg}P_2}{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)^2} + \frac{KQ^{2.85}Z_2a}{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)}\frac{\partial Z_{avg}}{\partial P_2} + \frac{KQ^{2.85}Z_2Z_{avg}}{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)}\cdot\frac{\partial a}{\partial P_2} + \frac{KQ^{2.85}aZ_{avg}}{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)}\cdot\frac{\partial Z_2}{\partial P_2} \quad [24]$$

and

$$\frac{\partial Cy}{\partial P_1} = \frac{-2KQ^{2.85}Z_2aZ_{avg}P_1}{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)^2} + \frac{KQ^{2.85}Z_2Z_{avg}}{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)}\cdot\frac{\partial a}{\partial P_1} + \frac{KQ^{2.85}Z_2a}{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)}\frac{\partial Z_{avg}}{\partial P_1} + \frac{K_1D^2S^2}{2(S - P_1)^3} \quad [25]$$

Setting $\frac{\partial Cy}{\partial D}$ equal to zero, and multiplying all terms of the resulting equation by $\frac{D^{5.85}}{K_1\left[\frac{P_1}{S - P_1} + \frac{P_1^2}{2(S - P_1)^2}\right]}$ the first expression for minimum value of Cy is

$$D^{6.85} + \frac{BN}{K_1\left[\frac{P_1}{S - P_1} + \frac{P_1^2}{2(S - P_1)^2}\right]}D^{5.85} = \frac{4.85KQ^{2.85}Z_2aZ_{avg}}{10^6K_2^{1.85}(P_1^2 - P_2^2)K_1\left[\frac{P_1}{S - P_1} + \frac{P_1^2}{2(S - P_1)^2}\right]} \quad [26]$$

Equating $\frac{\partial Cy}{\partial P_2}$ to zero, and multiplying all terms of the resulting equation by $\frac{10^6K_2^{1.85}D^{4.85}(P_1^2 - P_2^2)}{KQ^{2.85}Z_2aZ_{avg}}$, the second expression for the minimum value of Cy is

$$\frac{2P_2}{P_1^2 - P_2^2} + \frac{\partial \ln Z_{avg}}{\partial P_2} + \frac{\partial \ln a}{\partial P_2} + \frac{\partial \ln Z_2}{\partial P_2} = 0 \quad [27]$$

Using the empirical relationship for methane gas

$$a = 56.8 \ln P_1/P_2 + 5.1 \quad [28]$$

and finding that $\frac{\partial \ln Z_{avg}}{\partial P_2}$ and $\frac{\partial \ln Z_2}{\partial P_2}$ are very small numbers from $P_2 = 0$ to $P_2 = 2000$ psi, Equation [24] reduces to

$$\ln [P_1/P_2] = \frac{1}{2}(P_1^2/P_2^2) - 0.5898, \text{ or } P_1/P_2 = 1.33 = Cr \quad [29]$$

Following the same method of approach, Equation [25] reduces to

$$\frac{-2}{P_1C} + \frac{56.8}{P_1a} + \frac{10^6K_2^{1.85}D^{6.85}S^2P_1^2CK_1}{2(S - P_1)^3KQ^{2.85}Z_2aZ_{avg}} = 0 \quad [30]$$

from which

$$P_1 = \frac{S}{1 + D^{2.283}\left(\frac{K_2^{1.85}S^2K_1}{KQ^{2.85}Z_2Z_{avg}}\right)^{1/3}} \quad (17.40) \quad \ldots\ldots [31]$$

Equations [26] and [31] may be solved simultaneously for P_1 and D by plotting P_1 versus D for both equations. The intersection of the two curves in the positive quadrant then yields the desired values of P_1 and D. As a convenience in evaluating D in Equation [20] for trial values of P_1 it may be considered to be of the form

$$D^{4.85} + mD^{4.85} = n$$

or preferably

$$D^{4.85} = \frac{n}{m + D}$$

Two or three trial values of D should then be sufficient to obtain the proper value of D.

The station spacing L may then be found from Equation [21], and the minimum total yearly cost then computed from the cost Equation [17].

It is obvious that there is but one such set of positive values of P_1, P_2, and D. The total cost Cy is either a maximum or minimum, and that this set corresponds to a minimum value of Cy may be seen from the total yearly cost Equation [20]. The value of Cy can be made larger than any previously assigned value by increasing suitably the numerical values for P_1 and D. Obviously, the maximum value of Cy is infinite, and the values

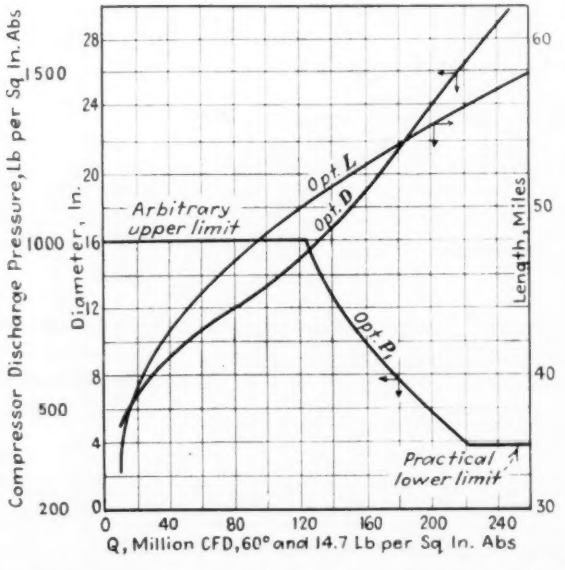

FIG. 1 OPTIMUM VALUES OF P, L, AND D FOR VALUES OF Q, BASED ON OPTIMUM COMPRESSION RATIO, Cr = 1.33 AND MINIMUM YEARLY COST

found from the partial derivatives must represent a minimum. The solution of Equation [26] for a range of values of P_1 and subsequent determination of Cy by means of Equation [22] as a function of P_1 is in many cases a more rapid and convenient method for determining the optimum operating conditions.

Using hypothetical values for material and labor costs which are approximately averaged over the country, but which do not represent any particular case, a set of optimum design conditions for the transportation of several different amounts of methane have been computed and plotted in Fig. 1. It may be seen that for quantities of methane up to approximately 100,000,000 cu ft per day, the optimum compressor-discharge pressure is over 1000 psi which was taken as an arbitrary limit. For greater gas quantities, the optimum compressor-discharge pressure decreases until, at approximately 220,000,000 cu ft per day, it is about 400 psi which was taken as an arbitrary lower limit. Both the optimum pipe diameter and compressor-station spacing increase with increasing gas quantities.

For methane at ordinary temperatures, the optimum compression ratio is not affected appreciably by deviation from the ideal gas laws, but for hydrocarbon gases which show greater deviations, the optimum compression ratio increases, the optimum operating pressures increase, and the optimum pipe diameter decreases.

COSTS ON A MINIMUM INITIAL BASIS

If minimum initial investment is taken as the goal for gas-pipeline design, the total investment may be computed from the yearly cost Equation [17] by omitting the yearly charges and the estimated loss figure. Thus

$$C_1 = \frac{XQZ_2a}{L10^6} + (Y + G)(28.2)D^2\left[\frac{P_1}{S - P_1} + \frac{P_1^2}{2(S - P_1)^2}\right] + ND + H \quad \ldots\ldots [32]$$

On setting $\frac{\partial C_1}{\partial P_2}$ equal to zero, the optimum compression ratio is found to be 1.33, identical with the first case considered when methane or an ideal gas is considered.

On setting $\frac{\partial C_1}{\partial D}$ equal to zero, the form of this equation is similar to that found before

$$D^{4.85} + \frac{N}{(Y + G)(28.2)\left[\frac{P_1}{S - P_1} + \frac{P_1^2}{2(S - P_1)^2}\right]} D^{4.85} = \frac{4.85 \times Q^{2.85}Z_2aZ_{avg}}{10^6K_2^{1.85}(P_1^2 - P_2^2)(Y + G)\left[\frac{P_1}{S - P_1} + \frac{P_1^2}{2(S - P_1)^2}\right](28.2)} \quad \ldots\ldots [33]$$

and may be solved in the same manner.

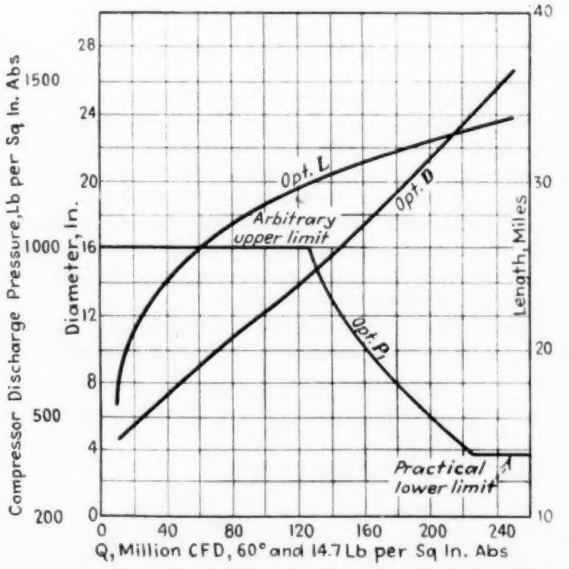

FIG. 2 OPTIMUM VALUES OF P, L, AND D FOR VALUES OF Q, BASED ON OPTIMUM COMPRESSION RATIO, Cr = 1.33, AND MINIMUM INITIAL COST

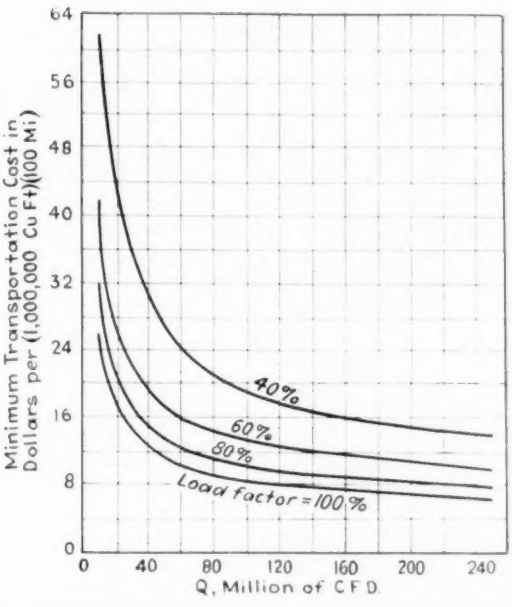

FIG. 3 MINIMUM TRANSPORTATION COST VERSUS DAILY QUANTITY TRANSPORTED, BASED UPON OPTIMUM CONDITIONS FOR MINIMUM YEARLY COST

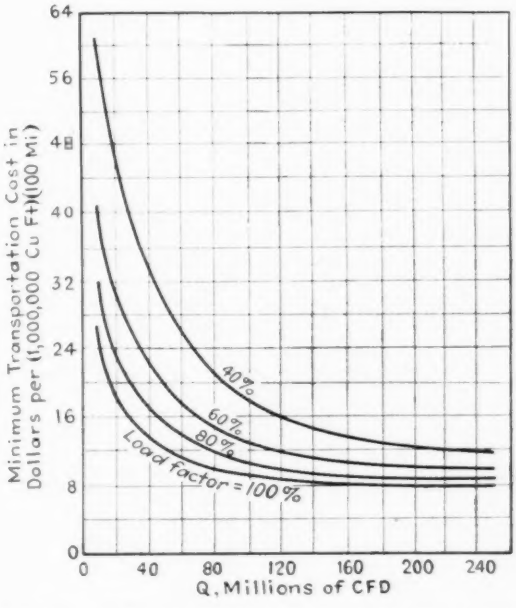

FIG. 4 MINIMUM TRANSPORTATION COST VERSUS DAILY QUANTITY TRANSPORTED, BASED UPON OPTIMUM CONDITIONS FOR MINIMUM INITIAL COST

The third defining equation for minimum initial investment, found by setting

$$\partial C_T/\partial P_1 = 0$$

becomes

$$P_1 = \frac{S}{1 + D^{3.283}\left(\frac{K_2^{1.85}S^2(Y+G)(28.2)}{XQ^{2.85}Z_1Z_{avg}}\right)^{1/3}(17.40)} \quad \ldots\ [34]$$

Simultaneously, Equations [33] and [34] may now be solved graphically for any value of Q. In most cases of practical interest, however, it is more practical and instructive to solve Equation [33] for a range of pressures, and to plot C_I from Equation [32] as a function of P_1 for the gas flow under consideration. The results of a series of such solutions are shown in Fig. 2, wherein L is computed from the flow equation as before. It may readily be seen that, although the optimum operating pressures have not changed appreciably, the best pipe diameters and station spacings are smaller than for the case when minimum yearly cost was the goal. Actually, the percentage of total capital invested in compressor stations has increased, and the portion of total capital invested in pipe has decreased compared to the first case. Obviously, the cost of transporting a given quantity of gas per year is greater than that in the first case studied.

The effect of load factor on transportation cost may readily be computed from the yearly cost Equation [17] by segregating the fixed and variable operating expenses, and introducing the term F, load factor, expressed as a decimal. The new total operating cost is equal to F (operating expense) + (fixed charges), and the cost of transporting any given quantity of gas in dollars per cubic foot is given by the equation

$$\text{Cost} = \frac{F\,(\text{Operating expense}) + (\text{fixed charges})}{FQ \times 365} \times \text{miles} \ldots [35]$$

The effect of load factor on the minimum transportation cost is shown in Fig. 3, and on the transportation cost for minimum initial investment in Fig. 4 for the cases already discussed.

GENERAL CONCLUSIONS

While no specific conclusions may be reached without the substitution of actual cost figures in the equations advanced, some generalizations may be made. The optimum compression ratio is entirely dependent upon the nature of the gas handled. This dependence is threefold, based upon the power necessary to compress a given standard volume of the gas, the manner in which the power changes with compression ratio, and, to a lesser extent, on the change in compressibility of the gas with suction pressure. The best operating pressure for the system is increased as the quantity of gas to be transported decreases, as the allowable pipe stress increases, and as the compressibility of the gas increases. Pipe diameter and station spacing are rather complex functions of all of the design conditions, increasing with an increase in the quantity of gas to be handled.

It must be emphasized that the numerical data represented by the curves in this paper are derived from purely hypothetical cost figures and do not necessarily represent conditions for any actual gas pipe line.

Limiting Isothermal Flow in Pipes

By R. C. BINDER,[1] LAFAYETTE, IND.

An explicit formulation is given for the limiting isothermal flow of a gas in a horizontal pipe. For isothermal flow, the ratio of critical pressure to initial pressure equals the initial Mach number times the square root of the ratio of specific heats. The critical-pressure ratio for isothermal flow is higher than that for adiabatic flow. Some comparisons are drawn between isothermal, adiabatic, and incompressible flow.

IN dealing with the general problem of the flow of gases through pipes, it is common to consider separately two cases, i.e., (1) adiabatic flow and (2) isothermal flow. Adiabatic flow has been detailed in the literature. Complete solutions, for example, can be found in the works of Stodola,[2] and Schüle.[3]

These solutions bring out some important differences between incompressible and compressible adiabatic flow. For one thing, expanding adiabatic flow is characterized by a limiting condition at which the fluid velocity equals the velocity of pressure propagation. The simple relations for incompressible flow do not indicate any limiting conditions. Limiting isothermal flow apparently has not received due and full recognition in the literature. The purpose of the present paper is to give a similar explicit formulation for isothermal flow, to detail limiting conditions, and to draw some comparisons between isothermal, adiabatic, and incompressible flow.

The following discussion will be confined to the flow in horizontal, constant-diameter pipes. It will be necessary to examine some basic relations first before investigating limiting conditions.

Basic Relations

The following nomenclature will be used:

- c = velocity of pressure propagation
- D = internal diameter of pipe
- f = pipe friction coefficient
- g = gravitational acceleration
- k = ratio of specific heat at constant pressure to specific heat at constant volume
- l = pipe length
- M = Mach's number, V/c
- p = absolute pressure at any point in pipe
- v = specific volume
- V = velocity of fluid

Let dl represent the length along a pipe of an infinitesimal element of fluid. The specific volume of the fluid in this element is v. The pressure drop across the element is dp and the velocity change is dV. The general energy equation, in differential form, can be written as

$$v\,dp + \frac{d}{2g}(V^2) + dh = 0$$

where dh is the lost head. The usual practice will be followed, in expressing the lost head in the form

$$dh = f\frac{V^2}{2gD}\,dl$$

The general energy equation can then be written as

$$\frac{2gv}{V^2}\,dp + \frac{2dV}{V} + \frac{f\,dl}{D} = 0 \quad \ldots\ldots\ldots\ldots [1]$$

For isothermal flow, the Reynolds number is constant along the pipe, and hence the friction factor is also constant. The equation of state gives the relation

$$\frac{dp}{p} = -\frac{dv}{v} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

The equation of continuity gives the relation

$$\frac{dV}{V} = \frac{dv}{v} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

Limiting Conditions

The velocity of pressure propagation c is given by the relation

$$c = \sqrt{kgRT} = \sqrt{kgpv}$$

where R is the gas constant, and T is the absolute temperature. For isothermal flow c is constant along the pipe.

Let the subscript 1 refer to inlet conditions, and the subscript 0 refer to limiting or critical conditions. For example, p_0 is the limiting pressure. As gas flows along the pipe, the pressure decreases below the inlet pressure p_1, and the velocity increases above V_1. The pressure in the constant-diameter pipe cannot drop below p_0.

Equations [1], [2], and [3] can be combined to give the form

$$\frac{gpv}{V^2}\left(\frac{dp}{p}\right) - \frac{dp}{p} + \frac{f\,dl}{2D} = 0 \quad \ldots\ldots\ldots\ldots [4]$$

Limiting conditions are reached at the end of the pipe when $f\,dl = 0$. For these conditions, Equation [4] shows that

$$\frac{gpv}{V_0^2} = 1$$

$$V_0 = \sqrt{gpv} = \sqrt{gRT} = \frac{c}{\sqrt{k}} \quad \ldots\ldots\ldots\ldots [5]$$

The maximum velocity that can be developed in the pipe is V_0; this velocity is less than the acoustic velocity.

Mach's number is a convenient parameter for studying compressible flow. Mach's number M is defined as the dimensionless ratio V/c. The ratio of inertia to elastic force is directly proportional to the square of Mach's number. Let M_1 represent the inlet Mach number.

The critical pressure ratio p_0/p_1 can be determined by using the equation of state, equation of continuity, and Equation [5] to give

Contributed by the Main Research Committee and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

$$\frac{p_0}{p_1} = \frac{v_1}{v_0} = \frac{V_1}{V_s} = \frac{V_1\sqrt{k}}{c} = \sqrt{k}\ M_1 \quad \ldots\ldots\ldots [6]$$

For isothermal flow the ratio of critical pressure to initial pressure equals the initial Mach's number times the square root of k.

Various investigators have shown that the critical-pressure ratio for adiabatic flow can be expressed in the form

$$\frac{p_0}{p_1} = M_1^2 \left\{ \left(\frac{k-1}{k+1} \right) \left[1 + \frac{2}{(k-1)M_1^2} \right] \right\}^{1/2} \quad \ldots\ldots\ldots [7]$$

The solid line in Fig. 1 is for isothermal flow, whereas the dotted line is for adiabatic flow. Fig. 1 and subsequent plots in this paper were drawn for a value of $k = 1.40$; $k = 1.40$ for air, carbon monoxide, hydrogen, and oxygen. Fig. 1 shows that the critical-pressure ratio for isothermal flow is higher than that for adiabatic flow.

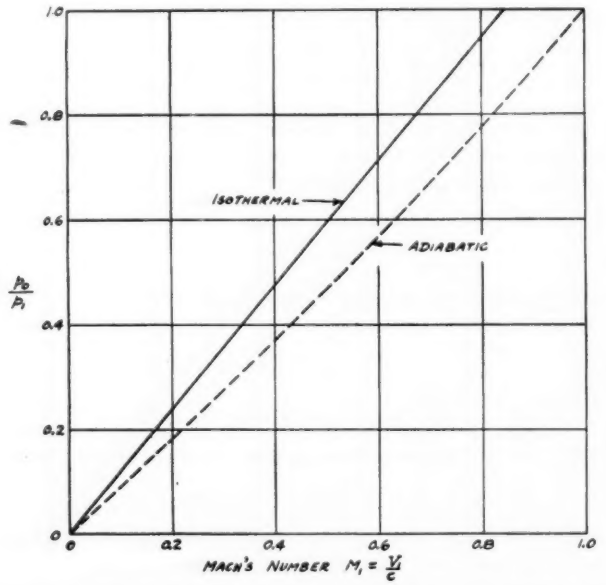

FIG. 1 LIMITING VALUES OF PRESSURE RATIO AS A FUNCTION OF MACH'S NUMBER, FOR GASES WITH $k = 1.40$

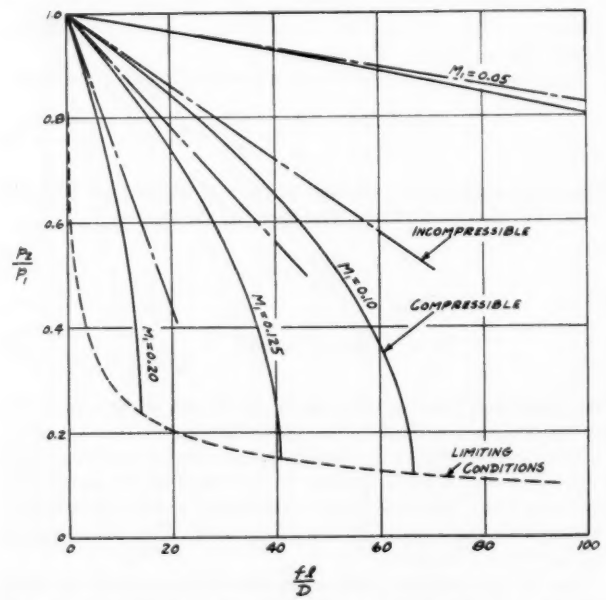

FIG. 2 VARIATION OF PRESSURE RATIO WITH fl/D AND MACH'S NUMBER FOR ISOTHERMAL FLOW, FOR GASES WITH $k = 1.40$

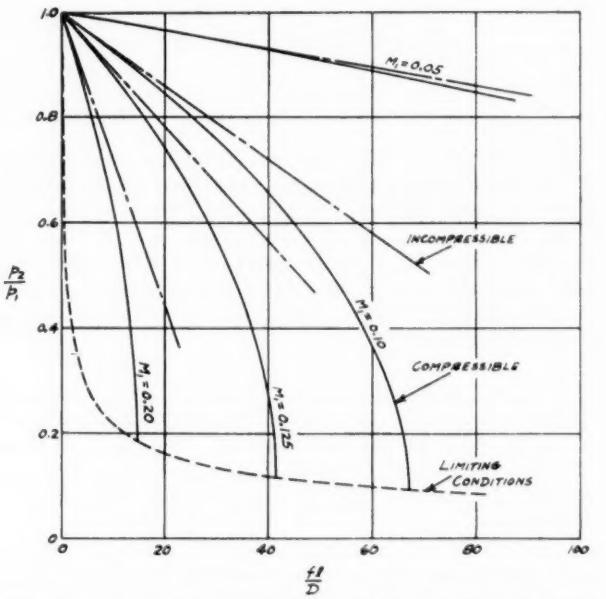

FIG. 3 VARIATION OF PRESSURE RATIO WITH fl/D AND MACH'S NUMBER FOR ADIABATIC FLOW, FOR GASES WITH $k = 1.40$

The continuity equation and the equation of state can be combined to put the first term of Equation [1] into a form convenient for integrating. The final result, after integrating, is

$$p_1^2 - p_2^2 = \frac{V_1^2 p_1}{g v_1} \left[2 \log_e \frac{V_2}{V_1} + \frac{fl}{D} \right] \quad \ldots\ldots\ldots [8]$$

where the subscript 2 refers to a condition for any length.

It is convenient to rearrange Equation [8] such that the dimensionless ratio fl/D is a function of k, the initial Mach number, and the pressure ratio. A regrouping of terms gives the form

$$\frac{fl}{D} = \frac{1}{kM_1^2} \left[1 - \left(\frac{p_2}{p_1} \right)^2 \right] - 2 \log_e \frac{p_1}{p_2} \quad \ldots\ldots\ldots [9]$$

Fig. 2 shows a plot of p_2/p_1 versus fl/D at several initial Mach numbers for isothermal flow. The dotted line in Fig. 2 represents limiting conditions. Fig. 3 shows the same type of plot for adiabatic flow. Except for a region close to limiting lengths, the solid curves in Fig. 2 are somewhat similar to those in Fig. 3.

COMPARISON BETWEEN INCOMPRESSIBLE FLOW AND COMPRESSIBLE FLOW

The relation for the flow of an incompressible fluid in a pipe is simpler than the relations for the flow of a compressible fluid. The question is frequently raised as to the limits of application of the incompressible-flow relations, and the possibility of using the incompressible-flow relation for studies of compressible flow. The question of application frequently depends upon the accuracy desired.

The pressure drop for the flow of an incompressible fluid in a horizontal pipe can be written as

$$p_1 - p_2 = \frac{flV_1^2}{2gDv_1}$$

$$\frac{p_2}{p_1} = 1 - \frac{k}{2} (M_1^2) \frac{fl}{D} \quad \ldots\ldots\ldots [10]$$

Equation [10] was employed to plot the straight dot-dash lines in Figs. 2 and 3. A comparison of a dot-dash line and a solid line, for the same M_1, brings out the differences between compressible and incompressible flow. Figs. 2 and 3 show that the difference between the incompressible and the compressible relations is not very great at low Mach numbers and short lengths. The difference becomes appreciable, however, at high Mach numbers and long lengths.

A more direct comparison between the two types of flow can be given by the type of plot shown in Fig. 4. Equations [9] and [10] were employed to plot the curves for the three initial Mach numbers. The difference between compressible and incompressible flow may be large. For example, the compressible-flow relation gives a pressure drop of $p_1 - p_2 = 0.6p_1$ for certain conditions with an initial Mach number of 0.30. The incompressible-flow relation for the same pipe length and same initial conditions gives a pressure drop of about $p_1 - p_2 = 0.305p_1$.

In some discussions of isothermal flow, the change in kinetic energy is considered negligible. The statement is sometimes made that, if the pipe is "long," the term $2 \log_e V_2/V_1$ is negligible in comparison with the term fl/D. If the change in kinetic energy is neglected, then Equation [8] takes the form

$$p_1^2 - p_2^2 = \frac{V_1^2 p_1}{g v_1} \frac{fl}{D} \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

Equations [10] and [11] can be written as

$$\text{Compressible flow} \left\{ \frac{p_1 - p_2}{p_1} = 1 - \sqrt{1 - \frac{flV_1^2}{gDp_1v_1}} \right.$$

$$= 1 - \sqrt{1 - 2B} \quad \ldots\ldots\ldots [12]$$

$$\text{Incompressible flow} \left\{ \frac{p_1 - p_2}{p_1} = \frac{flV_1^2}{2gDp_1v_1} = B \right. \quad \ldots\ldots [13]$$

where B represents the dimensionless ratio given in Equation [13]. Equations [12] and [13] can be compared for identical values of B. A graphical comparison is shown by the curve A in Fig. 4.

Sometimes the rule is given that the incompressible-flow relation can be used for isothermal compressible-flow problems if the pressure drop $p_1 - p_2$ is less than 10 per cent of the initial pressure p_1. Curve A illustrates the accuracy of this rule.

A comparison of curve A with the other solid curves in Fig. 4 shows the effect of the change in kinetic energy. There is a considerable difference between curve A and the curve for $M_1 = 0.20$, for example, at long lengths. For long lengths, it appears that the change in kinetic energy can be neglected only for low Mach numbers.

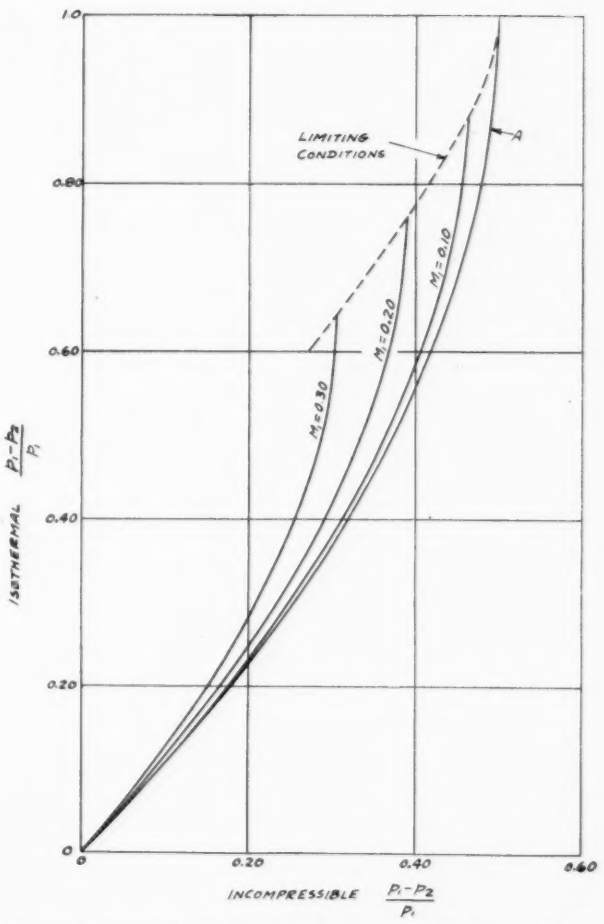

FIG. 4 PRESSURE-DROP RATIO FOR ISOTHERMAL FLOW AS A FUNCTION OF PRESSURE-DROP RATIO FOR INCOMPRESSIBLE FLOW

Application and Design of Package Conveyers

By H. C. KELLER,[1] SYRACUSE, N. Y.

Conveyers used for material handling are divided into two groups, namely, for bulk materials like ore, gravel, coal, ash, sand, and so on, and for unit loads such as cartons, boxes, barrels, sacked goods, tote boxes, etc. This paper will discuss the latter group, dealing with application and design. In giving the various formulas on design, certain liberties with theory are taken and short cuts are used, but all formulas have been checked and proved by actual performance.

Roller Conveyers

ROLLER conveyers, Figs. 1 and 2, consist of side rails in which rollers are mounted. The load then travels by gravity on the rollers or is propelled along the line of conveyer.

Application. The load to be conveyed must have a rigid riding surface in order to span the space between the rollers. Fragile loads should not be permitted to travel by gravity. The best results are obtained when the loads are constructed of similar materials and are approximately uniform in weight. Heavy loads (in excess of 100 lb) should not be allowed to travel by gravity, without first making a careful investigation of all conditions to be certain that no damage will result. Loads up to 40,000 lb have been handled on roller conveyers, but such loads should not be allowed to operate by gravity.

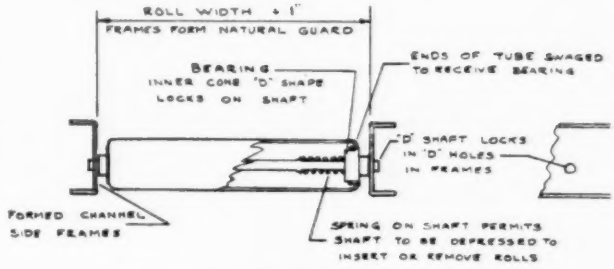

Fig. 1 Section Through Roller Conveyer

Design. The side rails are structural-steel members (usually angle or channel shapes), designed for maximum deflection of 0.33 in. in a 10-ft span.

The rollers are constructed of tubing with ball bearings adapted to the ends of the tubing. A shaft extends through the hubs of the bearings into the side rails. The tubing should be of sufficiently heavy gage to withstand damage due to impact of loads on the conveyer. The amount of impact is not always known,

Contributed by the Special Design Committee and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

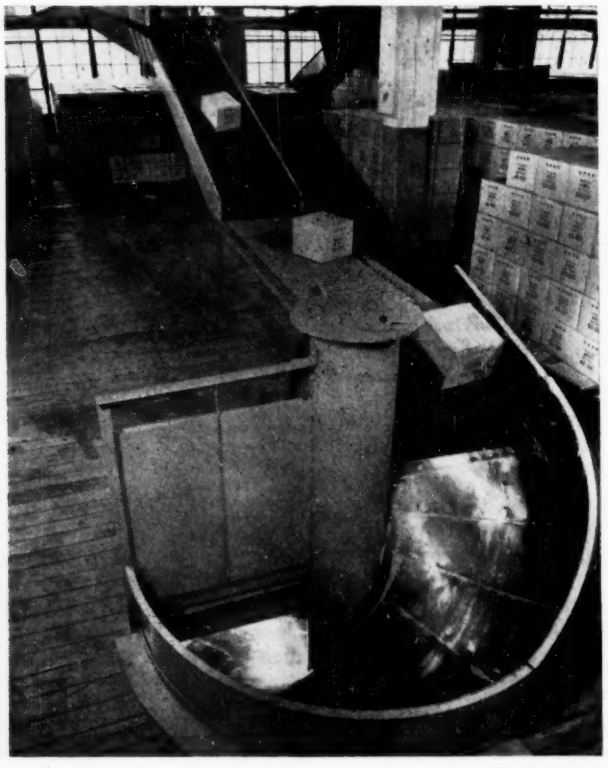

FIG. 3 STRAIGHT CHUTE RECEIVING LOADS FROM BELT CONVEYER AND LEADING TO A SPIRAL CHUTE
(S. C. Johnson & Son, Racine, Wis.)

and we must depend on past experience. The wall thicknesses, indicated in Table 1, have proved satisfactory.

In almost every case, the wall thickness is greater than required to make the tubing structurally as strong as the bearings and shaft.

The shafts are designed so that they lock in the side rails, and the inner races of the bearings are in turn locked to the shaft. This prevents the bearing from turning on the shaft, and the shaft from turning in the side rails.

Generally the ball bearings are of the open free-running type, but frequently wet, dirty, or acid conditions require a grease-packed ball bearing. These latter bearings are sometimes equipped with grease fittings so that the grease can be replenished.

As the bearings are mounted in the ends of the rolls and the bearings are always adjacent to side rails, the capacity of the roll is not materially decreased as the length increases.

There should always be at least three rolls under the load, and the spacing of rolls in the frame is determined by the formula

$$\text{Maximum spacing} = \frac{\text{Minimum length of load}}{3}$$

The grade at which the conveyer is set depends upon the weight of the load and the type of riding surface. The type of bearing used in the roll also affects the grade. As each manufacturer has his own standard diameter of roll, thickness of tubing wall (affecting the dead weight), type of bearing, and so on, it is impossible to establish gradients for the entire line of roller conveyers. Generally, a grade of $^1/_2$ in. per ft will be satisfactory for cartons; $^3/_8$ in. per ft for steel tote boxes or hardwood boxes weighing between 15 and 75 lb. On hard-bottom loads, the grade is reduced as the weight increases, and this is also true for some cartons, but in the latter case only to the point where the weight does not cause the bottom of the carton to drape over the rolls.

STEEL CHUTES

Description. These chutes, Fig. 3, are made straight, curved, and helical (better known as "spiral chutes").

The straight chute consists of a bedplate and two side plates or guards.

The curved chute consists of a bedplate with outer and inner guard plates.

The spiral chute is usually built around a center core with a bedplate and outer guard plate.

Application. As all chutes are used only to guide loads from an upper level to a lower point, they should not be used when there is great variation in weight; when the weight is over 300 lb, or for fragile loads. The spiral chute offers some opportunity for control of speed by varying the shape of the bed and the pitch and is therefore preferred in most cases to straight chutes.

Atmospheric conditions also affect the operation of chutes, especially when cartons or sacked goods are being conveyed. This type of conveyer very seldom gives satisfactory service where there is likely to be great variation in the humidity of the surrounding air.

Design. Table 2 gives the gages of metal usually used in chutes. Straight chutes are frequently made by bending up side guards from the bedplate, in which case the gage specified for the bed is the one to use.

TABLE 2 METAL GAGES FOR CHUTES

Type of load	Straight chute		Curved chute		Spiral chute	
	Bed	Guard	Bed	Guard	Bed	Guard
Cartons or sacks..	14	16	14	14	14	14
Wood boxes.....	14	14	14 to 12	14 to 12	12	12
Wire-bound boxes or steel pans....	12	14	12	12	10	10

Under average conditions, straight chutes are declined at a 20-deg angle for cartons, 18 deg for wood boxes, and 15 to 17 deg

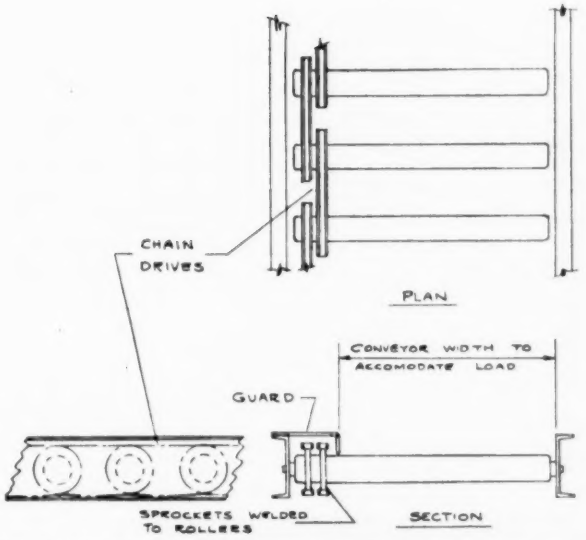

FIG. 4 MULTIPLE-STRAND, CHAIN-DRIVEN, LIVE-ROLL CONVEYER

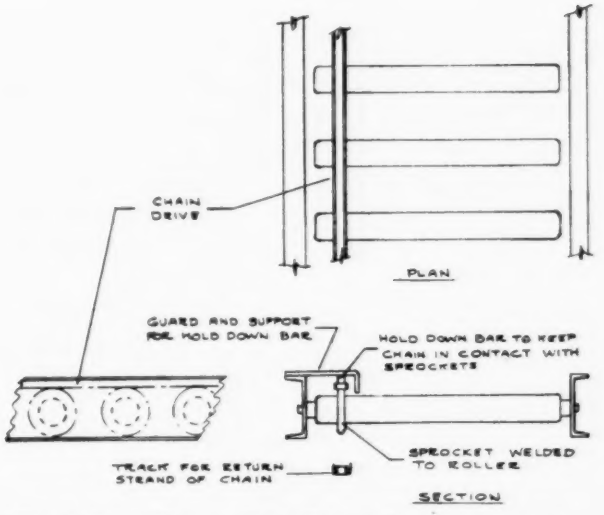

FIG. 5 SINGLE-STRAND, CHAIN-DRIVEN, LIVE-ROLL CONVEYER

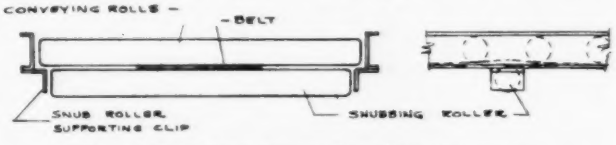

FIG. 6 FLAT-BELT-DRIVEN LIVE-ROLL CONVEYER

for steel pans. On curved and spiral chutes the angle at the outer guard rail is the same as the angle of decline specified for straight chutes. The height of the side guards on straight chutes should be no less than one third the height of the highest load. On curved and spiral chutes, the outer guard rail should be somewhat higher than the greatest height of the load. The height of the guard is measured at right angles to the bed.

LIVE-ROLL CONVEYERS

Description. This type of conveyer, Figs. 4 to 7, employs the use of roller-conveyer sections with various means used to power the rolls. Flat belts or round belts are snubbed against the underside of the rolls by means of snubbing rolls or sheaves, placed between the carrying rolls. The flat-belt type is used when the conveyer is straight and the round belt when there are curves in the conveyer. Another type of live-roll conveyer employs roller-chain drives over sprockets fitted to the roll shafts. In this case the roll and shaft are made integral and the shaft operates in bearings built into or mounted on the side rails. In other types of chain-driven conveyers, the sprockets are welded to the roll tubes, and the conventional roll with bearings adapted to the ends of tubing are used.

Application. As in the case of roller conveyers, the load must have a rigid riding surface but unlike the roller conveyer any variation in weight of the various loads is not important. Fragile loads should not be conveyed if the conveyer is to be used for storage, as blocking these loads will damage them.

Design. In addition to the features given for the roller conveyer, we must consider the matter of power required to operate the conveyer.

To determine the horsepower required to operate horizontal live-roll conveyers, the percentages of friction, given in Table 3, should be used.

TABLE 3 PERCENTAGE OF FRICTION IN LIVE-ROLL CONVEYERS

Type of conveyer	Weight of load, lb	Friction, per cent
Belt-driven.....	Up to 75	6
Belt-driven.....	Over 75	10
Chain-driven.....	Unlimited	5

The percentages, given in Table 3, are based on antifriction bearings. Also, it may be advisable to explain why different frictions are given for belt-driven live-roll conveyers. The belting on this type of conveyer should never be snubbed more than just enough to propel the loads. It naturally follows that greater snubbing action is necessary as the weight of the load increases.

FIG. 7 LIVE-ROLL CONVEYER DRIVEN BY ROUND BELT SHOWN OVER ROLLER CONVEYERS
(Norwich Pharmacal Company, Norwich, N. Y.)

The horsepower required at the head shaft of belt-driven conveyers is

$$\text{Hp} = \frac{(W + w) \cdot f \cdot S}{33{,}000}$$

where W = weight of live load on conveyer, lb
w = weight of all rolls and belting, lb
f = friction given in Table 3
S = speed of conveyer, fpm

In the chain-driven type of conveyer, one design consists of a

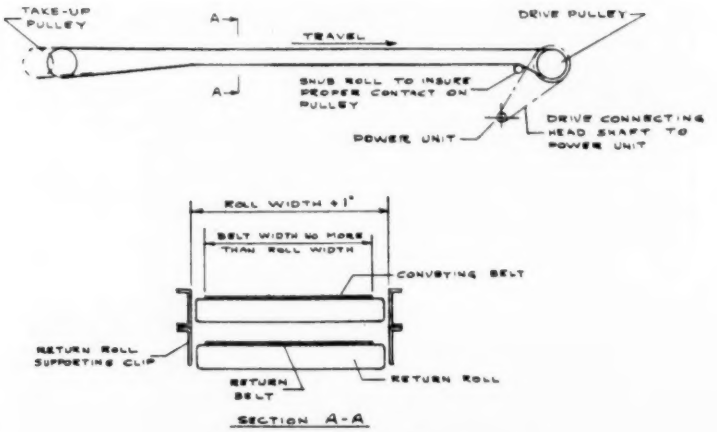

FIG. 8 TYPICAL BELT CONVEYER

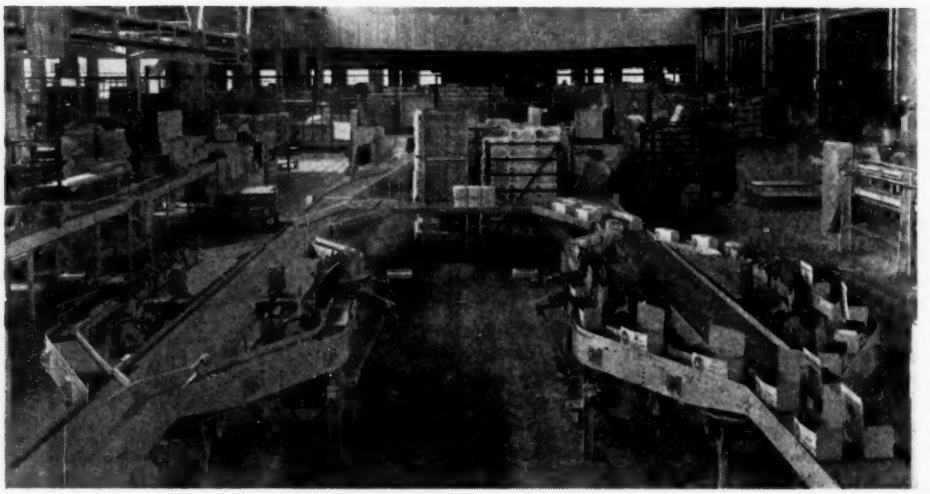

FIG. 9 TYPICAL BELT-CONVEYER INSTALLATION

(This shows two main-line belts bringing filled cartons from a packing table. Each belt carries a double line of cartons which are deflected to spur sidings where the cartons pass through closers and convey back into one line; the cartons now deflect to a table as shown for loading to trucks, or they may pass the deflector and deliver to the bundling conveyer.)

single strand of chain, while in another, multiple strands of chain are used. In the latter case two sprockets are employed on each roll and a complete drive is used from one roll to the next roll. The single strand of chain allows only a tangential contact with the sprocket and should only be used on light-duty conveyers. The multiple-strand design permits full 180-deg contact on each sprocket.

On single-straight-chain conveyers, the horsepower formula given for belt-driven conveyers can be used by changing the value of w. In this case, w = weight of rolls, sprockets, and chain.

On multiple-strand-chain-driven conveyers, the effective pull on each drive must be figured progressively, allowing 98 per cent efficiency for each chain drive.

BELT CONVEYERS

Description. Belt conveyers, Figs. 8 to 10, also employ roller-conveyer sections with belting supported by the rolls. In another type, the belting is supported by a steel or wood bed over which the belting slides.

Application. As the load is supported directly on the belting, almost any type of unit load can be conveyed on this conveyer. Unit loads weighing in excess of 50 lb per sq ft should not be con-

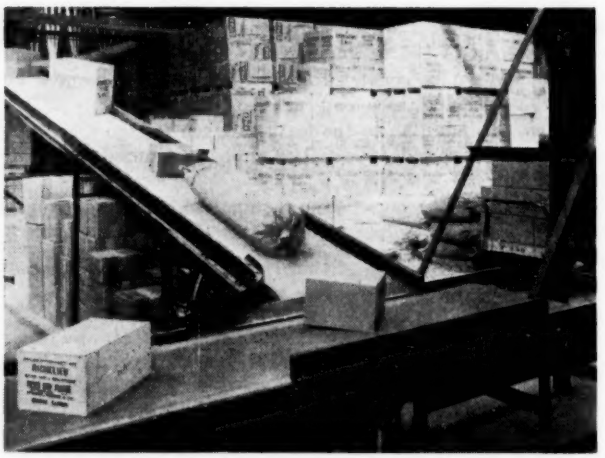

FIG. 10 HORIZONTAL AND DECLINED BELT CONVEYERS
(Sprague Warner)

veyed on the slider-bed type of construction, as excess weight causes the belting to seize to the bed of the conveyer.

Design. When the roller type of intermediate support is used, the spacing of the rolls on the load-carrying bed is determined by the length and weight of the load. When extremely light loads are to be conveyed rolls can be spaced 24 in. and in some cases 36 in. on centers. Heavier unit loads such as cartons, boxes, and so on, require roll spacing no greater than $^1/_2$ the length of the shortest load. The return belt on either type of conveyer is supported by rolls usually spaced no more than 10 ft on centers.

The horsepower required at the head shaft of horizontal belt conveyers is

$$\text{Hp} = \frac{(W + w) \cdot f \cdot S}{33{,}000}$$

where W = weight of live load on conveyer, lb
w = weight of rolls and belting, lb
f = friction given in Table 4
S = speed of conveyer, fpm

TABLE 4 PERCENTAGE OF FRICTION OF BELTING ON ROLLER AND SLIDER BEDS

Type of bed	Cotton or untreated-canvas belting, per cent	Rubber-impregnated canvas belting, per cent
Roller	3 to 5	3 to 5
Steel slider	20	21
Wood slider	22	30

There are numerous types of belting, each best suited for specific operating conditions. A complete study and analysis is impossible in this paper, but, generally, the cotton and untreated-canvas belt should be used where atmospheric conditions are fairly constant, as is the case in most indoor installations. The rubber-impregnated belt is used where there is great variation in humidity, and, in many cases where the belting is exposed directly to the elements, completely rubber-covered belting should be used. The latter belting is never used on slider-bed types of conveyers.

Belt conveyers can be inclined to elevate or to lower loads. Correction for the horsepower due to the incline must be made, and the conveying run of belting must be calculated independently of the return run. In elevating conveyers, the horsepower at the head shaft is

$$\text{Hp} = \frac{[0.05\ r + L \sin\theta + fL \cos\theta + 0.05\ l \cos\theta - l \sin\theta] \cdot S}{33{,}000}$$

where r = weight of all rollers, lb
L = weight of upper run of belting and live load, lb
l = weight of return run of belting, lb
θ = angle of incline, deg
f = friction given in Table 4
S = speed of conveyer, fpm

When the conveyer is used to lower loads the formula becomes

$$\text{Hp} = \frac{[0.05\ r + l \sin\theta + fL \cos\theta + 0.05\ l \cos\theta - L \sin\theta] \cdot S}{33{,}000}$$

It is frequently found that this formula gives a minus value, but it must be considered the same as a plus value in order to obtain the required strength in the drive gearing to hold back the load and prevent the conveyer from running away.

Another way of expressing the head-shaft horsepower is to substitute the term "effective pull" for all load factors in the preceding formulas

$$\text{Hp} = \frac{\text{Effective pull} \times \text{speed}}{33{,}000}$$

The effective pull permits us to determine other factors, such as total load on the head shaft, and the stress in the belting. The tension in the tight side of the belting at the head pulley is expressed as T_1 while the tension in the slack side is expressed as T_2. Table 5 gives the values of T_1 and T_2 for the most common conditions.

TABLE 5 TENSION IN BELTING AT HEAD PULLEY

Amount of wrap on pulley, deg	T_1	T_2
180	1.64	0.638
200	1.54	0.541
210	1.50	0.500
220	1.46	0.462
230	1.43	0.428

To obtain the maximum stress in the belting, multiply the effective pull by the proper factor for T_1. The maximum load on the head shaft is the sum of the effective pull multiplied by the factor T_1 plus the effective pull multiplied by factor T_2.

A take-up pulley is provided in the conveyer to compensate for stretch in the belting. The take-up is usually made by screw adjustment. The amount of adjustment varies with the type of belting. Canvas belting requires a take-up adjustment of 1 per cent of the length of the conveyer. Rubber belting requires approximately one half the adjustment provided for canvas belting.

Automatic weighted take-up pulleys are used on long conveyers and sometimes on shorter conveyers when there is a wide range in surrounding air temperature and humidity. The weight required to operate this type of take-up is twice the value of T_2 or

$$\text{Weight} = 2 \times \text{effective pull} \times \text{factor } T_2$$

If the conveyer is to be reversed to convey loads in opposite direction at different times, the weight should be twice T_1 or

$$\text{Weight} = 2 \times \text{effective pull} \times \text{factor } T_1$$

Slat Conveyers

Description. Slat conveyers, Figs. 11 to 13, are constructed with wood or steel slats (pallets) fastened to attachments on two strands of roller chain, which in turn travel in or on structural-steel tracks.

Application. This type of conveyer is used when the character of the load is such that it would damage the belting on belt conveyers or does not have a riding surface adaptable to travel on live-roll conveyers.

Design. The slats, Fig. 12, are designed as a simple beam supported at either end. The width of each slat is somewhat less than the pitch of the chain, i.e., about $3^1/_2$ in. wide for a 4-in-pitch chain, $5^1/_2$ in. wide for a 6-in-pitch chain, etc.

Wood slats are usually standard commercial sizes, as 2 in. × 4 in., 2 in. × 6 in., etc., dressed on all four sides.

Steel slats may be flat bar, with or without reinforcing members, formed or rolled channel shapes, etc.

When plain rollers are used in the chain, the tracks are structural angles or channels. On heavy-duty conveyers, a flanged roller is used in the chain, and standard rail sections are then used for the tracks.

The horsepower required at the head shaft of a horizontal slat conveyer is

$$\text{Hp} = \frac{(W + w) \cdot f \cdot S}{33{,}000}$$

where W = weight of live load on conveyer, lb
w = weight of chains and slats, lb
f = friction as given in Table 6
S = speed of conveyer, fpm

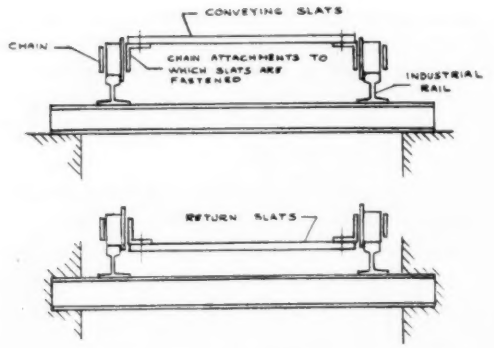

FIG. 11 SECTION THROUGH SLAT CONVEYER
(Showing construction using flanged rollers in chain.)

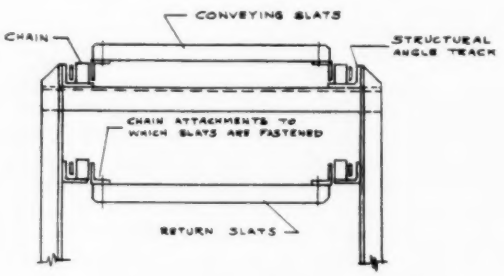

FIG. 12 SECTION THROUGH SLAT CONVEYER
(Showing construction using plain or straight rollers in chain.

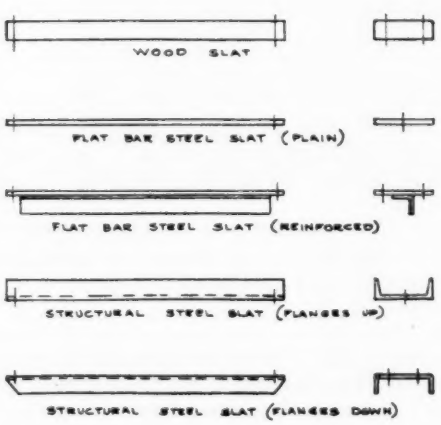

FIG 13 SOME OF THE MORE POPULAR FORMS OF SLATS

where L = weight of upper run of chains, slats and live load, lb
l = weight of return run of chains, and slats, lb
θ = angle of incline, deg
f = friction given in Table 6
S = speed of conveyer, fpm

and when loads are to be lowered

$$\text{Hp} = \frac{[l \sin \theta + f(L + l) \cos \theta - L \sin \theta] \cdot S}{33{,}000}$$

In the latter case, any minus value must be treated as a plus value as explained for belt conveyers.

Take-ups are provided to compensate for stretch in the chains. On this type of conveyer, the adjustment is of the screw type. The amount of adjustment is only enough to permit a chain link to be readily removed and has no relation to the length of the conveyer.

APRON CONVEYERS

Description. The apron conveyer, Fig. 14, is a modification of the slat conveyer in which the aprons or slats form a continuous bed. The aprons overlap one another and in some cases sides are provided so that the bed of the conveyer presents a continuous trough.

Application. This conveyer is seldom used in package conveying. It is employed only when small loads are to be conveyed and where the spaces between the slats on a slat conveyer would be objectionable.

Design. Refer to "Slat Conveyers," substituting the weight of aprons for slats in the horsepower formulas.

DRAG-CHAIN CONVEYERS

Description. In this type of conveyer, Figs. 15 and 16, single or multiple strands of chain slide in steel tracks conveying the load directly on the chain.

Application. Single-strand chains are employed successfully when a uniform-size load is to be conveyed, and multiple strands when loads vary in size. This type of conveyer can negotiate 90-deg corners very readily with most loads. It is particularly adaptable to bottling houses, dairies, and breweries where the loads generally are uniform in size and weight.

Design. Refer to "Slat Conveyers," substituting the weight of the chain only for chains and slats in the horsepower formulas, and use a sliding friction of 30 per cent for the chain on the steel track.

When horizontal turns are employed, the effective pull of each section must be figured progressively.

The turns are usually designed so that the chain is guided in a steel track. Wheels or rollers may be used to reduce the friction loss at the turns, but it is very difficult to make an economical design because of the necessity of clearing the load resting directly on the chain.

FIG. 14 DETAIL OF APRON CONVEYER

TABLE 6 PERCENTAGE FRICTION OF CHAINS ON STEEL TRACKS

Diameter of roller in chain, in.	1 1/2	2	2 1/2	3
Friction, per cent	20	20	15	12

The horsepower for inclined conveyers elevating loads is

$$\text{Hp} = \frac{[L \sin \theta + f(L + l) \cos \theta - l \sin \theta]S}{33{,}000}$$

OVERHEAD CHAIN CONVEYERS

Description. Overhead chain conveyers, Figs. 17 to 19, consist of a two-plane flexible chain supported from an overhead track by means of trolleys. Various types of attachments, from which the loads are suspended, are spaced on the chain. Frequently, cars or carriers are suspended from the attachments and the loads are then placed directly on the cars.

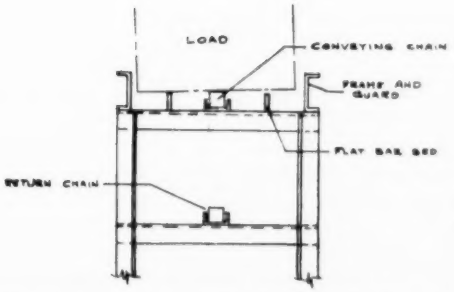

FIG. 15 SECTION THROUGH DRAG-CHAIN CONVEYER

FIG. 16 DRAG-CHAIN CONVEYER WITH PUSHERS AUTOMATICALLY CONVERGING LOADS FROM TWO LINES TO A SINGLE LINE OF ROLLER CONVEYER
(Pepsi-Cola, Long Island City, N. Y.)

Application. Almost any type of load can be conveyed by this conveyer. The conveyer is extremely flexible; loads may be deposited on the cars or hooked to the chain attachments at any working height, the load then being elevated to the ceiling or floors above for transportation and again brought down to a working height for unloading at the next operation. The conveyer makes an ideal storage unit or traveling stock pile as any load not removed at a station will recirculate and keep returning to that station until the operator is ready to take it off and perform his work. The floor between operations is kept clear for other work and the otherwise wasted space at the ceiling is utilized to good purpose.

Design. The most common types of conveyer are the 3-in. and 4-in. sizes. These sizes indicate the size of I-beam track used. Two-wheel trolleys, operating in the I-beam, support the chain, and the load attachments are usually arranged directly below the trolley so that the pull is on the trolley, the chain then becoming the propelling means for advancing the trolleys and loads along the path of the track.

Horizontal turns are made in two types, the multiple-roller curve and the traction wheel. The roller type is more generally

FIG. 17 OVERHEAD CHAIN CONVEYER TOWING TRUCKS

FIG. 18 TYPICAL LOADING-STATION DIP ON OVERHEAD CHAIN CONVEYER
(Glen L. Martin, Baltimore, Md.)

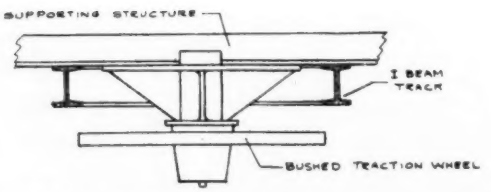

FIG. 19 TRACTION WHEEL FOR OVERHEAD CHAIN CONVEYER

used because of its lower frictional resistance and its adaptability to large radii. When the turn is to operate in high temperatures (over 400 F), the traction wheel should be used, as it is provided with a special bushing and a large oil reservoir supplying ample lubrication.

The drives are made in two types, the corner-sprocket drive and the caterpillar drive. The corner-sprocket drive is used when conditions permit, and the caterpillar drive where the radius of the corner is too large for sprocket drives. The drive should be placed at the point of maximum pull and, preferably, near a down curve so that any slack in the chain will automatically be taken away from the drive. Drives should never be placed inside oven or spray-booth enclosures.

Take-ups are usually provided to permit removal of links when slack in chain becomes excessive. Take-ups may be omitted on long conveyers or those with several dips where links may be removed from the chain without the necessity of adjusting a sprocket or corner. Take-ups should always be provided on conveyers subjected to great temperature changes. In this latter case, the track should also be provided with expansion joints based upon a coefficient of 0.0000065 per unit length per deg F.

Radii of vertical bends or dips should be as large as practical for smooth operation.

The technical data, given in Table 7, will be helpful in designing the conveyer.

TABLE 7 DESIGN DATA FOR OVERHEAD CHAIN CONVEYERS

	Size of system	
	3 in.	4 in.
Chain:		
Pitch	3.031	4.031
Weight per foot, lb	2.25	3.125
Ultimate strength, lb	18,000	30,000

Trolley spacing, minimum radius	30 in.–10 ft	32 in.–12 ft
Trolley spacing, minimum radius	24 in.– 8 ft	24 in.–10 ft
Trolley spacing, minimum radius	18 in.– 6 ft	16 in.– 8 ft
Trolley spacing, minimum radius	12 in.– 5 ft	...

To determine the horsepower at the head shaft, the formula is

$$\text{Hp} = \frac{W \cdot f \cdot S}{33{,}000}$$

where W = weight of chain, trolleys, cars, and live load, lb
f = friction, depending upon type of bearing in trolley
S = speed of conveyer, fpm

When the conveyer has small dips or vertical bends, they usually balance, and there is no appreciable extra pull in the chain. If, however, the inclines are long, the extra pull must be added to the calculation, and the horsepower formula then becomes

$$\text{Hp} = \frac{(W \cdot f + L \sin \theta) \cdot S}{33{,}000}$$

where L = live load on incline, lb
θ = angle of incline, deg

When the conveyer has more than four horizontal turns, the pull on the chain must be calculated for each section progressively, adding 5 per cent friction loss for each turn.

VERTICAL CONVEYERS

There are numerous types of vertical conveyers (Fig. 20 is an example). There are special applications of vertical belt conveyers and vertical slat conveyers. In both cases, cars or shelves are attached to the belt or slats and the loads then placed on these shelves.

Other continuous-operating vertical conveyers employ single or double strands of chain, attached to which are rigid or pendant cars. The loads sometimes are placed on and taken off the cars manually. The cars can be designed with fingers or arms that pass through corresponding fingers on stations so that loads are deposited automatically on and off the cars. The fingers of the stations may be constructed of rollers so that loads travel automatically into or out of the path of the cars. The station fingers may also be narrow belt conveyers, slat conveyers, drag chains; in fact any type of powered conveyer.

Vertical conveyers may also be of the reciprocating type where a single car delivers the load to another station and then returns to the sending station to receive another load.

There are unlimited combinations and designs of vertical conveyers, and it would be impossible to describe in detail even a few of the more popular types in this paper.

SPECIAL CONVEYERS

There are a great many special conveyers which are really modifications of the more standardized types of conveyers discussed in

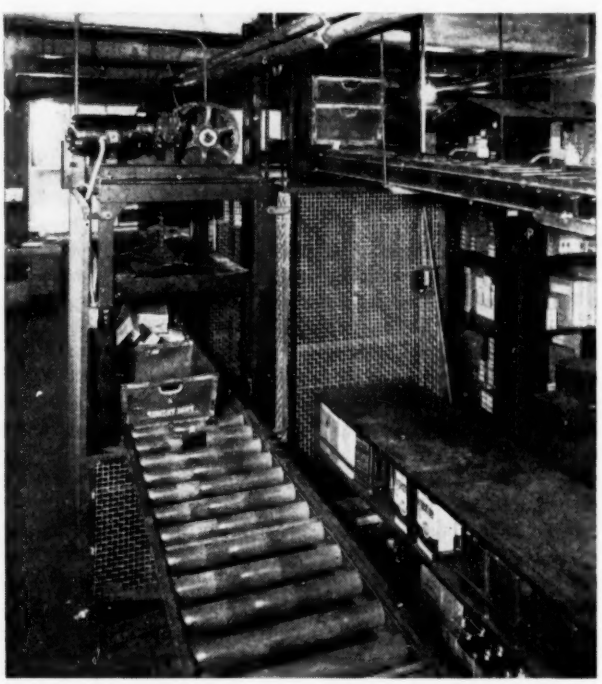

FIG. 20 RECIPROCATING-TYPE VERTICAL CONVEYERS, ILLUSTRATING TYPICAL AUTOMATIC LOADING AND UNLOADING STATIONS
(W. T. Gilmore Drug Company, Pittsburgh, Pa.)

this paper. There is one possible exception and that is the pusher-bar conveyers. This conveyer consists of two strands of chain with a bar extending between the chains. These bars push the load over a steel slider bed, a wood slider bed, or a roller bed. The pusher-bar conveyer at one time was very popular (it is still used extensively in bottling houses), but inclined belt conveyers are rapidly replacing the pusher-bar type of booster.

Automatic conveyers are frequently designed to pick up loads and discharge them at predetermined points. One design of fully automatic conveyer consists of a vertical conveyer with automatic loading and unloading stations. In this installation, an operator places a load on the loading-station platform and sets a dial indicating the station to which the load is dispatched. When an empty car approaches, it operates the loading station which places the load onto the car and sets a mechanism on the car. When that car reaches the designated unloading station (and that station is empty and ready to receive a load), the station picks the load off the car and deposits it on the unloading-station platform.

Another example of fully automatic conveyer consists of an overhead chain conveyer with reciprocating type of vertical conveyers, loading and unloading the cars on the overhead conveyer. In this installation, the loads are placed on the vertical-conveyer car near the floor level. When an empty car on the overhead conveyer approaches, the vertical conveyer elevates the load and deposits it on the car on the overhead conveyer. The overhead conveyer then delivers the load to another part of the building, or to another building, where a vertical conveyer removes the load and lowers it to a station near the floor level.

Pneumatic tubes are also used to convey unit loads, but the application and design features are too complex to be discussed in this paper.

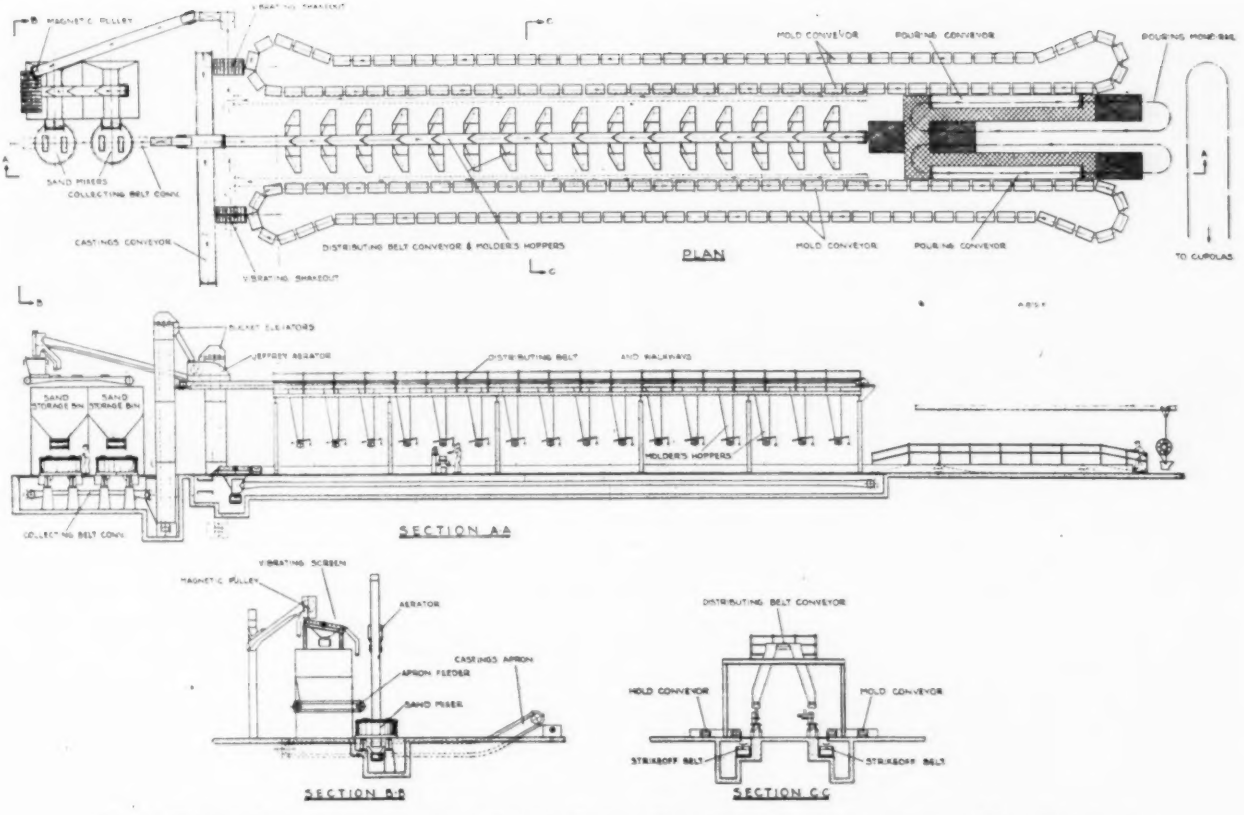

FIG. 1 TYPICAL LAYOUT OF A CONTINUOUS POURING SYSTEM, USING CONTINUOUS-POWER-DRIVEN MOLD CONVEYERS

Design Features of Conveying Equipment for the Foundry Industry

BY F. B. HENRY AND G. N. WILEMAN,[1] COLUMBUS, OHIO

The design of conveying equipment used in the foundry industry is covered in its general applications, with consideration given to the design of some of the more important details. Emphasis has been placed on equipment used in the handling of sand, molds, and castings, since they offer the major opportunities for economies and savings in manufacturing costs.

CONVEYING equipment for the foundry industry embodies conveyers and elevators handling practically all materials in the foundry, from raw materials to finished product. Raw materials, such as limestone, coke, sand, clay, pig iron, and so on, are handled mechanically from railroad cars to the point of usage.

Sand used in the molding process is handled mechanically from the shakeout through the reconditioning process back to the molding stations.

Molds, after being made (except in the case of very large castings) are handled mechanically from the pouring and cooling stations to the shakeout. Flasks are commonly returned from the shakeout to molders by means of conveyers.

Cores used in making the molds are handled on conveyers from coremakers through the baking process, and frequently distributed to the molders.

Castings from the shakeout are often handled by conveyer through the cooling step to the cleaning room, and, in the case of production castings, are handled through the cleaning process on conveyers. Remelt at times is also returned to the melting operation by means of conveyers.

From the foregoing, it can be seen that conveying equipment plays a vital part in the operation of a modern foundry, and a conveying system often represents the largest equipment investment in the plant.

A few general rules should be kept in mind when designing equipment for any foundry. These are as follows:

1 Due to the extremely abrasive nature of foundry sand

[1] The Jeffrey Manufacturing Company.

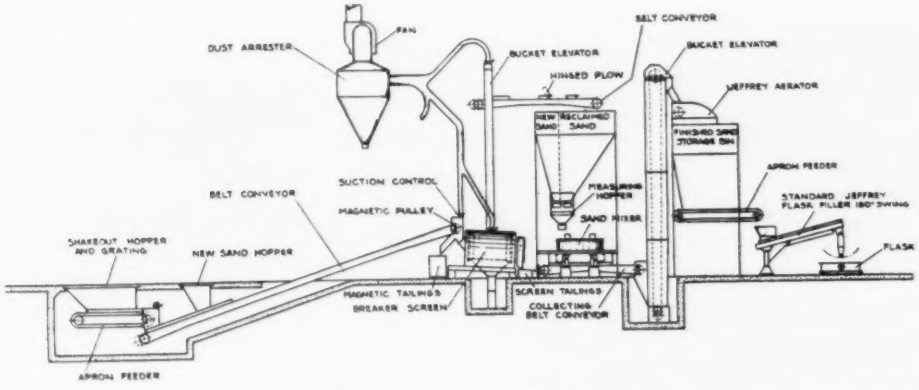

FIG. 5 TYPICAL LAYOUT OF STEEL FOUNDRY

and dust, friction parts should be entirely enclosed if possible, particularly those parts having high loads. This practically eliminates, or keeps to a minimum, all sliding types of conveyers.

2 Generous space should be provided in pits and walkways for proper maintenance and inspection.

3 Points in the system where dry sand is transferred from one conveyer to another, or from conveyer to bins, should have properly designed chutes and hoods for removal of dust, steam, smoke, and gases. Individual installations should be designed to meet state law requirements.

4 Chutes and hoppers handling prepared or damp sand should have angles of at least 60 deg, rounded corners, and generous cleanout doors.

TYPICAL ARRANGEMENTS FOR MECHANIZED FOUNDRIES

Before considering the individual types of conveyers used in the various applications, and their design features, it may be well to consider some typical layouts used in different types of mechanized foundries.

Layout of Typical High-Production, Continuous, Gray-Iron Foundry (Figs. 1 and 2). This arrangement lends itself to any foundry—steel, gray iron, malleable iron, aluminum, or magnesium—having high production of duplicate castings, with continuous hot metal available. Sand is prepared in the mixers, aerated, and distributed to the molders' hoppers at each molding station. After the mold is completed, it is placed on the mold conveyer for pouring, cooling, and conveying to the shakeout station. Sand passes through the shakeout machines, is screened, and conveyed to the storage bin for another cycle. The castings are collected from the ends of the shakeout machines and conveyed to the cleaning room.

Layout of Typical Gray-Iron or Brass Foundry; Noncontinuous (Figs. 3 and 4). This arrangement is applicable to any type of foundry having relatively small work and allows sufficient storage of molds to take care of intermittent metal supply. While this layout shows a paddle mixer in the sand plant, the muller type could be substituted if the sand required it. After mixing, the sand is distributed to the molders. Finished molds are stored on a roller conveyer for pouring and cooling. A car or conveyer will transfer the molds to the shakeout station, from which the sand is returned to the storage bin, while the castings may be put into boxes or conveyed directly to the cleaning room.

Layout of Typical Steel-Foundry System (Figs. 5 and 6). Steel foundries may use conveyers for handling molds from the molder to the shakeout, depending upon the class of work. Sand from the shakeout passes over a magnetic pulley, through a breaker screen to reduce lumps and remove refuse, then to the sand bins

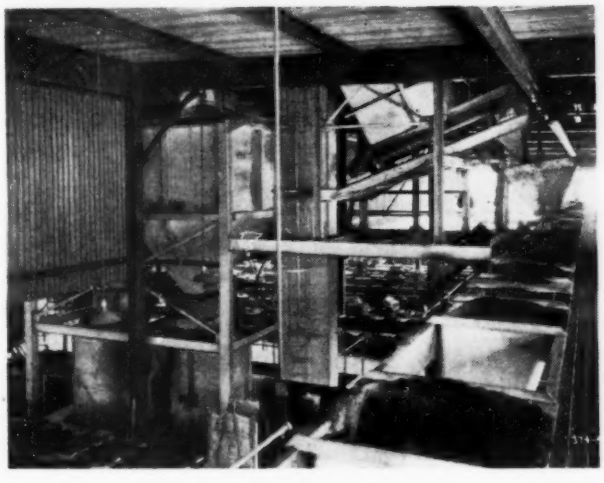

FIG. 6 STEEL FOUNDRY WITH TRAMRAIL DISTRIBUTING SYSTEM

and mixers. Prepared sand is distributed by conveyer or bucket to the molding stations. In the case of large molds these are frequently hoppers fitted with feeders for filling the flasks.

TYPES OF CONVEYERS USED

Following is a detailed discussion of various types of conveyers used in the typical systems described:

Shakeout (Figs. 7 and 8). The mechanical shakeout is now very widely used in all types of foundries and is available for molds from small snap molds, weighing possibly 100 lb, to very large molds weighing as much as 50 tons. They consist fundamentally of a vibrating perforated deck or grid on which the mold is placed, the sand falling through the grid to the conveying means underneath, with the flask and casting remaining on the grid or being discharged from one end. Large molds are frequently stripped before being shaken out. Supports for shakeout machines must be extremely heavy and rugged.

Feeder Under Shakeout. Means must be provided for conveying the sand from the hopper underneath the shakeout machine. This hopper is always designed to contain at least the total amount of sand in the largest mold being handled. This sand frequently is very hot and may contain considerable metallic refuse, such as gaggers and rods, as well as fins, sprues, and so on, which may be broken from the casting in the shakeout process. There are three types of conveyers used for feeding the sand from the shakeout:

(*a*) A belt feeder, Fig. 9, is sometimes used in cases where the castings are very light and the sand does not contain any ma-

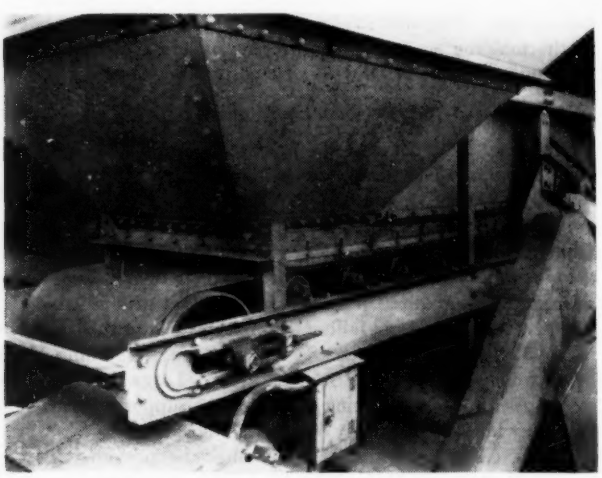

FIG. 9 BELT FEEDER UNDER SHAKEOUT

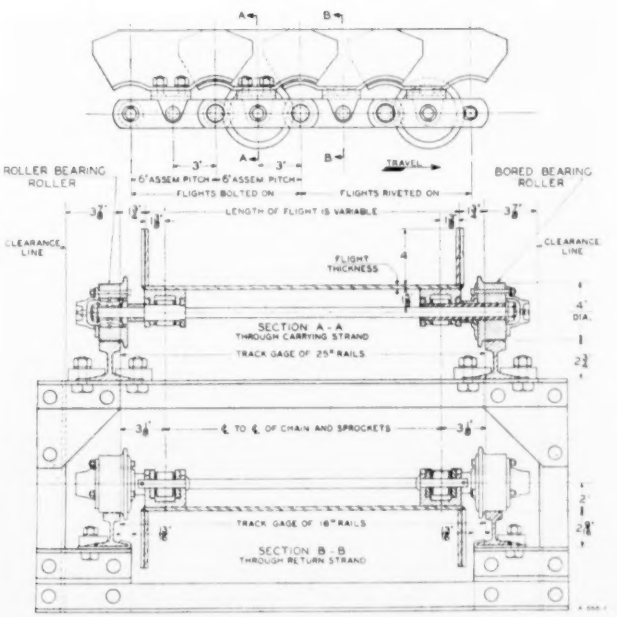

FIG. 10 CROSS SECTION OF APRON FEEDER

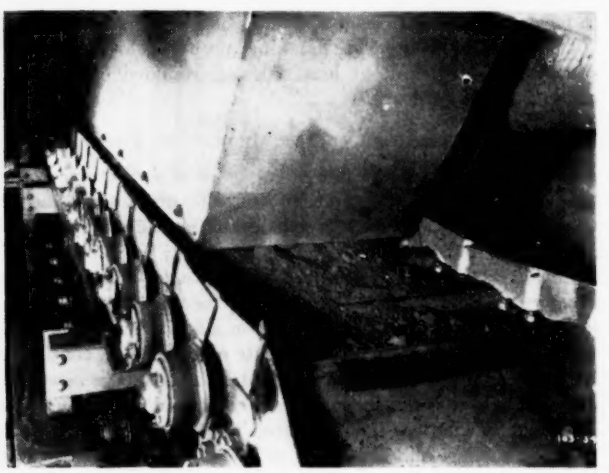

FIG. 11 APRON FEEDER UNDER SHAKEOUT

terial amount of metallic refuse such as in a foundry making very light iron or brass castings. Closely spaced idlers or flat steel plate are required under the load.

(*b*) Apron feeders, Figs. 10 and 11, are commonly used for this service and where used should be of the leakproof type, with a tight-fitting enclosed outboard roller. Pans have welded ends to prevent leakage of dry sand and are removable from the conveyer without dismantling the chain. The drive should be protected by a shear pin or similar device. While the apron will stand heat in a satisfactory manner, damage frequently results to the pans from gaggers or rods which get through the shakeout grating.

(*c*) During the last few years, the electric vibrating feeder, Fig. 12, has come into wide usage in this application. It offers a perfectly smooth deck with no obstructions for rods or gaggers; it can stand the heat without injury, and is free from dribble since it has no return run.

Belt Conveyer Having Magnetic Pulley (Fig. 13). In the usual installation, sand is fed from the shakeout hopper to a belt conveyer equipped with a magnetic head pulley, for removal of magnetic refuse such as gaggers, rods, nails, sprues, shot, and so on. This is important for various reasons. It is essential that foreign material be removed to prevent injury to some of the other parts of the equipment. Gaggers and rods are salvaged for re-use. Sprues, shot, and other parts of the casting metal

are returned for remelt. Rubber belt is used when the sand is comparatively cool, with heat-resisting, impregnated-fabric belts for hot sands. Belt-conveyer idlers should have a high-pressure type of lubrication which forces out the old grease. Closely spaced idlers or a plate should be placed under the loading point of the conveyer to take the load.

A short belt with a magnetic pulley may be applied over the main belt for picking off large pieces of metallic material.

Screens (Figs. 14 to 16). Screens may be either of the rotary type or of the vibrating type and are used principally to get rid of nonmagnetic refuse such as wood wedges, tiles and rags, etc. Rotary-type screens are ordinarily used where heavy work is encountered, as they have a very definite lump-breaking and sand-cooling action. Vibrating screens are used where very fine sand is required, such as, in foundries making small castings. It is the usual practice to provide hoods and air suction on these screens for the removal of dust, fines, steam, etc.

Bucket Elevators. Bucket elevators used in the foundry industry are almost always of the centrifugal-discharge belt-and-bucket type, although chain elevators are used infrequently. Malleable buckets are universally used. Foot pulleys are of the slatted type with internal cones so that sand falling inside the belt will not build up on the foot pulley. Boots should have large and readily accessible cleanout doors.

Main Storage Bins (Figs. 17 and 18). Design of the storage bins depends upon the particular application and the method of feeding the sand from them to the mixers. The tendency in modern installations is to make them relatively large in capacity. In continuous systems, a minimum of 2 hr supply of sand is ordinarily used. Storage bins are often designed to include, in addition to the main compartment for old sand, one or more compartments for new sand or binders. Bins having apron feeders should be fitted with regulating baffles to insure a uniform sand withdrawal along the entire length of the bin.

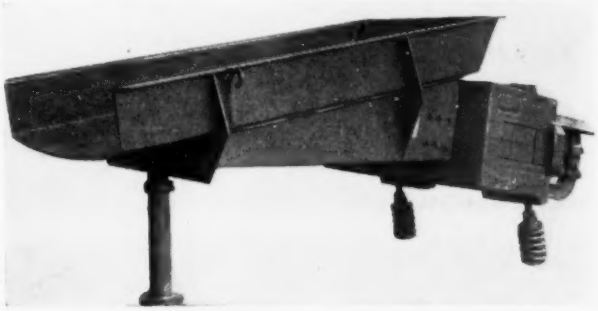

FIG. 12 VIBRATING FEEDER FOR USE UNDER SHAKEOUT

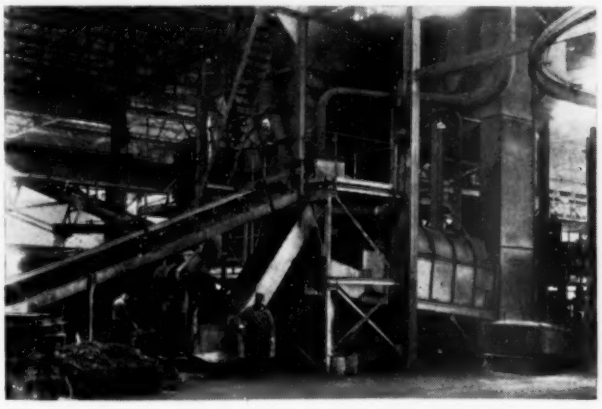

FIG. 13 SHAKEOUT BELT CONVEYER HAVING MAGNETIC HEAD PULLEY

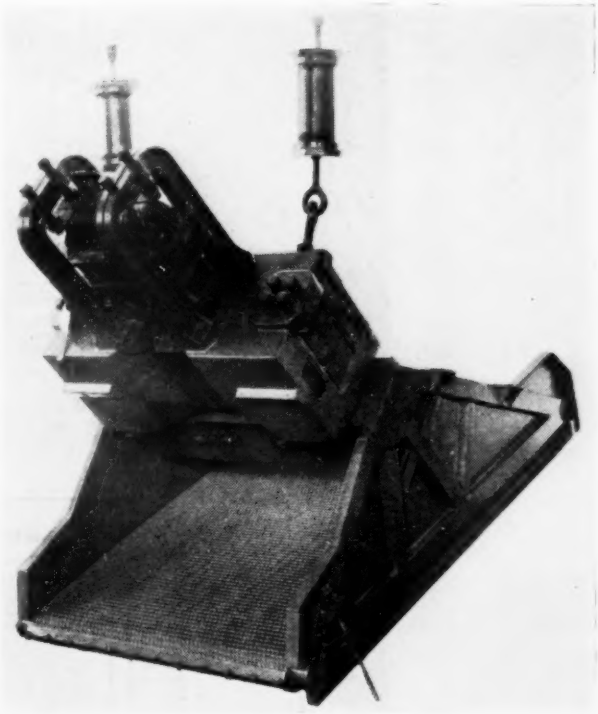

FIG. 14 VIBRATING SCREEN

Feeders From Storage Bins to Sand Mixers. There are two common methods of feeding the sand from the main storage bin to the sand mixers, either with gates and measuring hoppers, or apron feeders.

If muller-type mixers are used, the sand must be batched in suitable quantities. One method is the use of volumetric batch hoppers or of weigh hoppers, the batch hopper or weigh hopper containing the proper charge for the mixer. Weigh hoppers have the advantage of being able to properly proportion shakeout sand and new sand. The storage bins used with this type of batch method are gravity-type bins, provided with clamshell valves for feeding the batch hoppers which, in turn, are discharged by clamshell valves into the mills. With this type of bin it is best practice to divide the bin into two compartments, with two discharge valves, to prevent piping of the sand down through the center of the bin, Fig. 19.

The other method frequently employed uses apron-type feeders for charging the batch-type mixers. The feeders are arranged with either a limit switch, or timer so as to operate for a certain number of seconds to give the proper charge. This feeding arrangement will allow for more economical design of bin and one which is much lower in height, Fig. 20.

Paddle mixers use the continuous-moving-apron feeder almost exclusively. Vibrating feeders or small screw conveyers are used for feeding binders to the mixers, Fig. 21.

Sand Mixers. Sand mixers used are either of the paddle-mixer type or of the muller type. Paddle mixers are continuous mixers which give satisfactory results on natural sands. The muller-type mixers are batch mixers and are always used when synthetic sands are being made.

Aerators (Figs. 22 and 23). Aerators are used between the mixers and the distribution system on practically all installations.

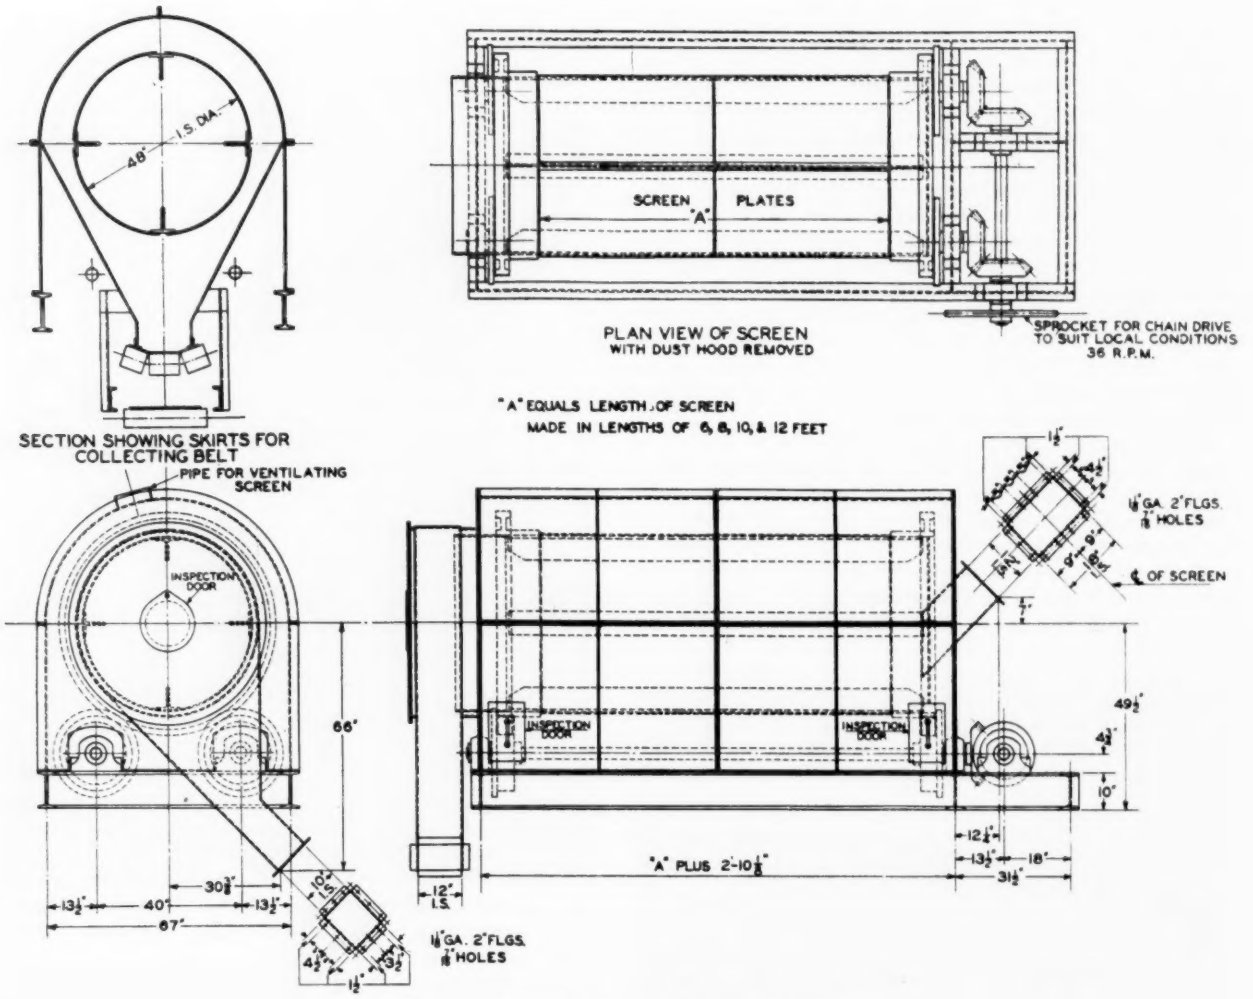

FIG. 16 DETAILS OF ROTARY BREAKER SCREEN

They are used for the final mixing and aeration of the prepared sand, before it is delivered to the molders.

Distributing System. Flat-belt conveyers with plows are most commonly used for distributing the prepared sand to the molders' hoppers. The belt is supported on flat idlers between the plows and on a flat plate directly under the plows. Plows are usually hinged, employing some simple mechanism for raising or lowering by hand. The part riding the belt should be edged with rubber to prevent injury. Belt cleaners should be installed at the head of this as well as any other belt handling prepared sand, Fig. 24.

In occasional installations, scraper-type conveyers are used. These scraper-type conveyers have the advantage that they will continuously and automatically fill the molders' hoppers. When one becomes full sand is scraped into next hopper, Fig. 25.

Hoppers for Molders. Hoppers and bins at the molding stations should be as small as practical. They usually contain from $1^1/_2$ to 2 tons of sand for smaller-size molds. They are designed with two vertical sides and with corners rounded to at least 3 in. radius. Clamshell valves are used for discharging the sand from the hopper to the mold. Quite frequently air cylniders are used for operating the valves, Fig. 26.

Where large molds are being made, it is necessary to provide a larger hopper, and in such cases the bottom of the hopper is fitted with an apron feeder for dragging the sand from the hopper into the flask, Fig. 27. Occasionally a swivel belt is employed between the end of the apron and the molding station. This allows the one hopper and feeder to service several molders, Fig. 28.

When facing sand is handled over the conveyer system, hoppers are provided on the floor, with shovelout openings. These hoppers are filled by separate plows and chutes from the distributing belt. In some few cases facing sand is stored in hoppers with feeders adjacent to the backing sand hopper, Fig. 29.

Mold Conveyers. Layouts for continuous pouring will ordinarily utilize continuous-type mold conveyers for receiving the molds at the molding stations and conveying them through the pouring stations to the shakeout. They must be designed so that sufficient cooling time is available from the pouring station to the shakeout. This may vary from as little as 5 min. for very light castings to ½ to 1 hr for larger molds. Air-cylinder pushers are frequently used to push the mold onto the shakeout. The use of a mold conveyer permits the molder to devote practically all of his time to molding, instead of using part of it for carrying out molds to the floor, Figs. 30, 31, and 32.

Where the pouring is not continuous, roller-type-conveyer layouts are used for handling the molds from the molders to the pouring station. This type of layout is also used where large numbers of alloys are encountered, so that the various types can be segregated for pouring, Fig. 33.

Pouring Conveyers. When continuous-mold conveyers are used and the speed exceeds about 15 fpm, moving pouring platforms are used. These operate in time with the mold conveyer so that the men pouring the metal can stand on this moving platform without any relative motion between the mold being poured and the ladle. These are apron-type conveyers with flat tops, Fig. 34.

Hot-Castings Conveyers. From the shakeout, it is necessary to take away the castings, and, in the case of smaller castings, this is frequently done with an apron-type hot-castings conveyer, Fig. 35. When used for this service, the apron should be of the leakproof type so that sand from the cores, etc., will not be spilled, but will discharge over the head with the castings, at one point. For heavier castings, such as cylinder blocks, the overhead-trolley-type conveyer is frequently used, Fig. 36, the castings being hooked on the trolley conveyer at the shakeout and frequently carried a considerable distance for cooling purposes.

Flask-Return Conveyers. Flasks must also be returned from the shakeout to the molders, and, in the case of smaller work, either the roller-type conveyer, Fig. 37, or the overhead-trolley conveyer, Fig. 38, may be used.

Sand Reclamation. Sand-reclamation systems have been introduced quite recently, and at the present time are occupying a prominent place in the plans for foundry improvements. As the name implies, they are systems for reclaiming sand which has outlived its usefulness and by special cleaning methods is returned to the foundry. The finished product compares very favorably with new sand, at considerably less cost. It also eliminates one of the present foundry problems, i.e., what to do with the spent sand.

Miscellaneous Conveyers. In modern installations, there is an increasing use of mechanical sand-unloading equipment. When dry sand is used, coming into the plant in boxcars, the power shovel has frequent application, Figs. 39 and 40. This power shovel may discharge into the bucket elevator, which will elevate the sand to the raw-storage bins. When the sand comes in hopper-bottom cars, it is common to use a track hopper with apron feeder to the elevating unit.

Concrete silos, either of the stave or monolithic type, are coming into wide usage for the storing of foundry sands, Fig. 41.

Several types of skip hoists have been used successfully for charging the cupolas in iron foundries.

Some of the larger steel foundries have used car hauls for handling the charging buggies to and from the open-hearth furnaces.

Coke and limestone have been handled from railroad car through track hopper, feeder, elevator, and belt conveyers to bulk storage.

The handling of bonding materials covers a wide range, going

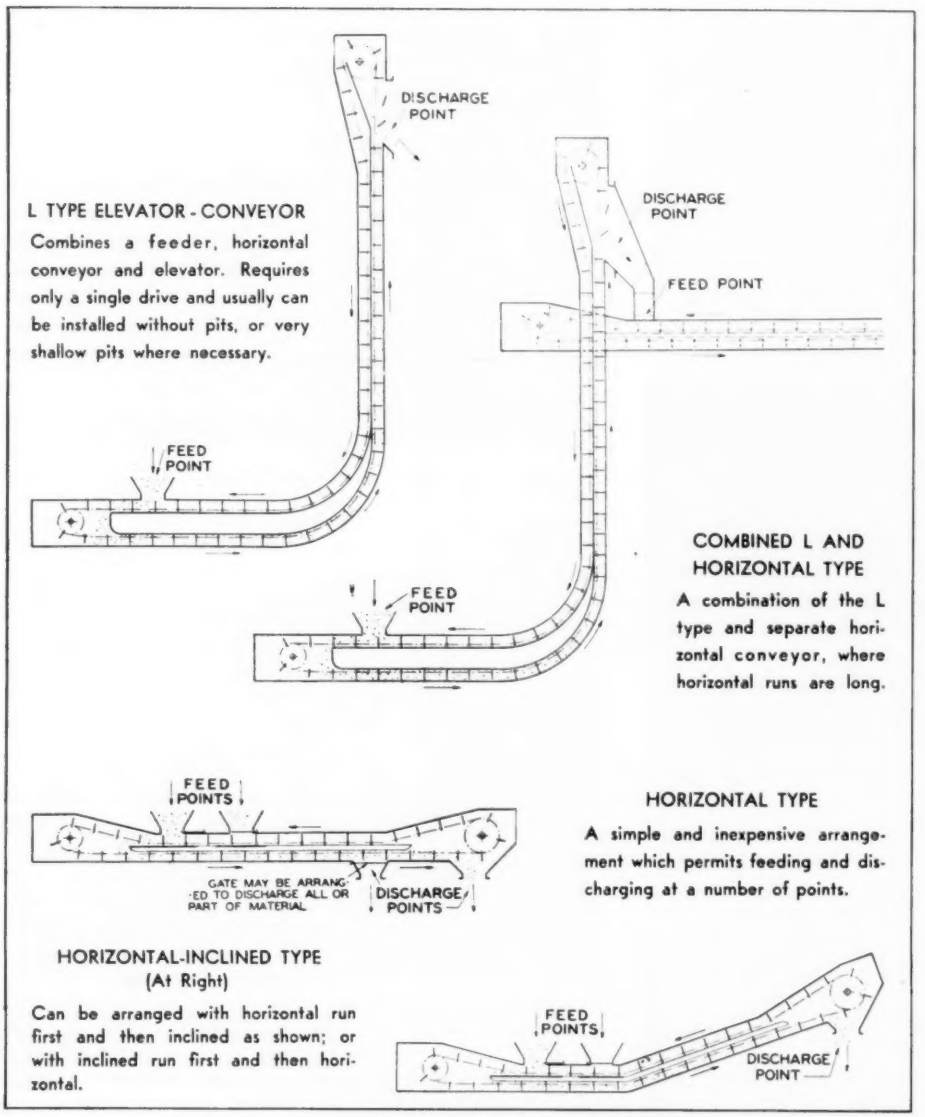

FIG. 42 BULK-HANDLING CONVEYERS FOR BONDING MATERIAL

from entirely manual operations to complete mechanization. They can be successfully handled from railroad cars through small track hoppers and bulk-handling conveyers, Fig. 42, to storage silos. From the silos, they are handled through the same type conveyer or screw conveyers to storage hoppers at the mixing stations. Small screw or electric-vibrating feeders can be

(*Continued at top of right-hand column*)

timed to feed out prearranged proportions direct to the mixers on continuous types, or into weigh hoppers on batching types of mixers.

Several types of pig-mold conveyers have been developed for the nonferrous foundries for pigging the virgin metal and also the remelt, Fig. 43.

CONCLUSION

In conclusion, it is quite evident that conveying equipment for the foundry, regardless of the type, has been developed to a high degree, with individual units designed for particular requirements. The proper layout and selection of equipment results in material reduction in the pound price of castings produced. This is accomplished in several ways, i.e., by increasing the output of the molders, reduction of labor, greatly increasing production with no increase in building space, reduction of scrap losses through better control of sand characteristics, and providing better working conditions for employees. Conditions caused by the war have influenced the installations in recent years. A manpower shortage has required that machinery be employed to the greatest possible degree. This has resulted in better working conditions, which have reacted favorably to the mechanized foundry. Foundries so equipped have a material advantage in the competitive market which will probably develop after the war.

FIG. 43 PIG-MOLD CONVEYER FOR MAGNESIUM, USING APRON CONVEYER TO ELEVATE PIGS TO BOXES

Discussion

W. S. Giele.[2] Materials handling in foundry operations is characterized, first, by its relative magnitude. Conditions of foundry operation vary so widely that exact data on any particular operation would have little application in other operations.

It may be said, however, that the total weight of material passing over the shakeout may easily be 20 times the net weight of castings finally shipped. In other words, the shipment of each 100 lb of castings may involve the handling of a ton of material at the shakeout, and every pound of that ton will have been handled several times before it gets to the shakeout.

Materials handling in foundry operations is further characterized by the abrasive nature of the materials handled and by the high temperatures frequently encountered.

The authors have referred to the application of high-pressure-type lubrication to belt-conveyer idlers in order that new lubricant may force out the old and the abrasive grit with it. Where feasible, it is believed to be desirable to go a step further by installing a centralized lubrication system, piped to the various bearings, in order to eliminate the introduction of the abrasive dirt that accumulates on the high-pressure fittings.

It is, of course, advantageous to keep speeds low and to operate with a minimum of lubrication. Ball and roller bearings in conveyer rolls often last longer when run dry than when lubricated, in foundry applications. Impregnated bushings of wood or of metal often give good service in the foundry. Powdered graphite carried into a bearing by some volatile liquid like kerosene gives good service in the wheel bearings of mold-oven cars and in car-hearth annealing furnaces. Where plain bearings are used it is often advantageous to use a wear sleeve on the shaft.

Materials handling in foundry operations is characterized also by wide load surges and by the frequent introduction of foreign material; and equipment must be designed with ample overload protection and surge capacity at every point.

The authors refer specifically to the use of shear-pin hubs on apron-feeder drives. The use of this device or its equivalent is recommended on all drives where an overload might cause serious damage to equipment. It is desirable, also, so to connect the drive that the motor stops automatically when the pin shears.

In any system including a number of units, each feeding the next in sequence, it is important to interlock the electrical controls so that the units will start or stop only in the proper sequence. Pilot lights, to indicate whether or not units not visible from the operating station are running, are desirable.

It is well, also, in a system of this sort to make each unit of a capacity slightly larger than the capacity of the unit which feeds it to make sure that there will be no flooding.

Bucket elevators should have provision to prevent backtracking in the event of power failure. Self-energizing friction brakes are often used. Positive ratchets are better. They may be of the silent type. Bucket elevators are not well adapted to handling facing sands. An inclined belt conveyer or a skip hoist is preferable for this service.

The authors make a good point in recommending storage bins of large capacity. While the 2-hr supply mentioned in the paper is adequate for continuous systems, as there stated, a much larger capacity is required to absorb the wide surges common in intermittent operation. A 10-hr supply is none too much for a foundry which pours and shakes out all its molds on a Saturday night and resumes operation on the following Monday morning.

[2] Walter Giele Company, Lebanon, Pa.

The authors develop some very good points on bin design. The writer would add only that, if molding sand did not have the property of bridging over an opening, it would never be possible to lift a cope. Vibrators will often relieve a bridging bin. Volumetric or gravimetric hoppers will deliver more nearly uniform batches if provided with vibrators to insure complete discharge at each cycle.

Vibrators are frequently of advantage on molders' hoppers, particularly on facing sand in steel foundries. Where facing hoppers are supplied with shovelout openings, it is possible to make them larger at the bottom than at the top to minimize the tendency to bridge.

Bins with downwardly converging sides opposite each other, particularly when in the shape of inverted cones or pyramids, have a marked tendency to bridge when used for prepared or other damp sand. A vertical partition will often reduce this tendency.

Roller conveyers work to good advantage wherever it is desirable to transfer loads from one conveyer system to another by means of cranes or tramrails. Roller-conveyer systems also work well with high-lift fork trucks. Roller-conveyer lines may be double-checked to segregate finished work from unfinished or to permit return of empty containers, as between a molding station and a pouring station.

Trolley conveyers are adaptable to intermittent operation on miscellaneous jobbing work as well as to continuous mass production.

Among their peculiar advantages are the following:

1 They can be made to travel in any path and will follow vertical as well as horizontal curves. They can be made to go around or over or under obstructions and to serve one or more floor levels.

2 They do not obstruct the floor.

3 The wheel bearings and track surfaces are above the dirt level.

4 They consume very little power.

5 They are endless and will return empty containers.

6 They will assemble components from a series of stations to a single assembly point or distribute to a series of stations. For illustration, they will collect cores from a series of core-making stations, bring them all to one spray station, and then distribute them to racks according to size.

7 They will carry work through process as through a spray booth, a dipping tank, or a drying oven.

8 They will accommodate any time interval between operations by changing length while keeping speed constant, as is done in castings-cooling conveyers.

Authors' Closure

Mr. Giele has brought out several interesting points in his discussion.

Regarding the use of centralized lubrication systems in connection with sand-handling machinery, while this may be desirable, it is hardly practical in the case of belt conveyers, elevators, etc., as this would involve piping the grease over very great distances. In many cases belt conveyers may be several hundred feet long.

We are very much interested in his comments on the running of ball and roller bearings dry. In foundry mold conveyers, which run at a very slow rate of speed, we have found that by running the roller bearings in the wheels dry their life is considerably lengthened. Only a small amount of light oil is added, to prevent the bearings from corroding.

On the subject of bucket elevators, back-stops are certainly desirable. We use the self-energized band brake type. Inclined belt conveyers are certainly preferable in handling facing sands, but in many instances bucket elevators are used successfully when

space limitations are such that inclined belts cannot be used.

Regarding the use of vibrators on storage bins, these are sometimes necessary to relieve bridging. However, if the opening or gate at the discharge point of the bin is not open, the vibrator may tend to pack the sand. The vibrators should be operated only when the discharge of the bin is open.

Air jets have been used in large storage bins for the purpose of relieving sticky and bridging action.

The Theory and Design of Electronic-Control Apparatus

By W. D. COCKRELL,[1] SCHENECTADY, N. Y.

Since the mechanical engineer is vitally concerned with control mechanisms involving electronics in some form, the author believes the explanation of theory involved and design of electronic apparatus given in this paper should be helpful. The almost infinitely fast and inertialess electronic tube can supplement mechanical control to produce many results hitherto considered impossible. After outlining the fundamental conceptions of the electronic tube, describing the types of tubes used, and explaining something of the operation of individual control circuits, the author indicates practical applications of electronics to standard control circuits. Examples of such controls are the photoelectric relay, electronic timer, motor control, resistance welding, photoelectric register control, and others.

Introduction

THE mechanical engineer has a larger stake in electronic control, particularly in photoelectric control, than many realize. In this new tool he has a means of supplementing his own mechanical operations in many ways. The almost infinitely fast and inertialess electronic tubes can supplement his mechanical control to produce many results hitherto considered impossible. The beam of light, or the small voltage, or change in magnetic or electrostatic field, produced by mechanical or chemical means, may act as a lever, pushrod, cam follower, or trip latch. On the other hand, since most electronic control must eventually end in mechanical motion, the electronic engineer must depend upon the mechanical engineer for assistance in solving problems of vibration, high-speed operation, and hunting or stabilization problems. No complete apparatus can be considered satisfactory unless it is correct both electronically and mechanically.

Electronics

Electronics has been defined as the art of working with an electric charge or current in the form of a stream of electrons or ions, free from the restraint of conventional conductors. As such, electronics includes the high-frequency phenomena of radio and television. However, in this paper we will simplify considerably the theoretical background to be covered. The theory required for industrial electronics, for instance, compares with that required for short-wave radio as the gravitational theory of Isaac Newton compares with that of Dr. Einstein.

Speed of Electrons and Electronic Radiation. It is sometimes difficult for one accustomed to dealing with mechanical things to realize the terrific speed at which electronic equipment can function. Airplane designers worry when the speed of their plane approaches that of sound, about 1100 fps. The propagation of electronic radiation is that of light, 186,000 mps. In a vacuum, an electron is accelerated by a difference of potential of 1 volt to a speed of 386 mps. Compare this with the pull of gravity which produces a speed of only 32 fps in the first second.

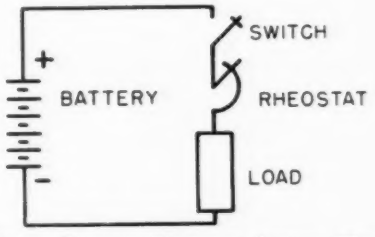

Fig. 1 A Direct-Current Electric Circuit With Rheostat Control
(Conventional current flow is clockwise; electron flow is counterclockwise.)

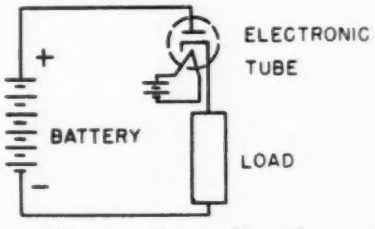

Fig. 2 A Direct-Current Circuit With Electron-Tube Control
(Electron flow is counterclockwise.)

Nature of the Electric Current. Modern electrical theory considers the current as a flow of electrons through the circuit. These electrons, the ultimate particles of negative electricity, are drawn to a potential more positive, just as a ball rolls down hill under the pull of gravity. To control a current is to control this flow of electrons. Those materials which permit a free flow of electrons are called "conductors," and those which resist the electron movement are called "insulators" or "dielectrics."

Control of Electric Current. The usual method of controlling an electric current is to change the resistance of a part of the circuit, or to replace part of the conducting path by an insulator, such as by opening a switch, Fig. 1. Another way is to control the electron flow by means requiring no mechanical movement; this is the electronic way, Fig. 2.

The Electronic Tube. The electronic switch consists of a device which may be inserted in the conductor path, and through which we may control the flow of electrons at will. Fundamentally it must consist of two parts, i.e., a source of electrons or emitter, called the "cathode," and an element to receive the electrons, called an "anode." To permit the best movement of the electrons, these elements are enclosed in an evacuated envelope.

Types of Emission. Electrons may be made available at the surface of the cathode in one of three ways. The electrons may be drawn out of the cold cathode by a positive charge placed very close to the surface. This method of obtaining electrons is used in cold-cathode voltage-regulator tubes and in ignitrons. A second method is the application of heat to special cathode

FIG. 3 METHODS OF OBTAINING ELECTRON EMISSION FROM A CATHODE

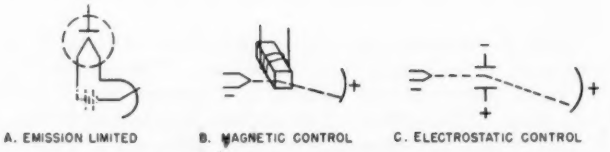

FIG. 4 METHODS OF CONTROL OF ELECTRON STREAM

materials so that the electrons are literally boiled free from the cathode surface. This is the customary method. Finally, some cathode surfaces are sensitive to the action of light and liberate electrons when struck by light of various colors. This includes both visible light, that beyond the red (the infrared), and the waves too short to be seen by the human eye (the ultraviolet). By these three methods electrons are liberated, which may be drawn by a positive potential in a steady stream of negative electric current to the anode, Fig. 3.

Control of Electron Stream. The control of the electron stream may be accomplished in three different ways, or by a combination of them. The most obvious way is to change the amount of energy for liberating the electrons. Thus if we remove the light from a photoelectric surface, or if we decrease or stop the heat from the thermionic cathode, we will reduce or stop the number of electrons available for the stream. These methods are shown in Fig. 4.

Since the stream of electrons represents an electric current, it may be acted upon by a magnetic field just as the current in a motor armature reacts to the magnetic field of the motor. This magnetic control of the stream has been used to a certain extent for television picture tubes, for the generation of high-frequency oscillations, and for a few other purposes, but has not been utilized to the extent to which the third form of control has been exploited.

The third, and most important, form of control is that of electrostatic deflection. This means simply that, if we insert a third element in the tube between the anode and cathode, and if this element is made negative, it will repel or deflect the electron stream away from it, and if positive, will assist in accelerating the electrons. This control element may consist simply of a plate, which will bend the stream of electrons toward or away from itself and thus change the point at which they strike the anode. This has a limited use in the cathode-ray oscillograph and in indicator tubes. A much more important effect, however, is obained by making this element a grid, or series of parallel wires, through which the electron stream must pass on its way to the anode. If this grid is made sufficiently negative, the electron stream is throttled down or even stopped entirely, and no current can flow between the cathode and anode, Fig. 5. A very important item to be noted in this form of control is that the grid, being negative, attracts no electrons, and hence there is no current flowing to the grid. Electric power consists of the product of current and voltage. Since there is no current there is, theoretically, no work done here so that the electron stream can be controlled with the expenditure of a minimum of power.

Sometimes more than one grid is used in a tube, Fig. 6. If positive with respect to the cathode, these other grids will assist in speeding up the electrons past the first grid. If negative, they will reduce or stop the flow of electrons in the same manner as a series of valves in a pipe.

We have now done two things. We have reduced the electric current to a stream of pure electrons, and we have found means

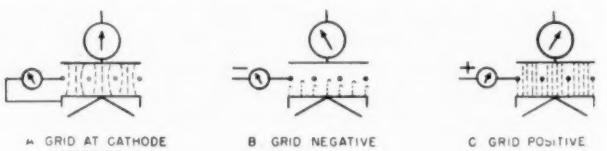

FIG. 5 GRID CONTROL OF ELECTRON STREAM

(The grid is placed in the electron stream between the cathode and anode. When the grid is at the same potential as the cathode, it affects the flow of electrons very little. When the grid is made more negative than the cathode, it repulses the electrons, and thus decreases the flow from cathode to anode. When the grid is positive with respect to the cathode, it increases the flow of electrons, but also attracts a flow of electrons to it.)

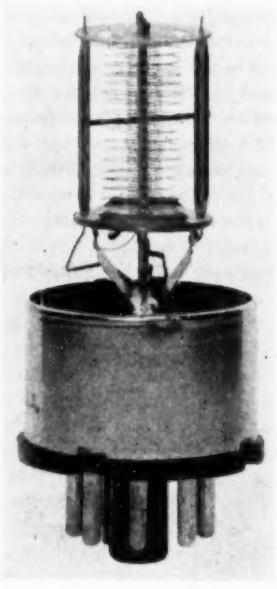

FIG. 6 A PENTODE, 3-GRID, AMPLIFIER VACUUM TUBE WITH GLASS ENVELOPE REMOVED

to control this stream with a minimum amount of power. Finally, since the speed of the electrons between cathode and anode is so great, we can, by changing potential of the grid fast enough, start, stop, and control the flow of electrons at a much more rapid rate than would ever be required for use with mechanical devices.

USES OF HIGH-VACUUM ELECTRON TUBES

We have described the electron tube as a valve, but since we have made only one of the elements capable of emitting the electrons, current can flow in but one direction, so it is a one-way valve. Some functions make use of the one-way effect, others use the throttling effect, while a few use both effects.

Rectifiers. The one-way action may be used like a mechanical pawl-and-ratchet action or, if preferable, like a crank-and-piston action, to change the alternating current normally supplied by the power companies to direct current which is more useful for such things as operating variable-speed motors, charging batteries, and for many chemical processes. The usual alternating voltage supplied to a transformer reverses its potential 120 times per sec. If we connect our two-element electron tube in such a circuit, it will permit the electrons to flow only when the anode potential is positive. This will permit the current to flow through the load in only one direction; but, since the power supply is reversed half the time, this load current will be intermittent. This is similar in action to a one-cylinder gasoline engine and, like the gasoline engine, a large electrical flywheel is necessary to provide continuous power to the load, Fig. 7. To secure a more even flow of power, we may use a reverse transformer winding to supply a positive potential to a second rectifier during the half-cycle that the first is inoperative, Fig. 8. This, of course, provides better direct-current output with a smaller electrical flywheel. Finally, by using a number of tubes, 3, 6, or 12, and a multiphase alternating-current supply, we may produce a smooth direct-current power, just as a multicylinder gasoline engine produces a smooth flow of power with a minimum-sized flywheel, Fig. 9.

The Electronic Amplifier. A second most important use of electronic tubes is to amplify, or step up, a weak input signal to a strong output signal. This input signal must be applied to the

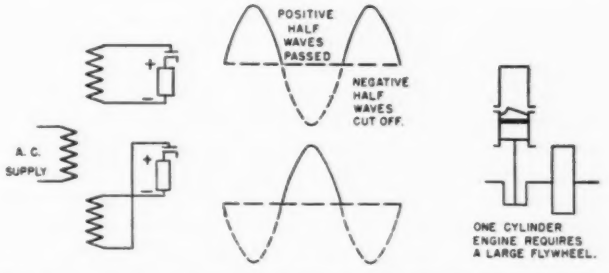

FIG. 7 HALF-WAVE RECTIFIERS COMPARED WITH A ONE-CYLINDER GASOLINE ENGINE
(The cathode heater circuit has been omitted for simplicity. Curves are graphs of power output against time.)

FIG. 8 A FULL-WAVE OR BIPHASE, HALF-WAVE RECTIFIER
(It will be noted that this is a combination of the two half-wave rectifiers of Fig. 7. Curves are graphs of power output against time.)

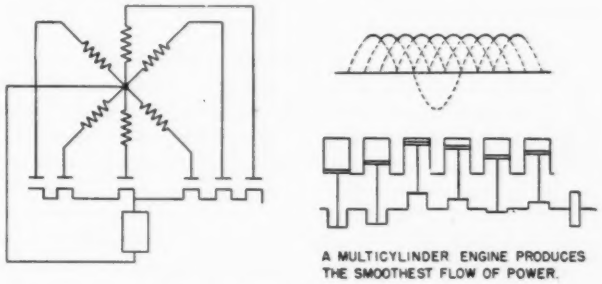

FIG. 9 A MULTIPHASE RECTIFIER PRODUCES A SMOOTH DIRECT-CURRENT OUTPUT

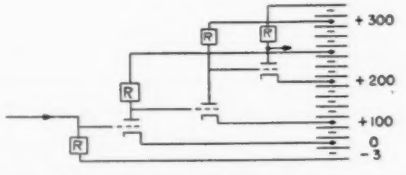

FIG. 10 A 3-STAGE VACUUM-TUBE AMPLIFIER CIRCUIT
(The current through each tube flows through the resistor R to produce a potential, which is applied to the grid of the next tube. The power is taken from a battery of 303 v, off which are tapped the required potentials for the individual tubes. Such an amplifier can step up the incoming signal many thousand times.)

grid of the amplifier tube as a voltage or potential change. If the weak signal is in the form of a small current, it must be transformed to a voltage by forcing the current through a high resistance to obtain a large potential difference across it. It is similar to obtaining a high-pressure reading from a small flow of water by forcing the water through a small pipe. This resistance may be many millions of ohms, so that even should the input signal consist of currents expressed in millionths, or even billionths, of an ampere, the voltage produced will be usable. It will be remembered that no power was required on the grid of the tube, but some power is required in this input resistor.

The change in potential on the tube grid will cause a change

in the current or electron flow between cathode and anode. If, we place in series with the anode another resistor, or impedance, through which the tube current must be forced, the potential change in this impedance will be much greater than that of the grid potential change. If this, in turn, is transferred to the grid of a second tube, and its anode current is again passed through an impedance to control the grid of a third tube, it is evident that immense amplification or magnification of the first potential change will be available at the anode of this final tube, Fig. 10. Most amplifier circuits transfer their signal between an anode and following grid through a capacitor or transformer, but the principle remains the same.

Let us pause to note that no power has been produced by the tubes. They have simply acted as valves to release a larger amount of power from some external power source, such as a battery which forces current through the tubes and their connected impedance.

Theoretically we can amplify signals thousands of times in a single tube, and, in standard industrial applications, a voltage amplification of hundreds of times, and power amplification between input and output of millions of times, is quite common.

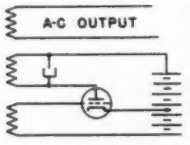

FIG. 11 A VACUUM-TUBE OSCILLATOR TO CONVERT DIRECT-CURRENT POWER TO ALTERNATING CURRENT

(The transformer at the left feeds the alternating-current power to the load and supplies a small amount of alternating-current power to control the electron-tube action. This is similar to the action of the valves and mechanism of a steam engine, which takes the constant pressure from the boiler and from it produces the necessary reciprocating action.)

Oscillators. Since the power required at the grid of the tube is only a very small part of the output-controlled power, we may take a very small amount of this output power and feed it back to control the grid at the proper frequency thus obtaining a controlled alternating-current output from the direct current supplied to the tube, Fig. 11.

Rotating equipment can generate frequencies up to 5000 or 10,000 cycles per sec. Because of the immense speed of the electrons, electronic equipment can generate frequencies up to many millions of cycles per second.

Oscillator tubes provide the type of power necessary for radio broadcasting, dielectric heating of plastics, and induction heating of small pieces of metal. However, it must be remembered that to control, by the use of high-vacuum tubes, any large amount of power, such as needed for industrial purposes, is extremely expensive, so that most electronic control of industrial power is ultimately obtained from the gas-filled tube which will now be discussed.

GAS-FILLED TUBES

When in a simple two-element vacuum tube, the electrons are being drawn from cathode to anode, an interesting thing happens. Electrons move across the space because they are negative charges, being attracted by the positive anode. However, since they themselves are negative, they will tend to shield all electrons between themselves and the cathode from the action of the anode in the same manner that the negative grid does. This effect is so great that, in order to obtain the 1 amp current necessary to light a 100-w lamp, it might be necessary to apply 1000 v between anode and cathode. This means that high-vacuum tubes are most useful at low currents or with high-voltage loads.

However, if we introduce into our vacuum-tube envelope a small amount of gas, about 0.0001 of atmospheric pressure, a remarkable change in this space charge takes place. The gas may be one of the inert gases, such as Argon or Xenon, or the mercury vapor above a small drop of mercury at normal room temperature.

Ionization. If the positive potential on the anode is less than 8 v, the electrons leaving the cathode bump into the many gas molecules on its path to the anode so that their progress is slowed down very much and the current flowing is very small. However, somewhere between 8 and 12 v, depending upon the type of gas and the pressure, some electrons attain sufficient velocity so that, in striking these gas atoms, they knock an electron or two from them. Then, for each original electron, we have two free electrons moving toward the anode, and the atom, losing an electron, becomes a positive ion which drifts toward the cathode. The glancing electron may hit other atoms and knock out other electrons on its erratic course to the anode, until finally almost the whole area between cathode and anode, no matter what its shape or length, is filled with flying electrons and positive ions. Of course many atoms recombine with electrons giving up their energy in the form of the familiar glow seen in gas-filled tubes. Yet, on the whole, this so-called "plasma" is composed of approximately equal numbers of positive ions and negative electrons. Electrons are always arriving at this plasma from the cathode and are leaving at the anodes, but the plasma maintains always a potential of about 10 or 15 v positive with respect to the cathode for, if more electrons should leave than arrive, the average potential of the plasma will rise, accelerating the electrons to a higher speed and thus knocking more electrons from the neutral atoms within the plasma. If more electrons arrive than leave, the potential of the plasma will be lowered and the average potential of the arriving electrons from the cathode will be less. Thus, no matter what the current from the cathode, even though it be thousands of amperes, the potential of the plasma will change very little. Fig. 12 gives an idea of the potential gradient or voltage distribution in a vacuum tube and in a gas-filled tube.

Cathode Abuse. It must be noted that this low voltage potential of the anode for high current depends upon having a sufficient number of electrons available at the cathode for the ionization. If for any reason there are not sufficient electrons available, the plasma potential may rise above 22 v. At about this potential, the heavy positive ions are drawn toward the cathode with sufficient velocity to damage the cathode surface, and may even chip off flakes of the active material, ruining the surface within a very short time. Thus it will be understood why it is so necessary that hot-cathode tubes be permitted to warm up to obtain an efficient emitting temperature before the anode circuit is closed.

Mercury-Pool Rectifier and the Ignitron. In the mercury-pool or tank rectifier, and in the ignitron, the cathode consists of a pool of mercury. Once ionization has taken place in these tubes, the positive ion, drifting near the cathode, draws out the electron by the potential gradient effect. In this manner, a plentiful supply of electrons is assured at a potential drop between 15 and 20 v. These, then, are the tubes which are used for the high currents required for resistance welding, railroad electrification,

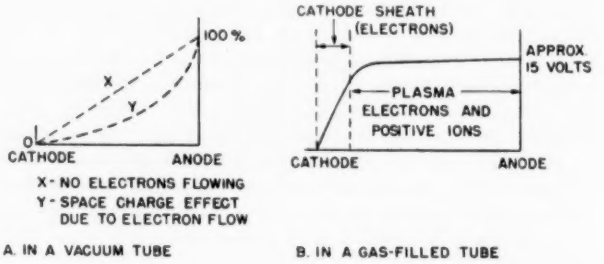

FIG. 12 ELECTRICAL POTENTIAL GRADIENT BETWEEN THE CATHODE AND ANODE OF A VACUUM TUBE AND A GAS-FILLED TUBE

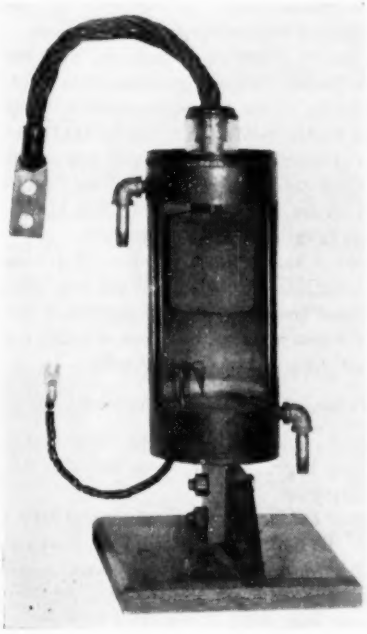
(In the vacuum tube, the anode potential may be many hundred volts. In the gas-filled tube it should never be more than 20 v.)

and electrochemical processes. Fig. 13 shows the construction of an ignitron.

Before the ionization action can take place, however, the plasma must be established. In the tank rectifier, this is done



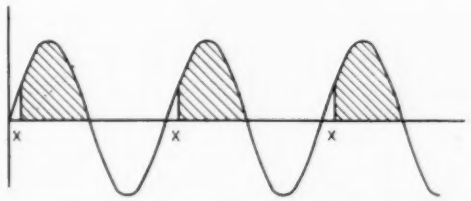


FIG. 13 CUTAWAY VIEW OF AN IGNITRON

(Normally there is a pool of mercury in the bottom of the tube, into which the igniter, shown at lower left, projects. The anode in the top of the tube is a large block of graphite, which, with its heavy stranded lead projecting from the top of the tube, is designed for the heavy current conducted by this tube. The cathode connection is the copper lug by which the tube is mounted. Inlet and outlet pipes are shown for the water, which circulates within the hollow shell of the tube for cooling.)

by mechanical means, and in the ignitron by the action of a small piece of crystal dipping into the mercury, which is called an igniter. For most precise applications the igniter is controlled by a hot-cathode thyratron.

a. THYRATRON (OR IGNITRON) STARTS CONDUCTION AT X, EARLY IN THE POSITIVE HALF CYCLE. THE AVERAGE CURRENT, SHOWN IN THE SHADED AREAS, IS ALMOST MAXIMUM.

b. THYRATRON (OR IGNITRON) STARTS CONDUCTION AT Y, LATE IN THE CYCLE. THE AVERAGE CURRENT, SHOWN IN THE SHADED AREAS, IS LOW

FIG. 13(a) OPERATION OF A THYRATRON

(The average current of a thyratron or ignitron is changed by retarding the time of beginning conduction in each cycle. These tubes may be connected in multiphase circuits also to permit a smoother flow of output power.)

Gas-Filled Tubes With Grids. Since the gas filling in the tube makes possible its use with low losses when conducting high currents, it is the one which we must use for the usual applications requiring power, such as driving motors or operating a solenoid. We wish to control these gas-filled tubes also by some form of grid, as in the case of the high-vacuum tubes. Unfortunately, however, the control cannot be attained in the same manner so that a slightly different method of control must be obtained from the grids in the gas-filled tubes.

The Hot-Cathode Thyratron. It should be fairly evident that the conventional grid, inserted in the gas-filled tube in the plasma between cathode and anode, would have little effect on the erratic and random motion of the electrons and ions filling the space. It is true that, when the grid is made quite negative before a positive potential is applied to the anode, it may keep

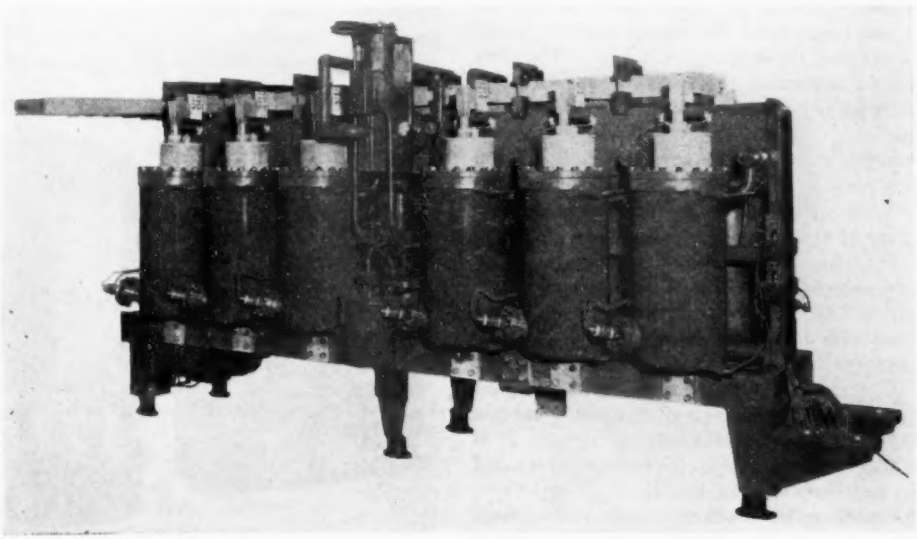

FIG. 14 A LARGE MULTIPHASE IGNITRON RECTIFIER

(Six large ignitrons are shown. They are connected in a circuit similar to that of Fig. 9, to convert alternating current into the direct current required in a large aluminum plant.)

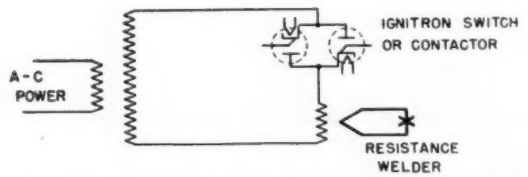

FIG. 15 INVERSE-PARALLEL IGNITRON CONNECTION, ACTING AS AN ALTERNATING-CURRENT SWITCH TO CONTROL A LOAD SUCH AS A RESISTANCE WELDER

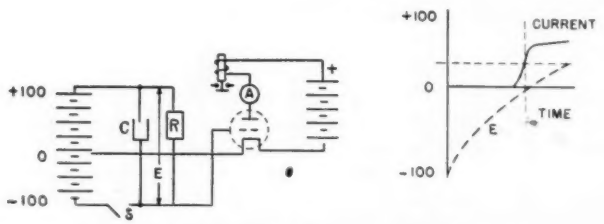

FIG. 16 ELEMENTARY ELECTRONIC-TIMER CIRCUIT

(The battery at the left charges the capicator C to a potential of 200 v. The grid of the electron tube is connected to the negative end of the capacitor, and hence is 100 v negative with respect to its cathode. Therefore no electron flow takes place in the tube. When the starting switch S is opened, the capacitor charge leaks off through the resistor R, and the grid potential gradually rises until the grid approaches the cathode potential, and electrons begin to flow in the tube, sufficient to pick up the relay and close the control circuit.)

all electrons from flowing from the cathode and thus prevent the formation of the plasma. But once the plasma has formed, the grid is powerless to stop the electron flow.

Since the grids can only prevent the conduction through the thyratron, but cannot stop it once it has begun, a question may arise as to the usefulness of this type of tube. The answer lies in its use on alternating-current power. It will be remembered from the discussion on rectifiers that, when alternating-current power is applied to the tubes, the anodes become positive one half of the time and negative for the other half. During the time that the anode is negative, no electrons will flow, and the positive ions may recombine with the electrons, or deionize, thus permitting the grid to regain control. If the grid is negative when the next half cycle begins, the electron flow cannot begin until the grid becomes positive, and thus it can determine the point in the positive half cycle where conduction starts. By retarding the grid firing angle to the desired point within this positive half cycle, one may control the *average* current passed by the thyratron and, thus, the output to the load. The same reasoning may be used concerning the action of the igniter in the ignitron, to decrease the maximum current which may be passed by that tube.

Thyratron and Ignitron Circuit. The thyratron and ignitron may be used in the rectifier circuits discussed previously, but with much higher efficiency for larger loads. In fact, multiphase ignitron rectifiers have become the basic means of obtaining direct current from alternating current in many industries. Thyratrons, so connected, supply variable power for the control of direct-current motors and similar uses, Fig. 14.

Although electronic tubes are inherently rectifiers, two of them may be connected in the "inverse-parallel" circuit, to permit passing both halves of the alternating-current wave and thus become an effective alternating-current switch which combines both high-speed switching action and throttling action. It is this type of circuit that is used to supply the precisely measured amount of power for resistance welding, Fig. 15.

Miscellaneous Control Circuits. Both thyratrons and vacuum tubes may be used in connection with the more conventional electrical components, such as capacitors and inductances, to produce a variety of functions.

If the energy is stored in a capacitor and then is permitted to be dissipated through a resistor, the capacitor potential will be reduced at a well-known and easily calculable rate. If this potential is applied to the grid of an electron tube, the anode current will be varied, or the thyratron grid will reach the firing potential in a definite time. In this way, an accurate and unvarying timing relay is developed, Fig. 16.

Combinations of resistors, capacitors, and inductances are used to obtain the grid and anode phase relations required for the proper functioning of the thyratron control circuit. Electronic tubes are used for the excitation of the fields of electric generators in many jobs in both the industrial and military fields. Thyratrons supply the direct-current power for the large saturable reactors such as used for the Radio City Music Hall lighting and for critical electric-furnace applications.

Needless to say these are only a few of the functions of the tubes and the methods by which they are controlled. There are many others, and the number will continue to grow, as long as man exercises ingenuity and the types of tubes are improved or modified to suit the new uses and demands.

STANDARD ELECTRONIC-CONTROL CIRCUITS

Now that we have the tubes and the individual control circuits available, let us begin to put them together to obtain some practical applications.

A Photoelectric Relay. Suppose we start with a simple photoelectric relay. To make this, we will take first a simple rectifier to obtain direct current from the alternating-current supply (which is usually the only kind available). At the output end of the rectifier, we will place a capacitor to store up energy between the positive pulses of the alternating-current circuit, and across this output we will also place a series of resistors which will act as a voltage divider to permit obtaining both anode and grid potential from the one direct-current source.

Next, we will add the necessary phototube to convert the change in light into a change in electric current. The drop across the phototube resistor is then applied to the grid of an amplifier tube, in order to step up the signal sufficiently to operate a small contactor placed in the amplifier-anode circuit.

As a finishing touch, we may add a rheostat so that we may vary the amount of direct current which is normally applied to the grid, in order to select the amount of light which must fall on the phototube before the grid is made sufficiently less negative to operate the contactor. As further refinements, we may add a very small capacitor between grid and plate of the amplifier tube

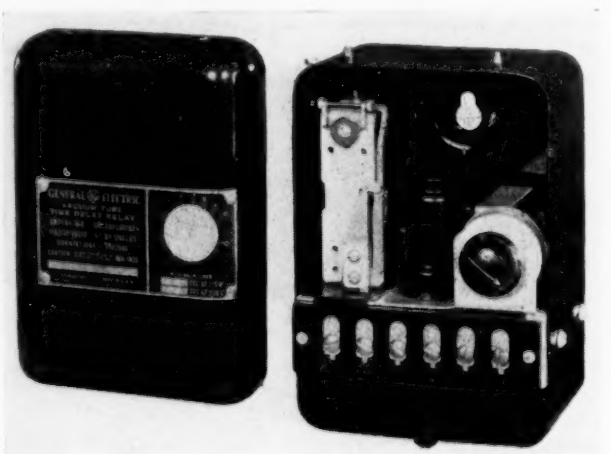

FIG. 17 COMMERCIAL FORM OF ELECTRONIC TIMER

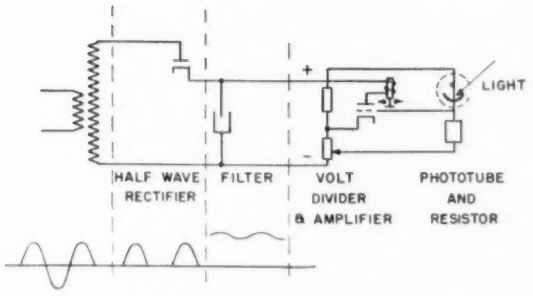

FIG. 18 PHOTOELECTRIC-RELAY CIRCUIT

(This combines the half-wave rectifier of Fig. 7 and a capacitor filter which acts as a flywheel to produce a steady direct current. Next, a tapped resistor voltage divider provides the necessary potential for the electronic amplifier tube and the phototube. When the phototube is dark, no electrons flow through it or its resistor, and the electron-tube grid is far negative, so that no electrons flow in the amplifier tube. When light strikes the phototube, the phototube electrons, forced through the phototube resistor, raise the grid of the amplifier tube sufficiently to permit it to conduct and pick up its relay.)

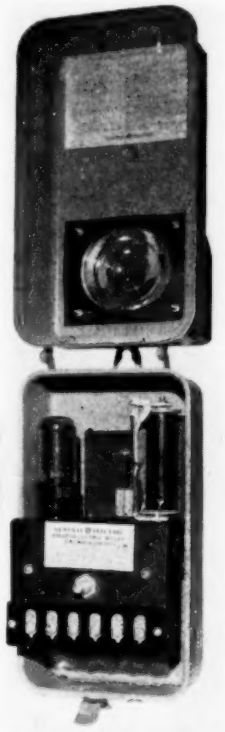

FIG. 19 COMMERCIAL PHOTOELECTRIC RELAY USING CIRCUIT OF FIG. 18; COVER THROWN UP

to prevent operation on slight light flickers and another capacitor between the direct-current potential and ground to prevent action due to slight changes in the alternating-current power supply.

The circuit is shown in Fig. 18, and the relay in Fig. 19. Hundreds of these relays have been sold and are now doing all sorts of useful jobs, such as counting people or autos, packages and cabbages, and cartons freshly painted.

An Electronic Timer. In a similar manner, we may build up an electronic timer by combining the capacitor-resistor fundamental timing circuit with an amplifier and a contactor operated by the amplifier, Fig. 17.

Tube Control of Motors. A motor control, Fig. 20, which will regulate the speed of the motor quite accurately may be made by a pair of rectifiers, one or both of which may be controllable, to supply the motor armature and field of a direct-current motor. Then we may obtain an indication of the motor speed, either by connecting a tachometer generator to it which will produce a voltage proportional to speed, or take the back-induced voltage from the motor. This is compared to a reference voltage, and the difference is amplified and applied to the control of the armature or field to hold the motor speed constant. If we wish, we can add other circuits which operate from the motor current to limit this current to a safe value for motor and tube in spite of the demand for speed. A control can even be added to compensate for the resistance of the motor armature to obtain a flat compounding which is superior to that which can be obtained from a direct-current compound motor.

Resistance Welding. The electronic control of resistance welding has played a major part in the fabrication of equipment used to fight this war. The principle of resistance welding is old, that of squeezing two pieces of metal together and then passing current through the resistance of their junction sufficient to melt the material and thus cause it to fuse together. This method of fabrication is extremely fast and, in some cases, the cost is only one tenth that of riveting. However, satisfactory welding of such materials as stainless steel, which must be melted at the junction point, but must heat and cool through the critical temperature quickly to prevent loss of its stainless properties, and aluminum, which is a very good conductor of both heat and electricity and is so soft that a little too much heat will quickly ruin the weld, is made possible only by the precise timing and heat control of the electronic device. To obtain the most effective control, we start with the electronic timer, Fig. 21 (*a*), or if this is to be a seam welder which produces a series of pulses rather than a single hot spot, with two timers, one to control the heating period and the other the cooling period between the heat pulses. We may then add a heat control which determines the phase angle at which the control thryratron and ignitron will fire to produce the desired amount of heat at each pulse, Fig. 21 (*b*). Finally, we have the large ignitrons themselves which pass

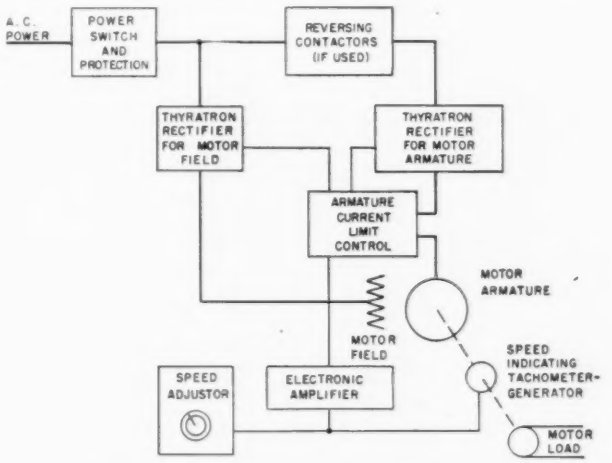

FIG. 20 ELECTRONIC MOTOR CONTROL

(The indication of motor speed, taken from the tachometer-generator, is compared with the speed-adjustment setting, and the resulting signal is amplified to control the power applied to the armature and field of the motor. The current-limit feature prevents overloading motor or tubes. Speeds constant to 1 per cent from no load to full load over a speed range of better than 20 to 1 are possible.)

(This is the type of panel used in the circuit of Fig. 15.)

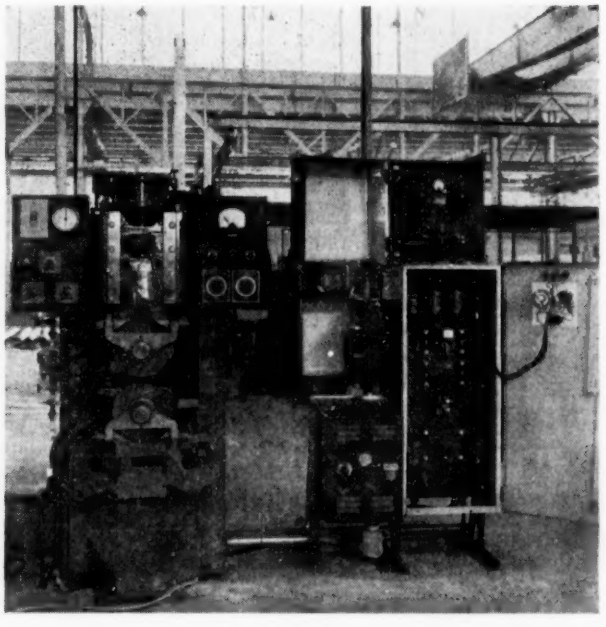

FIG. 21(*d*) THIS EQUIPMENT, SHOWN IN AN ACTUAL INSTALLATION, IS THE MORE USUAL FORM OF PANEL COMBINING FUNCTIONS OF THE THREE PANELS SHOWN IN FIGS. 21(*a*, *b*, *c*)

the actual power current required by the welder, Fig. 21 (*c*). These large tubes are capable of handling tens of thousands of amperes for the short time required to make the weld. They are cooled by a flow of water which circulates in their double shell.

Other types of welders use rectifiers to store up the energy in a large bank of capacitors, or in an inductance, and then discharge this energy suddenly into the weld. They are thus able to supply a large amount of energy in a very short time by storing up this energy from the power line over a period of time, rather than demanding it all at once from the electrical supply.

Photoelectric Register Control. The circuits described have been more or less self-contained electronic equipments operating a particular device. In the case of the photoelectric register control, that is, the registering of printing with some mechanical operation such as cutting or folding the printed paper, there is allowed much more freedom of engineering in the over-all application. For instance, for the simplest type, say that of a candy-wrapping machine where the paper moves very slowly and may be stopped each time that a bar is to be wrapped, an index mark may be printed along the edge of the sheet so that, when it intercepts the light to the phototube, either by transmitted or reflected light, the paper will be stopped in order that the required operation may take place before the paper is permitted to move forward again. Fig. 22 shows a typical wrapping machine.

On the other hand, when the paper moves somewhat more rapidly, it may be drawn forward slightly too much, each time, and then, when the register mark reaches the limit of the permitted tolerance (as determined by the position of a

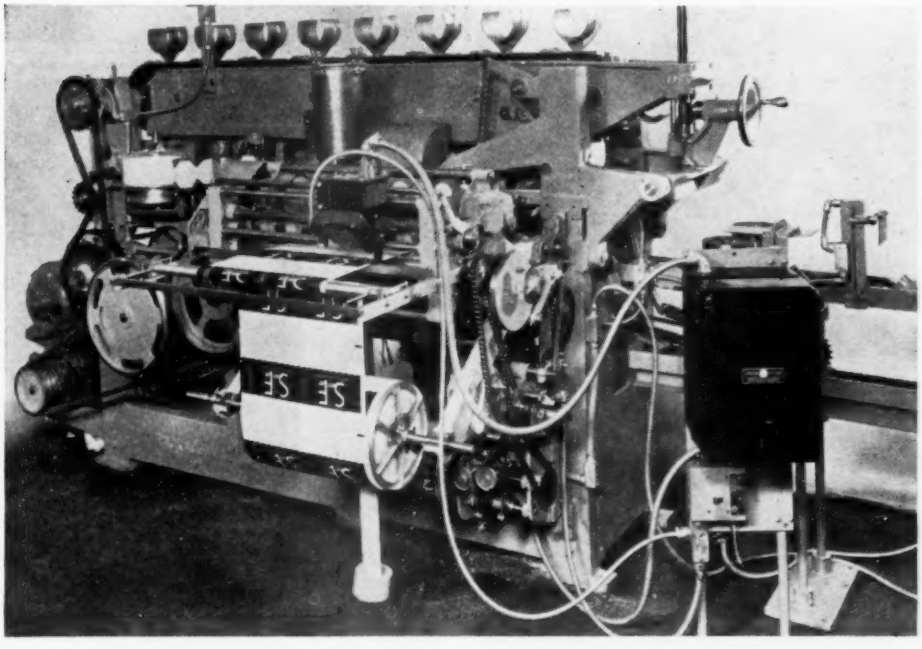

FIG. 22 PHOTOELECTRIC REGISTER CONTROL OF LABEL POSITION ON WRAPPING MACHINE

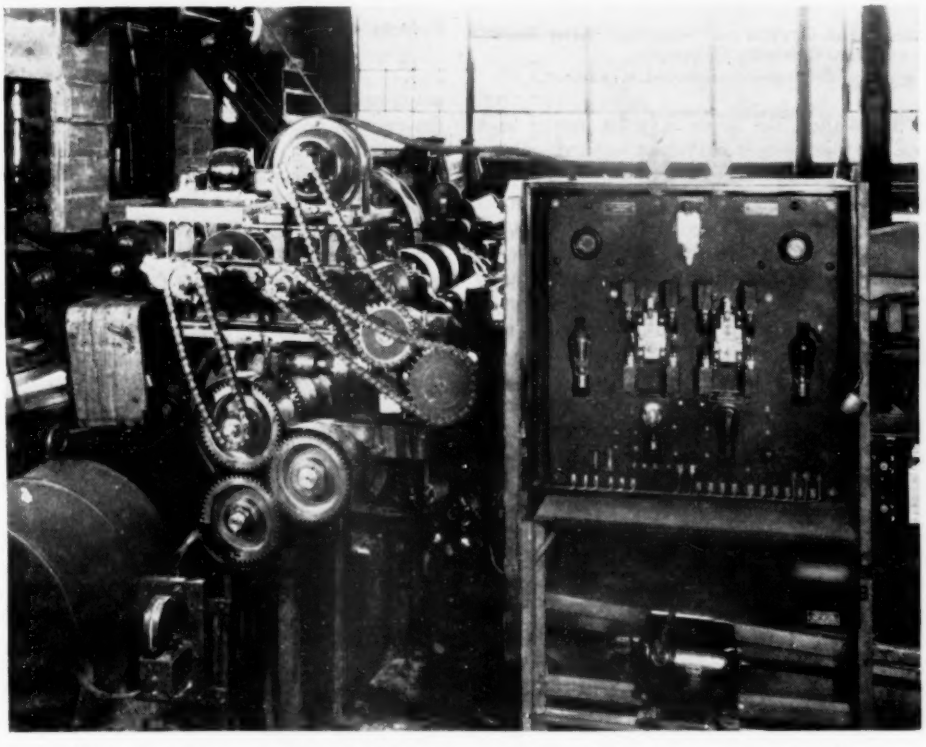

FIG. 23 ONE OF THE FIRST PHOTOELECTRIC REGISTER-CONTROL EQUIPMENTS, 1932
(Note mass of chain and gearing.)

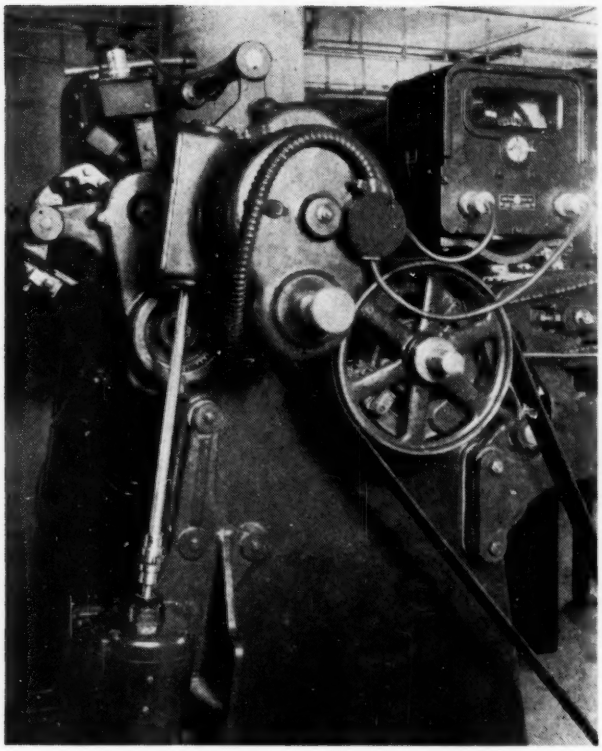

FIG. 24 (*a*) MODERN PAPER CUTTER OR "SHEETER" WITH PHOTOELECTRIC REGISTER CONTROL
(One correcting motor, electronically controlled, is sufficient.)

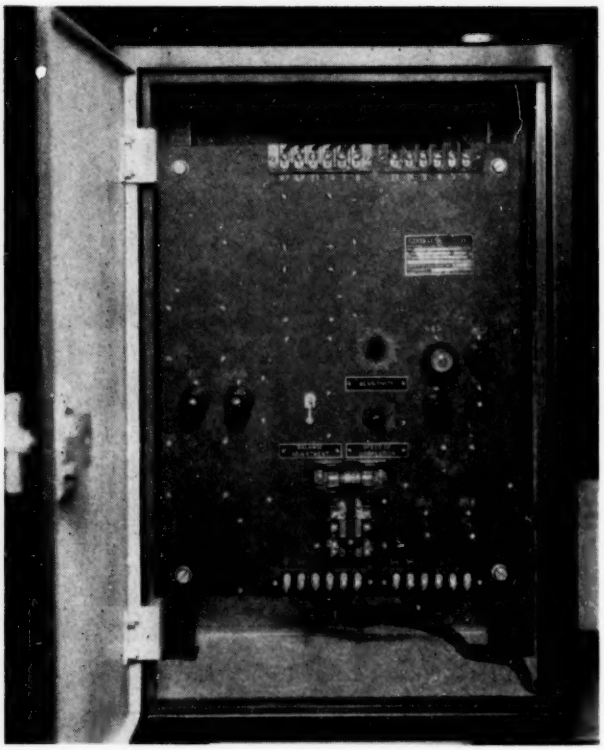

FIG. 24 (*b*) ELECTRONIC PANEL FOR CONTROL OF CORRECTING MOTOR ON MACHINE SHOWN IN FIG. 24 (*a*)

contact geared to the knife), the paper may be moved back by a notching action and then permitted to creep forward again.

As speed is increased, it becomes necessary to control the speed of the web accurately so that it will always be cut near the proper point. This can be done completely by electronic means, all the way from the phototube to the thyratrons supplying power to the correcting motor driving a differential to synchronize exactly the speed of the web and cutter. For most precise action at high speeds, a combination of phototubes and a slotted disk may be used to indicate the position of the knife.

However, at any point in this complete system from the first amplifier tube and its small contactor to the end, mechanical devices may be used to replace electrical devices. It is here that the ingenuity of the mechanical engineer is necessary to determine the best combination of electrical and mechanical equipment for that particular application.

It is interesting to note that through the years sound judgment, as shown by results, has dictated the ever-increasing part to be taken by the electronic components. Fig. 23 shows one of the first installations (1932) and is typical of the large part that mechanical operation played in the older equipment. Fig. 24 (*a*) and (*b*) shows a modern equipment in which tubes do many things formerly done by mechanical means.

Application of Electronic Control

By E. H. VEDDER,[1] EAST PITTSBURGH, PA.

This paper describes typical applications of electronic control. Motor control including an adjustable-speed drive for direct-current motors and a speed-regulator system are shown. The importance of resistance welding in production of sheet-metal assemblies and the use of ignitron equipment for control of time and current are discussed. Many uses for control using light, including loop, tin-flow, and paper-cutting regulation are described, as well as pinhole detection in steel strip, and general-purpose photoelectric relays. The importance of close co-ordination of design of the electrical and mechanical elements of a complete system is emphasized.

ELECTRONIC control is now used in a variety of ways as a component part of systems which are usually partly mechanical and partly electrical. Inasmuch as many functions may be done either electrically or mechanically, careful consideration must be given to co-ordination of the two elements to produce the best system.

The first principle we need to establish is that electronics will live up to its publicity only if it is really put to work as an accepted workaday tool. If electronics is allowed to become a gadget business, we have failed to utilize the tool properly. The gadget angle can be avoided only by critical survey of every application. Electronic control has been developed which will do many things better, less expensively, faster, or more precisely, as well as many things previously impossible. But electronics is not a cure-all for every trouble. It is merely a new tool which must be properly used within its limitations. To illustrate the type of things for which electronics is suited, a few applications will be described.

Motor Control

Many motor-drive problems, particularly those connected with machine tools, are best solved by the characteristics inherent in a shunt-wound direct-current motor. The almost universal availability of alternating-current power and relative unavailability of direct-current power has made it much more difficult to use the desirable direct-current motor for these drive applications. There has also been a growing desire for a greater nicety of control than can be readily obtained even if a direct-current system is available. An electronic control has now been developed which operates a direct-current motor from an alternating-current line and has additional desirable features not previously available. The electronic adjustable-speed drive shown in Fig. 1 consists of a direct-current shunt-wound motor whose field and armature are energized by separate thyratron rectifier circuits. These rectifiers are so controlled as to vary the input to the motor, regulate the motor speed to a preset value, and limit the maximum current furnished the motor during acceleration and reversal.

The control permits smooth stepless adjustment of motor speed over a range of at least 20:1 below the base speed of the motor, and over an additional field-control range of as much as 4:1 above the base speed of the motor. This speed control is readily obtained over the full range below and above basic speed by means of a small potentiometer located in the push-button station convenient to the operator.

Combined with the wide range of speed control are the very flat speed-torque characteristics over the whole range. This is obtained by speed-regulating circuits which insure that the motor will be held to the preset speed chosen by the operator. In a properly adjusted system, the speed over a 10:1 range below basic speed will not vary more than 4 per cent from a preset value, with torque varying from no load to full load, nor will it vary more than 8 per cent for any speed within the speed range of 20:1. Normal variations in alternating-current voltage have only a small effect on the speed regulation.

It is necessary that capacitors made of foil and paper be wound with uniform tension to insure good insulation. The electronic motor-speed control is used for this purpose. The operator controls speed in this application with a foot-operated speed adjuster consisting of a variable reactor with foot treadle. Continuous speed adjustment is available from zero to maximum winding speed. Greatly increased production resulted because of the smoother speed control by the operator.

FIG. 2 ELECTRONIC ADJUSTABLE-SPEED MOTOR DRIVE ON CAPACITOR WINDING MACHINE

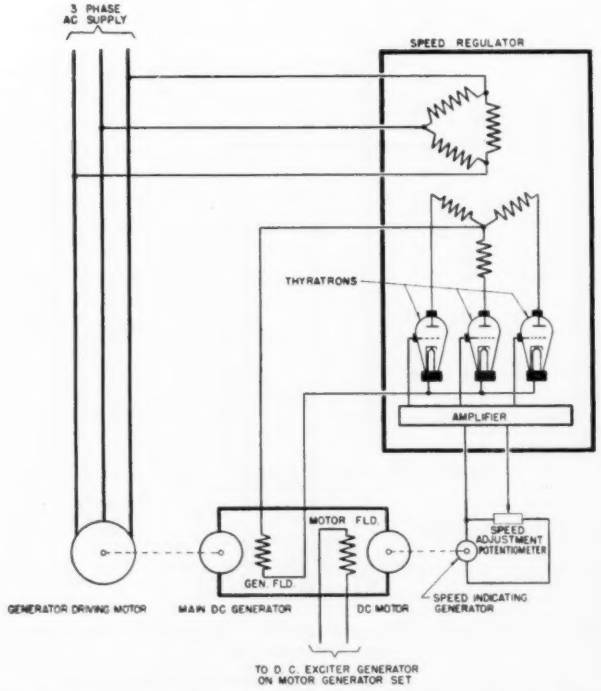

FIG. 3 SCHEMATIC DIAGRAM OF A VARIABLE-VOLTAGE SPEED CONTROL WITH ELECTRONIC SPEED REGULATOR

There are many motor-control systems where speed regulation is desired, but there is no advantage in full electronic control. For this purpose, a speed-regulator system has been developed as shown in Fig. 3. In this particular system, the direct-current motor is furnished with power by a motor generator set. The motor-generator-set field is energized from the electronic regulator. The motor speed is indicated by the speed-indicating generator whose output voltage is proportional to speed. The indicating voltage is applied through an amplifier and regulating circuit to the grids of the rectifying tubes which furnish the generator field. This device has found ready acceptance in paper mills for regulating the speed of a single-motor paper-machine drive. It maintains the speed to an accuracy of approximately 0.5 per cent and may be adjusted over a speed range of 10:1. A similar regulator is used to hold constant speed on the Wright Field 40,000-hp wind-tunnel drive.

RESISTANCE-WELDING CONTROL

Resistance welding is being extended rapidly to speed production of fabricated assemblies. It is particularly adaptable to manufacturing processes involving large quantities of repetitive assemblies. It is most commonly used on sheet metal, although heavier parts including heavy plate and premachined pieces are also being welded.

Resistance welding is accomplished by passing a heavy current through two or more pieces of metal. The resistance of the metal to current flow develops heat, which fuses the pieces together. The material is clamped between copper or copper-alloy electrodes which apply pressure and conduct the heavy current to the junction point. The welding machine itself consists essentially of a heavy framework supporting a special transformer, electrodes, and pressure head for the electrodes.

For many years, the use of resistance welding was confined almost entirely to the coarser sheet-steel structures which could tolerate a considerable amount of electrode marking, warping, and discoloration. The process has become in recent years more of a precision process and has been extended to a variety of alloy

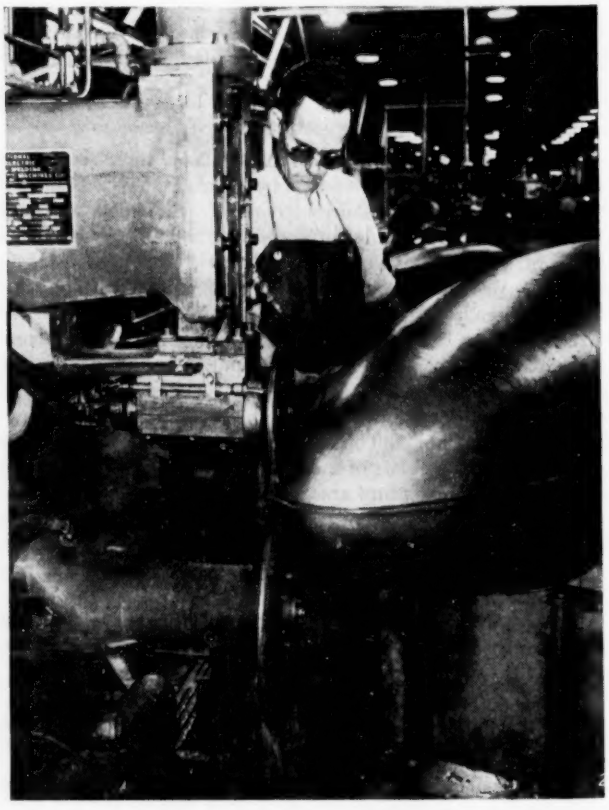

FIG. 4 SEAM-WELDING MACHINE

metals such as stainless steel, brasses, and bronzes, and to nonferrous metals of sharp fusion points such as aluminum. In wartime industries, welding has rapidly found its place in the manufacture of airplanes, trucks, shells, gasoline drums, airplane drop tanks, and other similar assemblies.

Resistance welding is divided into several different general types, the more distinct classes being spot, projection, butt, and seam welding. Spot, projection, and butt welding differ only in the type of electrodes and method of holding the materials during welding and use the same control unit. The control measures out one or more pulses of current to make an individual weld. Seam welding uses roller electrodes, and the control is quite different from that for spot welding. The control causes the current to flow in individual pulses of a few cycles' duration each and with a few cycles time between each pulse for as long as welding is proceeding.

Fig. 5 is a typical resistance-welding system, showing in this particular case spot-welding electrodes, although the diagram applies equally well to seam welding when roller electrodes are substituted for the pointed tips. The resistance-welding system consists of the welding machine with the welding transformer mounted in it, together with control equipment including an ignitron power assembly for controlling the energy fed to the welding transformer, a timing control, and the current or heat control. When the operator's foot switch is depressed, the welding electrodes are lowered to the work and when pressure has been fully applied, the timing unit causes the ignitron unit to conduct current to the welding machine. The timing control determines the length of time that welding current will flow and, after the predetermined length of time, causes the current to stop. The timing is usually between 1 and 30 cycles. For various work, it is necessary to have different values of current, and therefore the current input to the welder must be adjusted when setting up. The heat-control unit serves this purpose. For some special applications the current is modified automatically during the progress of the weld. Electronic control has proved valuable for resistance welding because of reduced maintenance at high operating speeds and also because of the precision obtainable.

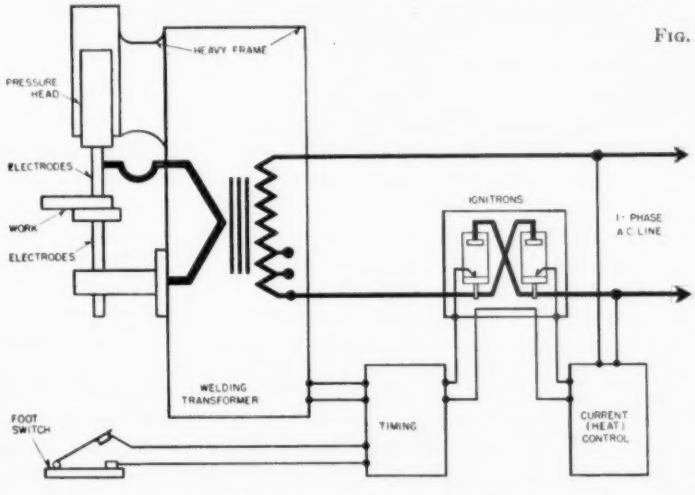

FIG. 5 SCHEMATIC ARRANGEMENT OF A SPOT WELDER AND ITS CONTROL

(The timing and current controls shown as blocks operate in the control circuit of the ignitron power tubes to time the duration of the flow of current and determine its magnitude. The proper time and current values are selected by experience and preset manually for the material being welded.)

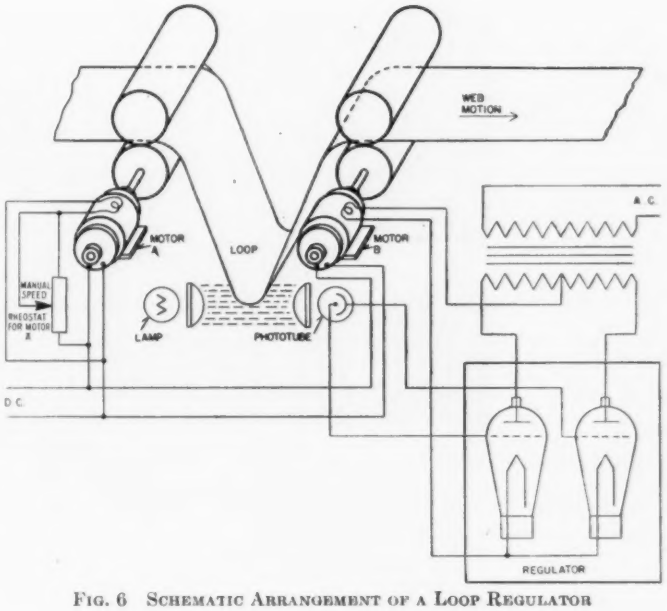

FIG. 6 SCHEMATIC ARRANGEMENT OF A LOOP REGULATOR

The ratings of welding control are based upon the current-carrying capacity of the control and the duty cycle primarily, the ignitron tubes being rated at currents up to 10,000 amp during the weld at low-duty cycle. Inasmuch as the welding transformer steps current up several times, this value of primary current would correspond to perhaps 80,000 or 100,000 amp in the weld itself. Most equipment operates from industrial voltages of 220 or 440 v, although control is now available for 2300-v operation. The high voltage operation is particularly desirable for large welding machines to minimize the effect of the high current demand on the line voltage and in many cases to save on the amount of bus required for feeding the power to the machine.

CONTROL USING LIGHT

Control utilizing light is called "photoelectric" because it is actuated by the response of a light-sensitive element called a "phototube." Photoelectric control is useful for actuating a system in response to a change of color, shade, density, shape, or position without mechanically touching the controlling object.

Many of the more important photoelectric applications may be classed as process regulators. Thus a loop regulator on a paper-coating machine or on a steel strip mill watches the loop position and calls for slowing down or speeding up one of the sections of the mill to maintain a constant loop. The system in Fig. 6 is a simplified arrangement used where the speed range is not more than about 4 to 1. The web is driven by motor *A* into the loop and taken out of it by motor *B*. Motor *A* and motor *B* can, for instance, operate two different sections of a conveyer or two separate stands of a mill. The speed of motor *A* is adjusted as desired, and the regulator then keeps the speed of motor *B* at the proper value to maintain a constant loop between the two sections. An increase of loop length reduces the amount of light reaching the phototube from the light source and modifies the field excitation of motor *B*, adjusts its speed, and brings the loop back to the proper position.

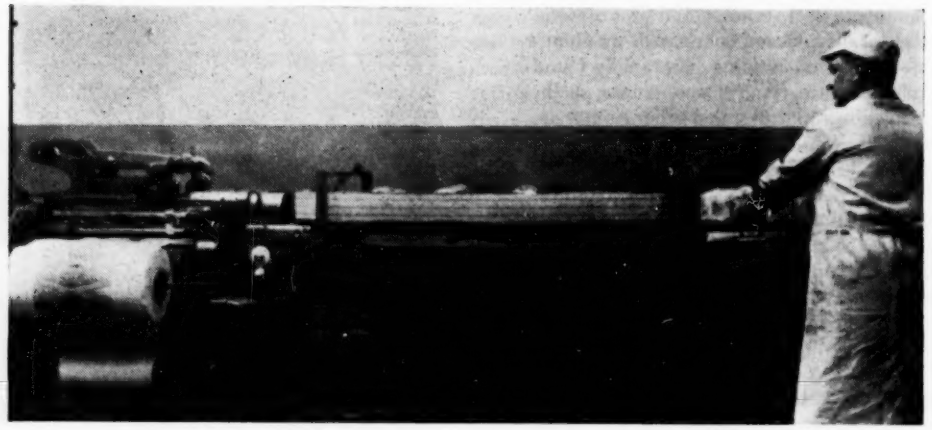

FIG. 7 BREAD-WRAPPING MACHINE WITH PHOTOELECTRIC CONTROL OF CUTTING TO PLACE TRADE-MARK AT SAME SPOT ON EACH LOAF

A regulator used frequently in the paper, cellophane, and glassine processing industry is that for maintaining the position of cut when taking from a roll of preprinted stock for making bags or packages. Although the machine feeds paper at a rate approximately correct to match the speed of the rotating knife, the cut will never remain registered perfectly without either manual or automatic supervision. A register regulator corrects for changes of paper slippage, stretch, and speed relative to the cutter speed. The position of the printed material is indicated by a rectangular register mark in the design or margin which is scanned by a phototube. The position of the mark with respect to the cutter is checked and the speed of paper feed modified if necessary. A typical installation of this type is shown in Fig. 7, for packaging bread.

When slitting strip material, it is often necessary to regulate the sideways position of the web to insure cutting at the proper point relative to a trade-mark or printed design. The slitter regulator in Fig. 8 scans the edge of the paper web or a line in the printed design. The proper web position is obtained by moving the roll of material to the position called for by the phototube in the scanning device. The same device is used to scan the edge of a web and correct the roll position to insure smooth roll windup when rewinding mill rolls. An installation of this device on a printing press is shown in Fig. 9.

The wartime shortage of tin brought about the necessity for thinner coating of tin on strip steel for cans. This has been accomplished by the electrolytic tinning process. The electroplating process leaves the tin surface with a silvery appearance and somewhat porous structure. It is necessary to heat the strip enough to melt and flow the tin and thus obtain a more perfect coating. Not only does an electronic high-frequency oscillator supply power for flowing the tin after electroplating, but it is also necessary to regulate the flowing of the tin so that exactly the right amount of high-frequency power is furnished, thereby avoiding spoilage. If too much power is furnished to the high-frequency induction heating coil, the flow line will occur much earlier in the heating coil than it would at lower power levels. It is therefore desired to maintain the power input to the heating coil at a level which will cause the tin to flow at a certain predetermined position in the coil. The flow line is readily distinguished because the tin coming directly from the plating tank has a very diffusing surface whereas that tin which has been flowed has a mirror surface. The regulating system is shown in Fig. 10 with a light source and phototube scanning the plated strip. The scanner detects the exact line at which this change of condition occurs. If the speed of the tinning line changes, it is necessary to modify the power input accordingly. This is accomplished through the scanner which observes that the position of flow line has changed, and which energizes through the thyratrons either relay F or R to start the induction-regulator motor. This adjusts the regulator so as to increase or decrease the power furnished to the oscillator and to bring the flow line back to the proper position.

DETECTING HOLES IN STRIP STEEL

Not all photoelectric applications are for regulation purposes. An important steel-mill application of another type is that for detecting holes in strip steel. This application is particularly desirable on steel which will be used for the canning industry. Prior to the use of pinhole detectors, it was difficult to inspect visually the strip effectively and food spoilage resulted. The pinhole detector, Fig. 11, will inspect steel strip at speeds up to 1500 fpm and detect $^1/_{64}$-in. or smaller holes. The detector operates a marker which places a visible mark on the strip at the location of the hole so that it can be readily located later on. In many installations, the detector also operates a classifier to reject defective sheets automatically, after they have gone through the shear which usually immediately follows the pinhole detector.

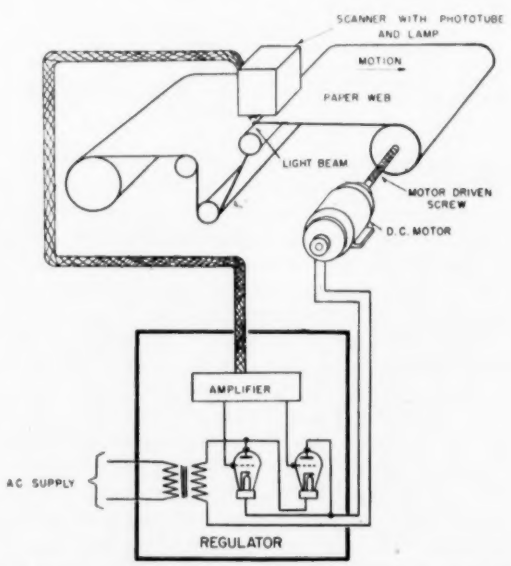

FIG. 8 SCHEMATIC ARRANGEMENT OF REGULATOR FOR CONTROLLING SLITTING OR REWINDING OF PAPER, GLASSINE, OR CELLOPHANE

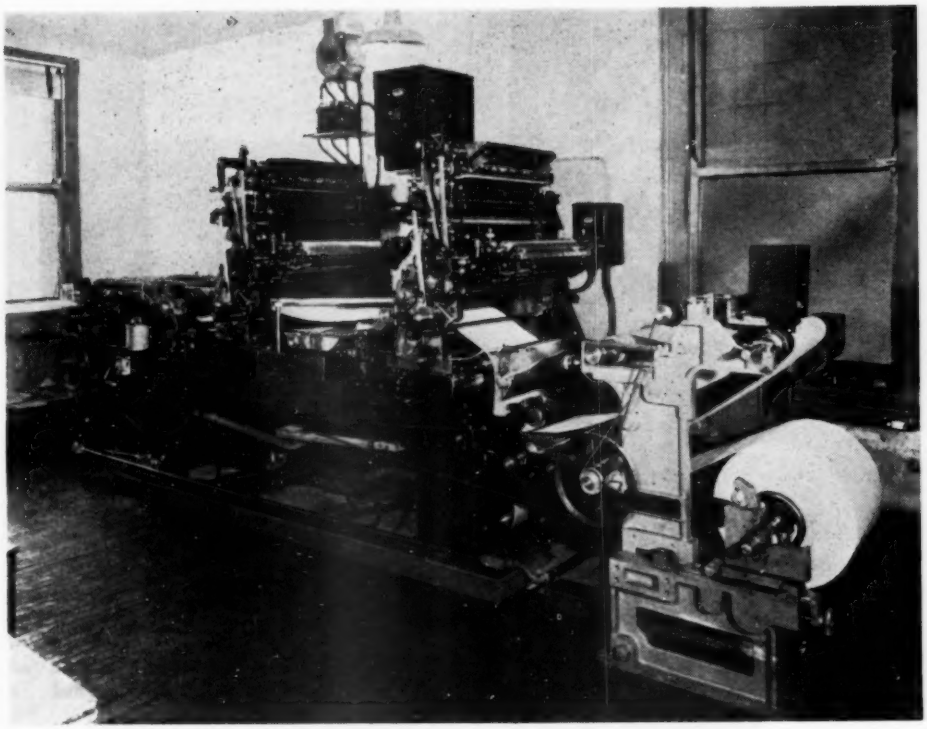

FIG. 9 SLITTER REGULATOR USED ON A PRINTING PRESS TO MAINTAIN POSITION OF PAPER WEB

The pinhole detector is probably one of the more prominent commercial applications of sorting.

Much loose publicity has been given to the use of phototubes for sorting applications. It should be realized that the phototube responds only to a difference of light energy reaching it and also in some degree to changes of the color of the light. The phototube does not have any intelligence and therefore cannot duplicate the performance of the human eye for the great majority of sorting problems. The only way in which a phototube can be made to appear to have judgment or intelligence is to design the optical system so that the phototube will receive a varying amount of light depending upon a particular characteristic of the material which it is desired to detect. The application of phototubes to sorting problems is usually very expensive because of the considerable development involved and many times cannot be justified for that reason alone. This development expense can be absorbed if the commercial possibilities for the finished design are sufficiently enticing, but if they are not, the individual user is not ordinarily willing to pay the development charges.

Many applications for photoelectric control can be taken care of by general-purpose devices called photoelectric relays which may be considered as light-sensitive limit switches. These are available in varying forms and at varying prices, depending upon the desired sensitivity and functions to be performed, and can be adapted by the purchaser to his own application. These include counting, drinking-fountain control, door control, and conveyer control as shown in Fig. 12, and numerous others known only to the many users.

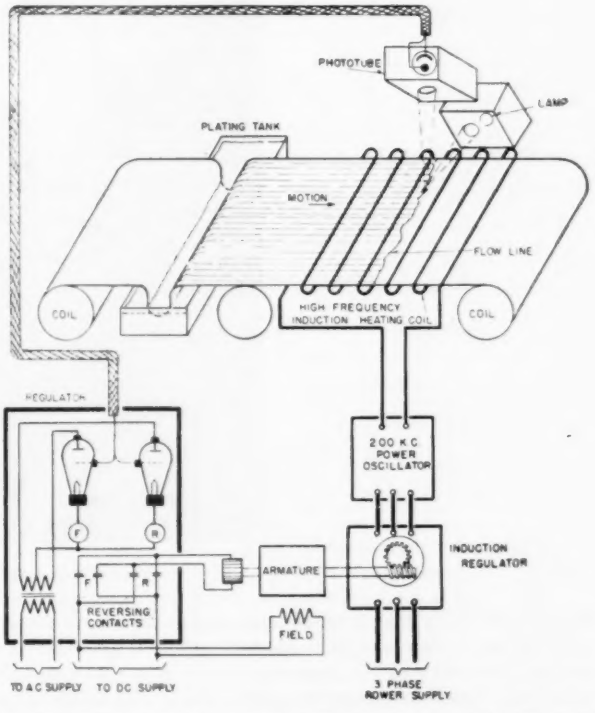

FIG. 10 SYSTEM FOR REGULATING POWER INPUT IN TIN-FLOWING PROCESS

—O— Relay coil F Forward relay
⊣⊢ Relay contact R Reverse relay

CONCLUSION

The applications described show a typical variety for electronic control. These have come about through close co-ordination of the electrical and mechanical design. Only by this co-operation has it been possible to insure that the electrical and mechanical equipment will match each other in precision and reliability. If they do not match, a regulator with $^1/_{64}$-in. accuracy may be attempting vainly to control a machine with $^1/_8$-in. backlash, or a

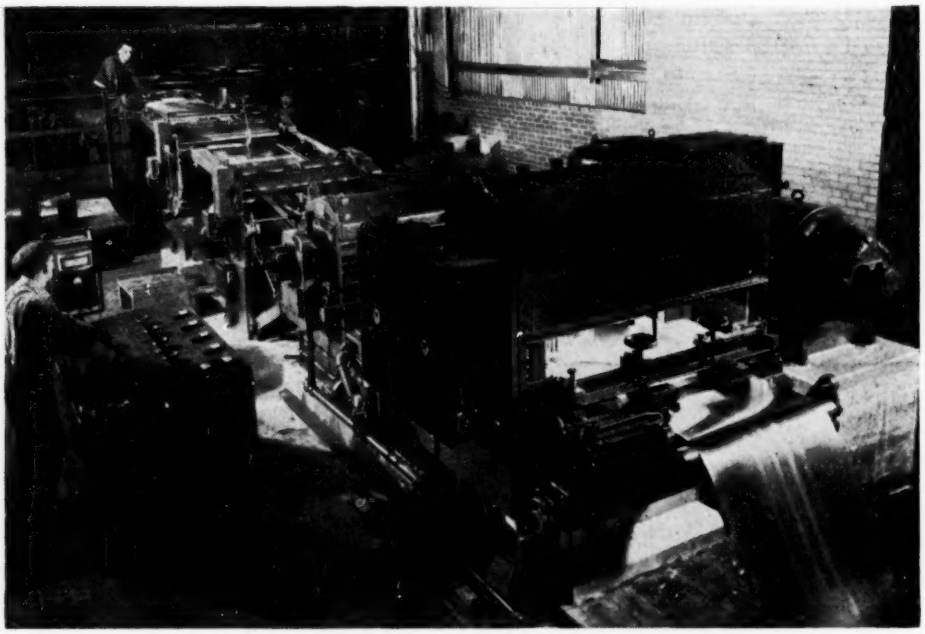

FIG. 11 PINHOLE DETECTOR IN A STEEL-STRIP SHEARING LINE

FIG. 12 COUNTING OR CONVEYER CONTROL

precision machine may lose its value because of coarse control.

Electronic control, properly selected for applications where it can perform better or less expensively, will do what seems to be miracles. This is so because new tools with incredible speed and versatility have been added to the designer's kit. His vision is thus broadened beyond the pure mechanical or the electromechanical device to the electronic tube which is purely electrical and has incredible speed and versatility. Through proper combination of all three of these tools designers are unfolding new engineering accomplishments with amazing possibilities.

Radiation Pyrometry in Turbosupercharger Testing

By V. P. HEAD,[1] WEST LYNN, MASS.

With increase in operating temperatures and speeds of turbines such as are used in turbosuperchargers, the demands for turbine-wheel and bucket temperature measurement have become increasingly exacting. Requests appear for such measurements under operating conditions with measurement tolerances varying from ±50 F in flight test to ±5 F in certain ground tests. This paper outlines the procedures used for measurements ranging from as low as 300 F up.

THE following alternate procedures have found limited application in measuring turbosupercharger turbine-wheel and bucket temperatures:

1 *Optical Pyrometry.* Bucket hot-spot temperatures have been determined with a monochromatic optical pyrometer of the disappearing-filament type. Above about 1400 F such readings have been accepted with an allowance of about ±30 F.

2 *Fusible Alloys.* Temperature versus radius curves on the wheel have been obtained with fusible-alloy plugs with accuracy limited by the interval between consecutive melting points of the alloys available. Maximum temperatures during the tests, rather than instantaneous values, were obtained and have been valuable in determining wheel operating temperatures with various cooling methods.

3 *Fusible Compounds.* Fusible compounds commercially available as pellets, with melting points at 50 F intervals, have been used to give wheel temperature versus radius curves with a probable error of 1 or 2 per cent of the absolute temperature. Again indications represent maximum values, but the pellets are made to indicate approximate instantaneous values by approaching desired test temperatures gradually with no overshoot.

4 *Contact Thermocouples.* Base-metal thermocouples, peened into the wheel at various radii, have been used successfully with slip rings to give instantaneous readings in comparing cooling methods, but speed limitations and complexity of rotating parts have prevented the more general application of this procedure.

General Methods and Applications of Thermoelectric Radiation Pyrometry

Thermoelectric radiation pyrometers commercially available have been applied to give the local temperatures at wheel-rim and bucket surfaces within about ±50 F at 1000 F, and with increase in accuracy at higher temperatures, by mounting and cooling appropriately. The area of the spot observed has been varied arbitrarily by the proximity of the pyrometer to the "target" (wheel or bucket surface), by the size of aperture, or by the use of lenses. A knowledge of the pyrometer-jacket temperature as well as the pyrometer output has been required, and the use of a cooled shutter for determining the magnitude of the "zero drift" (described in the section entitled "Theory") has helped to facilitate the readings. In flight tests, conducted by the General Electric Company and Boeing Aircraft Company in 1941, adequate results were obtained by scooping atmospheric air to cool the pyrometer mounting and prevent soot accumulation, where a spread of 50 F in the observed temperatures was permissible. The pyrometers used were of the glass-bulb vacuum thermocouple type.[2]

Such thermoelectric radiation pyrometers have been adapted to meet recent exacting demands for greater accuracy at lower temperatures. Calibration repeatability within ±5 deg over a range of temperatures from 600 F up has been obtained. The inherent error of base-metal thermocouples used to measure the calibrating-target temperatures has limited the absolute accuracy obtained.

The experimental miniature pyrometer described herein has provided instantaneous readings of wheel and bucket temperature during test and is now being employed as a guide for the control of test conditions when arbitrary temperature versus radius curves are desired.

The arrangement may be applied to the temperature measurement of gases and vapors by sighting into the end of a long "honeycomb"[3] in a well-lagged duct through which the gas may be passed.

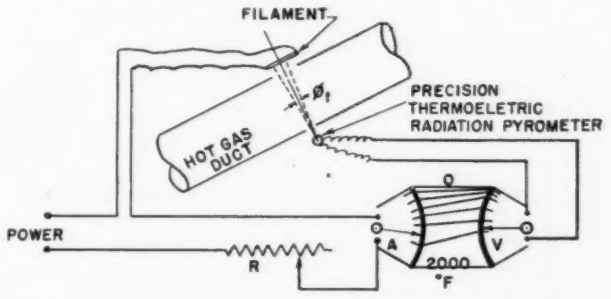

Fig. 1 Proposed Adaptation of Kurlbaum's Flame Method to Static Temperature of High-Velocity High-Temperature Gases Not Completely Transparent

(A: Ammeter calibrated for filament temperature. V: Galvanometer indicating filament temperature by thermoelectric radiation-pyrometer output, calibrated with clean, dry cold air in duct. The static temperature of hot gases at high velocity may be measured by replacing the optical pyrometer of Kurlbaum's flame method[4] with a precision thermoelectric radiation pyrometer. One possible arrangement is suggested in Fig. 1, in which the manual adjustment of a single resistor permits variation of a background temperature until the actual and indicated background temperatures are equal, when the indicated tempera-

ture will be actual gas-static temperature, regardless of gas emissivity.

It is proposed that the arrangement may be used as a secondary standard in the calibration of base-metal thermocouples, thermometers, and the like, for temperatures above 1000 F.

It is conceivable that rigorous application of thermoelectric radiation-pyrometry theory may permit sharper definition in the "International Centigrade Temperature" scale at elevated temperatures, reducing the spread entailed by the brightness-comparison methods of optical pyrometry, since the "readability" of the output increases with approximately the third power of the measured temperature.

An interesting application is the measurement of pressure at high vacuum, using a target of constant temperature such as a lamp with controlled voltage, and connecting the pyrometer chamber to the vacuum to be measured, as described further under "Tests."

Arrangements. Fig. 2 shows the arrangement of a mounting used in a high-velocity hot-gas stream. The commercial pyrometer, an evacuated-glass-bulb type, was wrapped in aluminum

foil and encased in a heavy-walled tube of high thermal conductivity and high specific heat, which acted as a heat "flywheel" to prevent sudden changes in pyrometer temperature. A thin layer of thermal insulating material supported the massive tube within a cylindrical water-cooled outer jacket. An additional jacket carrying air prevented soot accumulation at the sighting aperture. A water-cooled reference target permitted zero-drift observation, and even with the best combination of heat capacity and thermal insulation, corrections amounting to several times the full-scale reading of the galvanometer were frequently required. For this purpose a zero-drift compensator was inserted in the pyrometer circuit, Fig. 3, so that by introducing the proper electromotive force, the galvanometer could be rapidly set to zero. The reflection of extraneous radiation from the surface of the reference target left this adjustment open to some question, and the necessity for the elimination of zero drift, together with the need for reduced bulk in the pyrometer mounting led to the development of the miniature radiation pyrometer, Fig. 4.

Fig. 4 shows the essential features of a thermoelectric radiation pyrometer embodying the theoretical requirements for precision. Tests conducted on a model of this type show that its repeatability is well within the limits of error of the base-metal thermocouples employed in calibrating. It has the further advantage of small size and self-contained "heat capacity," so that the jacket required for mounting in a high-velocity hot-gas stream may be kept to a minimum bulk. The necessity for a cold reference target and zero-drift compensator has been eliminated.

Attempts to seal this model to hold a vacuum permanently have been unsuccessful to date and the device is employed at atmospheric pressure. The sacrifice of high output has been largely offset by the relative freedom from changes in calibration

with small changes in jacket temperature, a characteristic which is highly desirable. The output is read on a light-beam-type galvanometer of portable construction having a full-scale deflection (100 mm) at about 50 μv. The characteristics of the pyrometer are such that a relatively small target temperature range is conveniently spread over the upper 90 per cent of the scale range, Fig. 7(*b*). The use of a direct-reading galvanometer requires that there be no change in lead resistance between calibration and application, but no attempts to use a potentiometer have been successful. The time required to balance a potentiometer permitted inestimable zero drift with the commercial high-output-type pyrometer, and the readability of the potentiometers available has been inadequate for the miniature type.

NOMENCLATURE

The following nomenclature is used in discussing the theory of thermoelectric radiation pyrometry:

T_t = target absolute temperature
T_j = absolute temperature of pyrometer jacket
T_r = absolute temperature of pyrometer receiver
K_0 = constant governing radiation between target and receiver
K_1, U_1 = constants governing radiation between receiver and jacket
K_2, U_2 = constants governing convection between receiver and jacket
U_3 = constant governing conduction between receiver and jacket
ϕ_t = solid angle of radiant influx from target to pyrometer receiver
y = exponent of temperature difference applicable to convection between receiver and jacket

Theory of Thermoelectric Radiation Pyrometry

Fig. 5 shows an idealized radiation pyrometer: a small receiver of low heat capacity, a spherical jacket of high heat capacity and temperature T_j, and a transparent window through

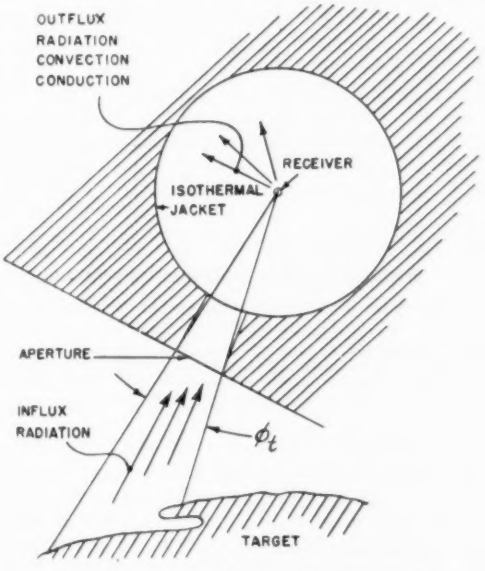

Fig. 5 Idealized Radiation Pyrometer

which a target of temperature T_t may be "seen" by the receiver through a solid angle of ϕ_t steradians. We may write the steady-state energy-flow equation governing the receiver temperature T_r

$$K_0(T_t^4 - T_r^4) = K_1(T_r^4 - T_j^4) + K_2(T_r - T_j)^y + U_3(T_r - T_j) \quad [1]$$

or in words, the influx radiant energy to the receiver is equal to the net energy transfer from receiver to jacket by radiation, convection, and conduction.

We may introduce a gross approximation for the convection term without seriously jeopardizing our qualitative conclusions

$$K_2(T_r - T_j)^y = U_2(T_r - T_j) \quad [2]$$

If the difference between T_r and T_j is less than, say, 1 per cent of either, the receiver-to-jacket radiation term may be written with fair precision

$$K_1(T_r^4 - T_j^4) = U_1 T_j^3(T_r - T_j) \quad [3]$$

On the left side of Equation [1], T_r may be replaced by T_j, since compared to T_t their difference is in general negligible.

We may now rewrite Equation [1] to give a function which is more readily scanned by eye, if slightly less precise

$$K_0T_t^4 = (U_1T_j^3 + U_2 + U_3)(T_r - T_j) + K_0T_j^4 \quad [4]$$

Then in order to measure T_t with precision, we must measure precisely a quantity proportional to $(T_r - T_j)$ and we must know T_j itself at least approximately.

Many forms of radiation pyrometers have been built in which radiation from a hot target is intercepted by a receiver to produce a temperature difference between the receiver's "hot" junctions and "cold" junctions located vaguely somewhere else. It must here be recognized that the criterion temperature difference is that between the receiver and the jacket walls. Failure to locate the thermoelectric cold junctions at the walls leads to a time lag between the walls and the cold junctions when the slightest drift in jacket temperature occurs. This will produce the "zero drift," previously referred to, which in low-temperature applications may frequently amount to *several hundred per cent* of the criterion temperature difference $T_r - T_j$, and render the output of the pyrometer meaningless. This random location of cold junctions "somewhere else" may be largely responsible for the prevalent notion that radiation pyrometry is impractical at temperatures appreciably below 1400 F.

Let us therefore locate in our ideal pyrometer a thermoelectric element with hot junction at the receiver and with cold junctions at the walls, and since we will require a knowledge of $T_r - T_j$ to within a few thousandths of a degree, let us use a massive high-conductivity jacket to assure that its temperature will be *uniform* throughout.

The term $K_0T_j^4$, Equation [4], will be found negligible for 0.1 per cent accuracy in target temperature measurement, when T_t is more than 4 times T_j, while a 4 per cent variation of T_j from that at which calibration was made will be negligible when T_t is only about 2.5 times T_j. Thus at normal room temperature, T_j may vary ± 20 deg with no effect when T_t is above about 800 F, so far as the influx of radiant energy from the target is concerned.

A more troublesome effect of jacket temperature deviation lies in the variation of radiant energy transfer within the pyrometer, indicated by the factor $U_1T_j^3$, Equation [4]. When we strive for high output by evacuating the pyrometer jacket and making the thermoelectric elements as slender as possible (decreasing U_2 and U_3), we make the effect of jacket temperature change more and more critical. By retaining a high convection rate at a sacrifice of output, and by polishing the inner jacket wall to reduce U_1, we may render the effects of small deviations of jacket temperature negligible.

The coefficient K_0, Equation [4], is dependent upon the geometry of the arrangement and the "blackness" of the target surface. It may be increased by increasing the value of ϕ_t by the change of aperture size, usually entailing an undesirable increase in area of the target portion viewed, or by the use of a lens. A lens or window is never perfectly transparent, and contributes to the effective jacket temperature. A large lens external to the heavy jacket proper is therefore apt to present difficult temperature-control problems and is to be avoided. Constant K_0 may be further increased by pretreatment of the target surface as described under "Tests." Here repeatability of calibration is even more important than the increase in output.

The radiation transmission within the pyrometer may be reduced for increased output by polishing the inner-jacket-wall surface. The conduction factor U_2 has been commonly reduced by using extremely thin thermocouple wires or ribbons.

The convection factor U_3 is a function of the shape, size, and pressure of the jacket interior. In general, evacuating a pyrometer will increase its output by a ratio of 7 or 10 to 1. The

transition of sensitivity occurs rather suddenly over a limited range of pressures, through which the mean free path of the molecules of gas in the jacket appear to be of comparable order to the linear dimensions of the inner jacket chamber. It must be remembered that the tempting increase in output will demand much closer control and measurement of the pyrometer jacket temperature, unless the radiation factor $U_1T_j^3$ can be reduced proportionately. A more detailed analysis of the constants involved and their bearing upon the problem of jacket temperature deviation has been given elsewhere.[5]

A rigorous analysis of pyrometer performance will yield an equation very different from Equation [4], involving among other things an integration of a function of "monochromatic" radiation "density" in a differential spectral band at varying temperature with respect to the spectral distribution of a non-black surface, further modified by the selective transmission of the particular window or lens material; hardly a feasible project in wartime. It is sufficient to say that the result is not a fourth-power function, nor is the pyrometer in any sense a "total radiation" pyrometer. Empirical formulas, involving a temperature exponent between 4 and 5, have been found to fit portions of the calibration curves, but they have contributed nothing to the usefulness of the project. Attempts to use Equation [4] for any but qualitative considerations should be avoided.

Tests of Commercial and Experimental Pyrometers

1 Tests of zero drift in a commercial vacuum-type pyrometer were conducted to determine the optimum arrangement of thermal resistance and capacitance between a water-cooled housing of fixed diameter and the pyrometer. No aperture or target was used. The criterion for zero drift was the pyrometer-output versus time curve of each arrangement, produced by a sudden drop of 30 deg F in water temperature. Fig. 6 shows the results obtained with seven such arrangements, which are numbered in order of increase of "heat-mass" concentration. The dashed line through the peaks of these curves shows the trend from high drift of short duration to low prolonged drift. Curve 7 was obtained with an arrangement similar to Fig. 2(*b*), which in service permitted zero-drift adjustment, a target observation, and a good zero check after observation.

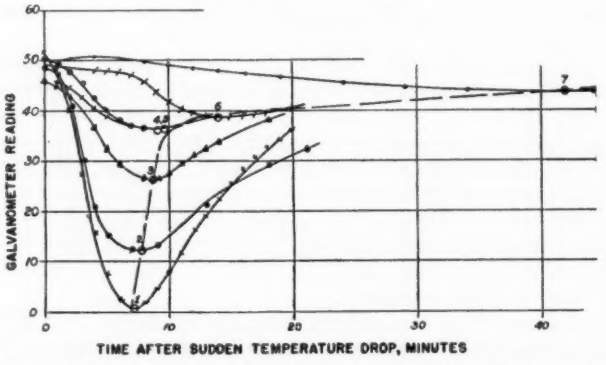

Fig. 6 Zero Drift in a Commercial Vacuum-Type Pyrometer
(Solid lines: zero-drift versus time curves produced by a sudden 30 F drop in cooling-water temperature with seven combinations of thermal resistance and capacitance confined in outer jackets of equal size. Dashed line: trend of magnitude and duration of zero drift with variation in jacket construction, indicated by the peaks, i.e., numbered points, of the solid lines. Point numbers go up with increase in "heat-mass" concentration of the jacket arrangements tested.)

Zero drift in the experimental pyrometer, Fig. 4, was determined by a sudden increase of 37 deg in the jacket temperature. The zero drift persisted for about 7 min, and its maximum value was about four galvanometer divisions at the end of 3 min. The effect of this zero drift is shown in Fig. 9 (*b*). Since no such sudden jacket transients occurred in service, the use of a zero adjuster and cold reference target was discontinued, eliminating the reference-target reflection error previously described.

2 Repeat calibrations at several jacket temperatures indicated the significance of jacket deviations in service. The commercial pyrometer required a correction of a little over 1 deg per deg deviation of jacket temperature at a target temperature of 1200 F, and an increase in the correction as the target temperature rose. The corresponding correction for the experimental pyrometer without vacuum was less than $^1/_4$ deg per deg, with a tendency to decrease with an increase in target temperature. This tendency is not apparent from Equation [4] and is best explained by the fact that the convection exponent y, Equation [1], is appreciably greater than unity, so that the value of U_2, Equation [4], increases with $(T_r - T_j)$. In words, the rate of heat transfer between the receiver and jacket by convection increases with target temperature faster than does the transfer by radiation. The effect upon the required correction is a real trouble saver.

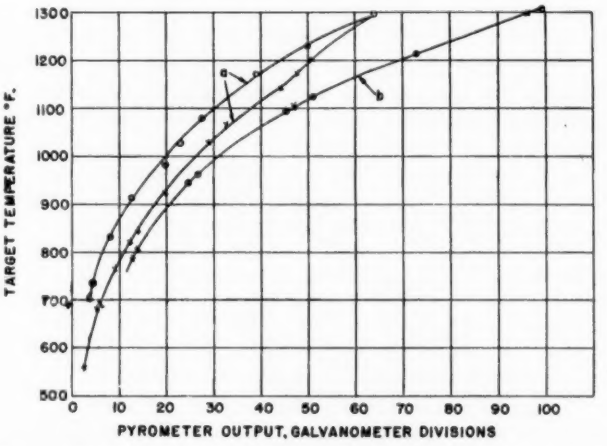

Fig. 7 Effects of Target Pretreatment on Thermoelectric Radiation Pyrometry
(*a*, Target polished before test. *b*, Target lightly sandblasted and preheated to 1400 F. Encircled test points indicate increasing temperature. Crossed test points indicate decreasing temperature. Point scatter, curve *b*, is typical of pyrometer repeatability.)

3 Tests on the effects of target emissivity drift were conducted by using a calibrating target of test-target material, initially bright, which was gradually heated and cooled. Readings of pyrometer output with increasing and decreasing target temperature were observed. Fig. 7 shows the results obtained with two initial surface conditions. It was found that a light sandblast of the calibrating target rendered the emissivity drift negligible, Fig. 7(*b*), though in subsequent tests where turbine-wheel temperatures were to be observed, both wheel and calibrating target were preheated to the highest contemplated test temperature (or as closely as possible without metallurgical damage) after a light surface sandblast.

4 The "calibration-repeatability" tests were identical with the target emissivity variation tests where no visible effect of emissivity variation occurred, Fig. 7 (*b*). In addition, a series of closely spaced calibration points was obtained and plotted on a highly expanded scale. The scatter of the test points about a smooth curve drawn through them is shown in Fig. 9 (*a*) and (*c*), where the greatest deviation noted is $3^1/_2$ deg, or a spread of

[5] "An Improved Radiation Pyrometer," by T. R. Harrison and W. H. Wannamaker; "Temperature—Its Measurement and Control in Science and Industry," American Institute of Physics, Reinhold Publishing Corporation, New York, N. Y. 1941, pp. 1206–1224.

7 deg. It was expected that the point scatter would decrease at elevated target temperatures because of the decrease in slope of the calibration curve. In practice, it was found that at temperatures above 1000 F, target-temperature versus time curves taken with the radiation pyrometer were much smoother than those taken with the base-metal contact thermocouple peened into the surface of the target. It is justifiable, therefore, to blame the persistent scatter at elevated temperatures on the poor adaptability of the contact thermocouple to precise measurement of surface temperatures when air or gases at different temperatures are present.

In early wheel tests, vibration produced occasional shift between pyrometer and jacket, changing the solid angle of sight. Another source of difficulty was sooting of the pyrometer aperture, which was eliminated by the use of an air jacket outside the water jacket. This also eliminated the water film formed occasionally by condensation on the aperture. Water is extremely opaque to infrared radiation. All of these possibilities must be carefully guarded against in any application.

5 Tests on the effect of varying internal pyrometer pressure were conducted on the experimental pyrometer, Fig. 4, by sighting on an electric lamp of controlled voltage and connecting the evacuating tube to a good vacuum pump. Fig. 8 shows the result and is comparable to the characteristic curve of a thermocouple-type vacuum gage. Note that rough evacuation produces no appreciable change in sensitivity and that there is a point, presumably where conduction and radiation transfer swamp out the remaining convection transfer, where further refinement of the vacuum is useless. It is interesting to note that the inflection point of the curve in Fig. 8 occurred at a pressure corresponding to a mean-free-path for air molecules of approximately 0.1 in., while the actual distance from receiver to inner jacket wall was about 1/8 in.

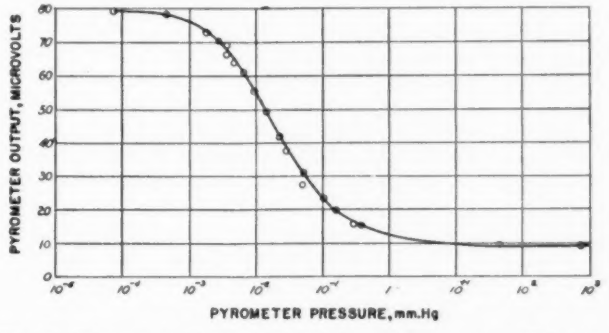

FIG. 8 EFFECTS OF INTERNAL PRESSURE VARIATION ON THERMOELECTRIC-RADIATION-PYROMETER OUTPUT WITH CONSTANT TARGET TEMPERATURE

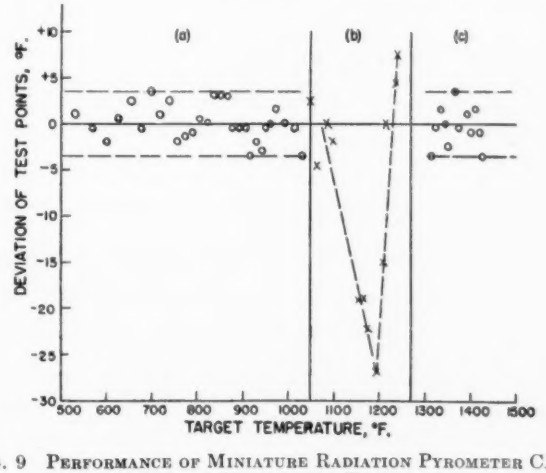

FIG. 9 PERFORMANCE OF MINIATURE RADIATION PYROMETER CALIBRATED AT ATMOSPHERIC PRESSURE

(*a*, *c*, Point scatter about a smooth curve. Pyrometer jacket held at 66 ± 2 F. *b*, Zero drift introduced by a sudden increase of 37 F in jacket temperature.)

To date, the device in Fig. 4 has presented sealing difficulties and has been applied in turbine-wheel temperature measurement at atmospheric pressure in mountings similar to that shown in Fig. 2, with considerable reduction of bulk. The resulting reduced sensitivity has been offset at low temperatures by the use of certain crystalline salt apertures, transparent to infrared, in place of glass. The relative freedom of this arrangement from the effects of small jacket-temperature deviation has reduced personal supervision of tests to a minimum.

CONCLUSIONS

The requirements for basically sound thermoelectric radiation pyrometry may be briefly stated as follows:

1 The target surface must be of constant "blackness" throughout calibration and application.

2 It is necessary to make a precise measurement of the difference in temperature between a receiver and its surrounding jacket, or the corresponding emf or galvanometer equivalent.

3 It is necessary to measure or know at least approximately, and in applications below about 800 F, precisely, the temperature of the jacket.

4 It is advantageous to sacrifice the high output associated with an evacuated pyrometer when freedom from the effects of small jacket-temperature variations is essential.

5 There must be interposed between the pyrometer cold junctions and a cooled outer jacket a high heat-capacity, high-conductivity jacket, surrounded by at least a thin layer of good thermal insulation.

Thermoelectric radiation pyrometers are normally free of the deteriorating influences to which high-temperature contact pyrometers of even the noble-metal thermocouple type are subject. A little regard for the thermodynamics governing their performance has lowered the minimum practical application temperature from 1500 F[6] to about 300 F, and there is no reason to state a minimum for further development. The field of application has been broadened from industrial-furnace applications, requiring about 1 sq in. of "target" area, to include local surface measurement with target diameters of 1/4 in. or less, with repeatability equal to or greater than that of the contact thermocouple. Procedures for improved hot-gas temperature measurement utilizing the thermoelectric radiation pyrometer are in sight. The integration of the laws of monochromatic radiation over the broad spectral band of a suitable window or lens material to create a reproducible high-temperature standard of long life is not beyond the realm of postwar probability.

ACKNOWLEDGMENTS

High-Speed Multiple-Point Potentiometer Recorder for Measuring Thermocouple Temperatures During Test-Plane Flights

By I. M. STEIN,[1] A. J. WILLIAMS, JR.,[2] AND W. R. CLARK[3]

Measuring exhaust-gas temperatures in flight-testing large planes requires the use of thermocouples of special design and requires also an instrument capable of recording rapidly, accurately, and directly a large number of temperatures. This paper describes a multiple-point, null potentiometer for this purpose. It accommodates 140 thermocouples and records each temperature in 1.63 sec. Flexible arrangements are provided for switching the numerous thermocouples, and this switching may be operated manually by push-button control and also automatically by the recorder. Operating characteristics and performance in flight tests are discussed.

Introduction

IN the early part of December, 1940, representatives of the National Advisory Committee for Aeronautics (N.A.C.A.) Special Subcommittee on Exhaust Gas Turbines and Intercoolers approached the A.S.M.E. Committee on Industrial Instruments and Regulators with a request for assistance in solving certain problems involved in the measurement of high temperatures in high-velocity gas streams. On December 4, 1940, the A.S.M.E. Committee on Industrial Instruments and Regulators appointed a Subcommittee on Exhaust Gas Temperature Measurement to co-operate with the N.A.C.A. subcommittee in solving these problems. The general problem assigned to this special A.S.M.E. subcommittee was made up of two parts, the first one involving the design of the sensitive elements, that is, the thermocouples, and the second one involving the instrumentation. A paper reporting on the first part of the problem has been presented by W. J. King.[4] The present paper deals with the instrumentation part of the problem.

Among the first steps taken by the special A.S.M.E. subcommittee was the circularization of all well-known domestic suppliers of thermocouples and measuring instruments for use with thermocouples, in an attempt to find what, if anything, might be available to meet the particular requirements of the exhaust-gas-temperature problem. In this way some information was obtained on sensitive elements, but all answers to the inquiries with reference to the availability of instruments were negative. As a result of the negative returns to the circular letters, the members of the special subcommittee were urged to encourage developments that might lead to the solution of the instrumentation problem.

The type of instrument needed was a high-speed multiple-point recorder, preferably of the potentiometer type. Fortunately, certain elements essential in the design of such an instrument were either fully or partially developed at the time the request was received from the N.A.C.A. subcommittee, and the availability of these elements shortened considerably the time needed for the development of the complete high-speed multiple-point potentiometer recorder described in the present paper. The paper is limited to a general description of the recorder and its adaptability to the exhaust-gas-temperature problem. A detailed discussion of the electrical circuits involved is reserved for a later paper, as are the applications of the recorder to other problems.

Recorder Requirements in Exhaust-Gas-Temperature Measurements

Number of Points. In each test installation, many thermocouples are involved, and it was felt that one instrument should be capable of recording temperatures of at least 50 thermocouples and preferably of 100 or more.

Ranges and Accuracy Required. The temperatures involved range from those approaching —100 F to those approaching 2000 F. A limit of error of 5 F was desired.

Recording Speed. A relatively high speed of recording was sought because the temperature measurements were to be made during flight tests of planes, and it was desired to record as many temperatures as possible while the plane was gaining or losing altitude at a rapid rate. If possible, the objective was to obtain 20 or more readings in 10 sec, that is, a recording speed of $^1/_2$ sec or less per point. However, it was desired to have the record appear immediately on a printed chart or tape. In other words, the time required for photographic development of charts or tapes was to be avoided. It was recognized that without resorting to photographic recording, it might be necessary to allow more than $^1/_2$ sec per point for recording.

Push-Button Operation. One requirement of the switching facilities was that the arrangement should be such that by means of push-button operation, the recorder could be promptly connected to any one of the many thermocouples and allowed to record continuously the temperature of that thermocouple.

Flight Requirements. Because its principal use would be in connection with flight-testing of planes, it was necessary for the recorder to meet the general requirements of flight instruments; namely, it must operate from the d-c power supply available on planes, its accuracy and reliability must not be unduly influenced by changes in level, by vibration, or by the wide range of ambient temperatures encountered in aerial navigation. In addition, the instrument should not produce radio interference and, naturally, should be as small and light as practicable. Because the instrument was to be used primarily in large planes, it was not considered necessary to reduce the size and weight to the extent that would be essential for use in smaller planes.

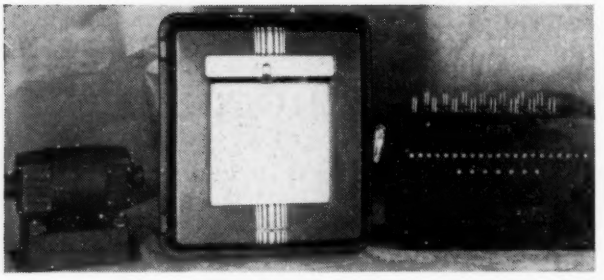

FIG. 1 FLIGHT-TEST RECORDER AND ACCESSORIES

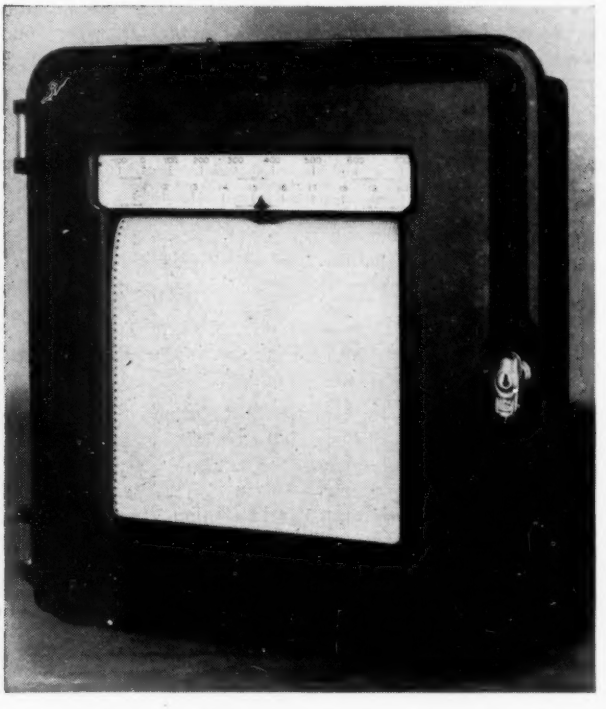

FIG. 2 FLIGHT-TEST RECORDER, SHOWING DETAILS OF SCALES

GENERAL DESCRIPTION

A general view of the recorder and its accessories is shown in Fig. 1. The accessories are a multiple-point switch box and a small rotary converter. The weight and dimensions of these items are as follows:

Recorder: Weight, 110 lb; size, $18^3/_8 \times 20^1/_8 \times 12^7/_8$ in. This weight is for a steel case. If aluminum were available, the weight would be 95 lb.

Switch box: Weight, 55 lb; size, $17^7/_8 \times 11^5/_{16} \times 9^{11}/_{16}$ in. This weight includes the 15 plug connectors which have a total weight of 4 lb.

Rotary converter: Weight 35 lb; size, $11^1/_2 \times 9^1/_4 \times {}_4{}^6$ in. This weight is for a 200 v-a unit. If available, a 150 v-a unit would be ample and the weight would be 26 lb.

Power Supply. The recorder proper is designed to operate from a 115-v, 60-cycle supply. The switch box and one or two auxiliary circuits in the recorder are designed to operate directly from the d-c supply available in the plane, usually 24 or 28.5 v. To provide for complete operation from the d-c supply in the plane, the small rotary converter is used to obtain the 115-v 60-cycle supply for the recorder proper. The total power requirement from the d-c supply is 220 w continuous, plus a maximum momentary requirement of 95 w when all stepping switches are being reset simultaneously.

Recorder. A large view of the recorder proper is shown in Fig. 2, and a block diagram of the circuits is shown in Fig. 3. From Fig. 2, it will be seen that the recorder is provided with two ranges, one spanning 800 F (—100 to +700 F) and the other spanning 950 F (1050 to 2000 F). The former is calibrated to correspond to the characteristics of copper-copnic thermocouples, and the latter to correspond to the characteristics of chromel-alumel thermocouples. These particular ranges and calibrations met the requirements of a particular problem. It will be noted that there is a gap of 350 F between the upper end of the lower scale and the lower end of the upper scale. If, in some other problem, temperatures were to be measured in the range where this gap exists, the matter could be handled in one of two ways: Either the two ranges could be expanded somewhat to close the gap, or a third range, closing the gap and overlapping the other two ranges, could be added. The former method would entail some sacrifice in accuracy whereas the latter would not. The range-changing is completely automatic in a

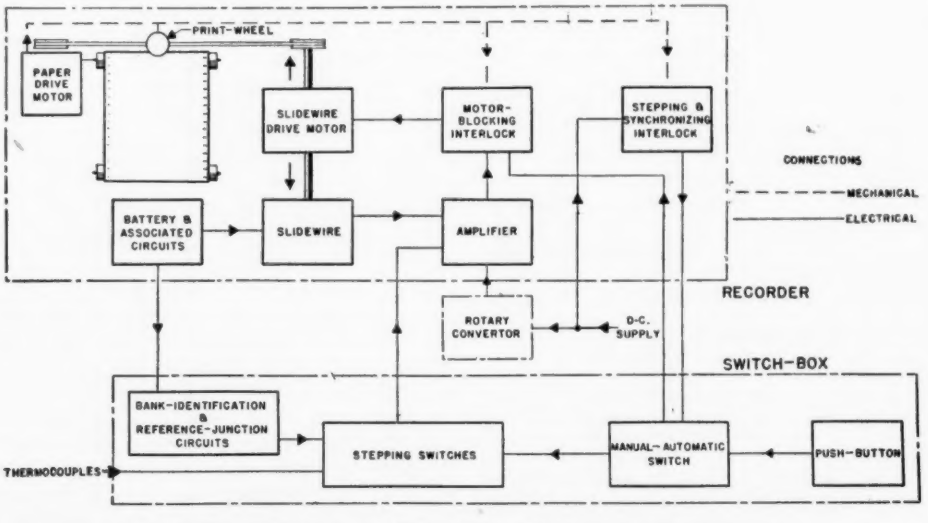

FIG. 3 BLOCK DIAGRAM OF FLIGHT-TEST RECORDER AND ACCESSORIES

manner which will be described more fully in connection with a discussion of the operating characteristics.

The recorder circuit is that of a null potentiometer. The recorder contains no galvanometer and is not affected by changes in level or by acceleration. It is built to withstand the vibrational effects encountered in plane service, provided only that it is mounted in the usual antivibration frame. The thermocouple voltage is modulated by a vibrating element and then passes through an electronic amplifier. The output of the amplifier is sufficiently powerful to operate a reversible motor, which moves the balancing contact on the slide wire of the potentiometer circuit. Associated with the potentiometer is a resistance-capacitance network, which provides appropriate damping. The vacuum tubes used in the amplifier are all of standard types, thus facilitating replacement should this be necessary. Life expectancy on these tubes is at least 1000 hr.

Switch Box. An enlarged view of the switch box is shown in Fig. 4. The seven telephone-type keys, shown at the center of the panel, control the circuits of 140 thermocouples arranged in banks of 20. As many of the seven banks as desired may be cut out of service by throwing down the respective keys. These may be cut out of service in any order, and even if all but one of the banks are cut out of service, the recorder will continue to recycle on the 20 thermocouples connected to the remaining bank. The bank on which the recorder is operating at any moment is indicated clearly by a signal lamp immediately above the bank key. The longer row of signal lamps above the bank signal lamps indicates the particular thermocouple, in any bank, that is being recorded at the moment. It will be noted that this row of signal lamps contains 21 lamps, although there are only 20 thermocouples in each bank. The additional point on each bank is used for "bank identification" on the recorder chart, as will be discussed under "Operating Characteristics."

The connections to the thermocouples are made by means of the plug connectors at the top of the switch box. Each plug connector handles 10 thermocouples so that there are two plug connectors for each of the seven banks. The "power" plug connector, at the extreme left in Fig. 4, handles the interconnections between the switch box and the recorder proper.

A quick-acting push button, shown below the fifth and sixth bank keys, provides push-button control of the bank switches, as mentioned in outlining the requirements. The telephone key, shown below the first and second bank keys, is a selector switch to give control of the switching to the recorder mechanism or to the push button.

The switch-box housing is lined completely with copper for the purpose of eliminating radio interference. The relays, switches, and other parts used in the switch box have been chosen to withstand satisfactorily the vibration and other conditions encountered in plane service.

The selector switches were chosen carefully to insure reliable operation and long life. They are of a type which has undergone exhaustive development for use in automatic-telephone circuits, and all sliding contact surfaces are heavily gold-plated, Fig. 5.

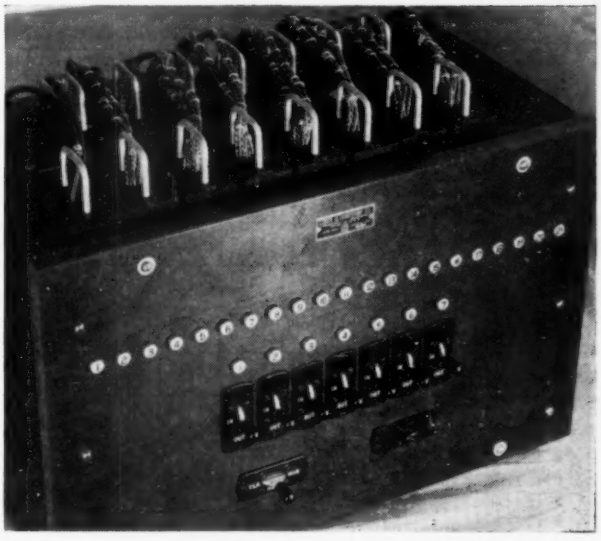

FIG. 4 SWITCH BOX, SHOWING PANEL DETAILS

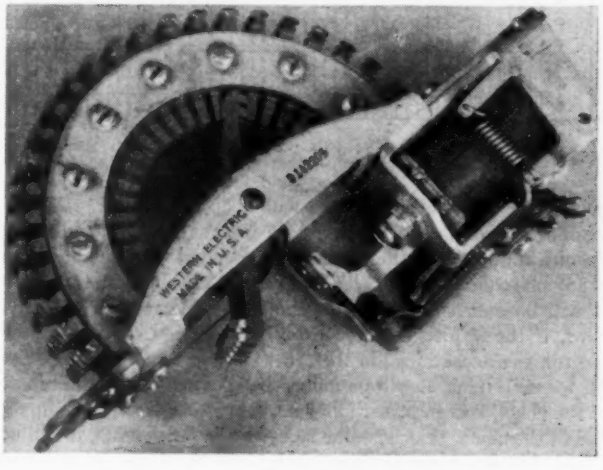

FIG. 5 SELECTOR SWITCH

OPERATING CHARACTERISTICS

Accuracy, Sensitivity, and Speed. The sensitivity of the recorder and the readability of the chart are better than ± 0.25 per cent of the scale range, and the limit of error is less than ±0.5 per cent of the scale range. In a range of 800 F, 0.25 per cent corresponds to 2 F and 0.5 per cent corresponds to 4 F. The time required for recording on each point is somewhat under 2 sec, specifically, 1.63 sec per point, so that all 147 points (140 thermocouples and 7 bank-identification points) are covered in a period of 4 min. The design of the recorder is such that the constant time-cycle of 1.63 sec is adequate to permit a complete null balance on each point regardless of whether successive points are at nearly the same temperature or are at the extreme ends of the 10-in. chart. The constant time-cycle makes it unnecessary to group the thermocouples according to their temperatures. Hence they may be grouped according to some other scheme as, for example, according to the units on which the temperature measurements are being made.

Fig. 6 is a reproduction of the recorder chart, showing a complete record of all 147 points. It will be seen that all 147 points are obtained without crowding on only an 8 in. length of chart. Because an 11 in. length of chart is always visible, at least one recording for each thermocouple is always visible. This is for a chart speed of 2 ipm. By throwing a lever, the speed of the chart may be reduced to 4 iph. This slower speed would be used in the event that it were desired to record continuously the temperature of one of the thermocouples. A careful examination of the chart will disclose a number of the operating features of the recorder. In examining the chart, it should be remembered that the normal motion is downward so that the record proceeds from the bottom to the top.

At the extreme left of the chart will be found, in order, the

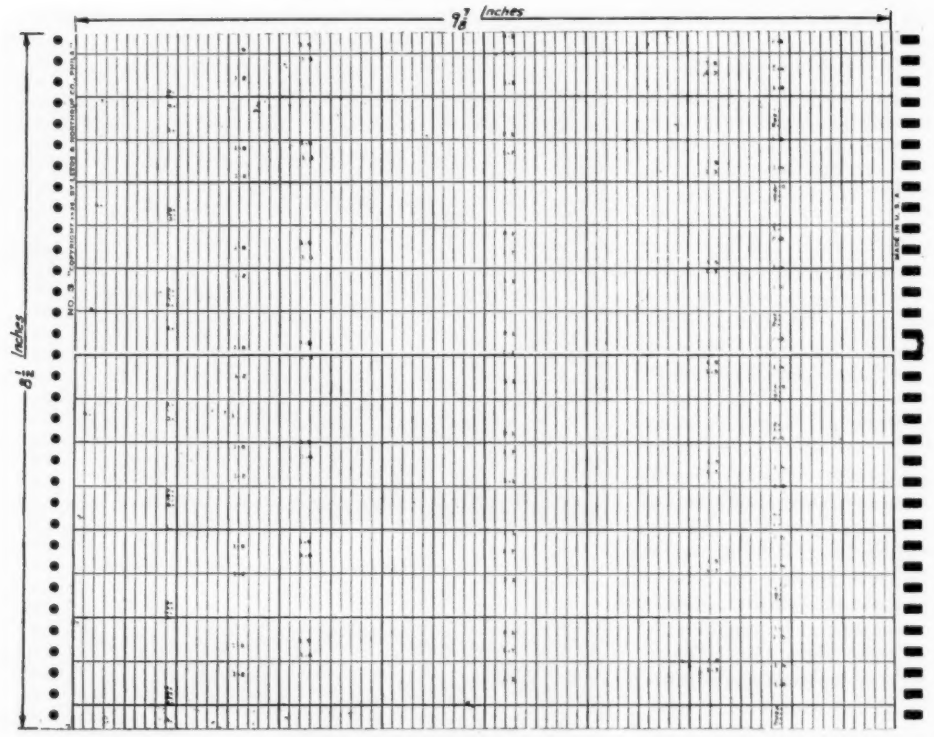

FIG. 6 REPRODUCTION OF RECORDER CHART

numerals 1 to 7, inclusive; these will be discussed later. The remaining six columns of numerals on the chart correspond to six definite voltages, and the small dots associated with each numeral in any one column should all fall at the same position on the chart. It will be seen that this condition is approached very closely. Now, if the sequence of recording is examined, that is, if the recordings are examined in the order of their numbers, from 1 to 21, for each bank, it will be found that point 21, near the center of the chart, was recorded following a printing toward the upper end of the chart, that is, point 20. On the other hand, it will be found that the recording for point 17 in the same column was made following a printing on point 16, which is much lower on the chart. Hence, the printwheel came in from a higher point on the scale to record point 21 and came in from a lower point on the scale to record point 17, and yet the two points are in nearly perfect alignment. This is a reliable index of the sensitivity and reproducibility of the recorder mechanism. If the first and the last of the six columns are examined, it will be found that, in a number of cases, series of successive numerals appear in the same column. For instance, near the upper part of the last column, points 7, 8, 9, and 10 were recorded successively. The recording for point 6 will be found to be near the other end of the chart. Hence point 7 was recorded after a large travel of the printwheel, whereas points 8, 9, and 10 were recorded without any occasion for travel of the printwheel, but the recording for point 7 is in perfect alignment with the recordings for points 8, 9, and 10. This is an indication that the 1.63 sec allowed for recording each point is ample to provide for complete balance, even when the temperatures to be recorded are widely spaced on the chart.

The balancing characteristic of the instrument may be recorded automatically by adding a pen to the printwheel carriage and by using an increased chart speed. The normal balancing characteristic obtained in this way is shown in Fig. 7, in the curve marked "damped." The balancing characteristic with the damping removed also is shown in Fig. 7. These curves are for a chart traverse approximating 40 per cent of the full width of the chart, and the chart speed was more than 20 times the normal chart speed of 2 ipm. Referring to the damped curve, it will be seen that about $^2/_{10}$ of the total cycle of 1.63 sec is required for the linear traverse (motor running at constant speed), and that about $^3/_{10}$ of the total cycle is required by the residual oscillations. The time for the linear portion of the traverse increases in proportion to the length of the traverse, and the time for the residual oscillation is a constant. Hence, for a full-scale traverse, one half of the full time-cycle would be required for the linear portion of the traverse. Adding $^3/_{10}$ for the residual oscillations gives a total time corresponding to $^5/_{10}$ of the complete cycle. As may be seen from Fig. 8, more than 92 per cent of the complete cycle is available for balancing. Similar analysis would show that, without damping, the oscillations would be sustained beyond the end of the cycle and would cause erratic operation.

Referring to Fig. 8, the diagram marked "automatic operation" shows the sequence of operations and the times available for them, when the switching is being done automatically by the recorder. It will be seen that 1.51 sec, or more than 92 per cent of the total cycle of 1.63 sec, are available for balancing.

Bank Identification. The numerals 1 to 7, inclusive, at the left of the chart, Fig. 8, are used for bank identification. It will be noted that each of these identification points occupies a specific position on the chart. The fact that each of these identification markings appears in its own particular position on the chart

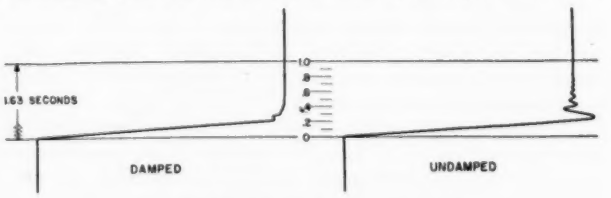

FIG. 7 BALANCING CHARACTERISTIC

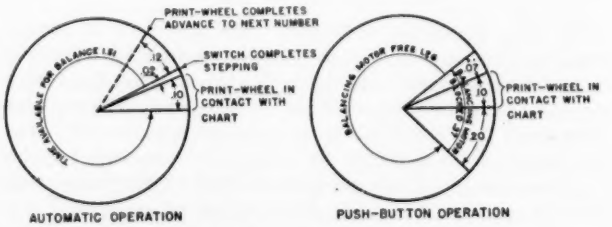

FIG. 8 SEQUENCE OF OPERATIONS
(Numbers on circle diagrams give time in seconds.)

indicates that there is complete synchronization between the switching mechanism and the printing mechanism. The bank identification is accomplished in the following manner: On bank No. 1 there is no thermocouple connected to the No. 1 switch point. Instead this switch point is connected to an electrical network so arranged that the recorder printwheel prints No. 1 at a specific location on the chart assigned for the identification of the No. 1 bank. Likewise, in bank No. 2 there is no thermocouple connected to the No. 2 point on the switch, the connections to the No. 2 point again being made to a network which causes the recorder printwheel to print the numeral 2 at a place on the chart specifically assigned for the identification of the No. 2 bank; and so on for all seven banks.

Automatic Range-Changing. In discussing the two or more ranges provided for the recorder, it was mentioned that range-changing is completely automatic. This is accomplished in the following manner: Each one of the seven banks of 20 thermocouples may be associated with a different network to provide a different recorder range for each bank, or several of the banks may be connected to provide the same range while the remaining bank or banks may be connected to provide another range. For instance, if most of the thermocouples were to be of the copper-copnic type for measuring temperatures in the range of —100 F to +700 F, the first six banks would be associated with that range on the recorder, and the seventh bank would be associated with the range of 1050 to 2000 F, calibrated for chromel-alumel couples. In that case, as part of the automatic cycling operation, the range remains unchanged when switching between banks, until bank No. 7 is reached and then is changed automatically. When bank No. 7 has been recorded and the recorder is switched to another bank, the range automatically changes back to the lower one. Automatic range-changing applies also to push-button operation.

Automatic Reference-Junction Compensation. The fourteen plug connectors, Fig. 4, which bring the thermocouple leads to the switch box connect to fourteen receptacles which are built into a "thermal-equilibrium" chamber, housed in the top of the switch box. This chamber is provided to keep all of the reference junctions at the same temperature regardless of what that temperature may be. This thermal-equilibrium chamber also houses one or more resistance-type compensators to provide automatic compensation for the temperature of the reference junctions.

Push-Button Operation. The push-button operation feature introduced certain problems that had to be met in a reliable way and without introducing undue complications. Obviously, when the switches are operated by push button, all synchronization between the switching and the recorder printing is lost so that, when the control of the switching is returned to the recorder mechanism, some provision must be made to resynchronize the switching and printing. This is accomplished by an electrical interlock between the printwheel and the automatic selector-switch advancing mechanism. Under automatic operation, the selector switches are always started from the No. 1 position and, by means of the interlock, the switching is not allowed to start until the printwheel is ready to print the numeral "1." By itself, this simple interlock feature is not entirely satisfactory because, even though the first active selector switch were thus synchronized, the remaining ones might be out of synchronism due to having been left in random positions as the result of push-button operation. Of course, after a full cycle, involving the automatic operation of all seven selector switches, the synchronization would be complete, but this might require an interval of 4 min, which is much too long. This delay is overcome by causing all selector switches to "clear" automatically at the time the switching control is transferred from "push button" to "automatic." The "clearing" operation sends all selector switches to their No. 1 positions in a maximum of 6 sec. The automatic synchronization of the printwheel, which follows immediately, requires a maximum of 34 sec, so that the total time for complete synchronization varies from a minimum of less than 1 sec to a maximum of 40 sec.

Although the constant-time printing cycle is advantageous in several respects, its use in combination with push-button operation introduced another problem. Under push-button operation, the selector switches are stepped quickly from one thermocouple to another without waiting for the recorder to balance and print. Hence the recorder might be attempting to rebalance at the instant the printwheel was in contact with the paper, thus causing damage to the chart, the printwheel, or both. This problem was met by interlocking the balancing motor with the printwheel, so that, at the moment the printwheel is in contact with the chart, the balancing motor is prevented from operating. This interlock is effective only when push-button operation is used. It is unnecessary during automatic operation from the recorder (see Fig. 8, diagram marked "push button").

"Grounding" of Thermocouples. In some applications, the thermocouples are not in direct contact with metallic structures and in other applications they are; that is, the thermocouples may be either "grounded" or "ungrounded." For this reason, it was necessary to arrange the measuring circuits so that satisfactory operation could be obtained under either condition. This is a matter of the detailed electric circuits, including their insulation and guarding, which is somewhat beyond the scope of the present paper.

Operating Experience—Availability

Operating experience with this recorder has necessarily been limited, but the observations so far made have been encouraging. During the many months involved in the development of the recorder, the selector switches were subjected to many thousands of operations and not a single failure was recorded. The automatic compensator for reference-junction temperature was subjected to ambient temperatures as low as 0 F, and no error outside the tolerance claimed for the instrument was observed. This test will be repeated with still lower ambient temperature, but the tests already made show a lag of 1 hr between the time a temperature change is made at the exterior and the time when one half of such change is effected in the interior of the "equilibrium chamber." This high degree of lagging is a fairly reliable indication that further lowering of the ambient temperature will not cause appreciable error, under expected service conditions.

The instrument has had approximately 12 hr of actual flight service at altitudes ranging up to 35,000 ft. The ambient temperature at the recorder was as low as —20 F, and this low ambient temperature did not appear to affect the instrument operation in any way. Accelerations caused no apparent effect on any part of the instrument. In fact, no difficulties attributable to the recorder or switch box were encountered during the whole flight-test period. During this flight test, the instrument was not provided with automatic compensation for the thermocouple reference junctions, the temperature of these being fixed by ice baths.

This new recorder is not now in commerical production and is available only in limited quantity for very urgent war problems.

Acknowledgment

Throughout the development work and the field testing, the authors have had the splendid co-operation of Messrs. W. J. King and S. F. Richardson, both of the General Electric Company, and their respective staffs, and wish to express their thanks for this assistance.

High-Temperature-Steam Corrosion Studies at Detroit

By I. A. ROHRIG,[1] R. M. VAN DUZER, JR.,[2] AND C. H. FELLOWS[1]

A program was undertaken by The Detroit Edison Company to determine the rate of corrosion and the relative corrosion resistance in an unstressed condition of various materials that could be used in the construction of steam generators, piping, and turbines. Specimens were exposed in a steam atmosphere at 380 psi and at temperatures of 925 F and 1100 F. The investigation required 5 years for completion; during that time 46 different materials were studied, including nickel, nickel-copper alloys, chromium and chromium-nickel stainless steels, medium- and low-alloy steels, carbon steels, and alloy cast iron. The tests were conducted under plant-operating conditions, and samples were exposed in superheated station steam for periods ranging from 4000 to 16,000 hr. Weight-loss, hardness, and metallographic data were obtained after successive exposure periods for many of the samples. Trends in the corrosion rate were plotted for some of the materials. The test results, reported in this paper, indicate that the weight loss of plain-carbon steel exposed to 1100 F steam continues at a high rate, whereas the rate of loss of the alloyed materials decreases with time. The high chromium-nickel and the 12-chromium stainless steels were the most corrosion-resistant. The corrosion rate of 0.50 molybdenum and 1.0 chromium steels compared favorably with that of steels containing 5 chromium. Nonferrous materials were not as corrosion-resistant in high-temperature steam as the high-alloy ferrous materials. Materials which corroded rapidly at 1100 F corroded only slightly at 925 F, and at this lower temperature there was little difference between the rate of corrosion of plain carbon and alloy steels.

Introduction

EXPERIENCE gained in the operation of two experimental installations utilizing steam at high temperatures located in plants of The Detroit Edison Company led to an investigation of the corrosion effects of high-temperature steam on a selected group of metals for superheaters, piping, and turbines (1, 2).[3] The results of an extended study of this subject are the basis for the present paper.

One of these experimental high-temperature installations was made at the Delray Plant in 1930; it comprised a turbogenerator and superheater. Materials in the superheater and piping were high-alloy stainless steels of high creep resistance that were known not to corrode significantly under the influence of high-temperature steam. In 1934, certain low-alloy steels were used in the tubing of the superheaters installed at the Connors Creek Plant to supply steam at 840 F. The alloys used at Delray, although highly corrosion-resistant, were too costly for this use. At Connors Creek, within the first 2 years of operation there were indications of corrosion resulting from the reaction between the high-temperature steam and the low-alloy steels used there. The experiences with both of these installations and concurrent development in high-creep-resistant low-alloy materials indicated that future installations for large-scale generation could be made with more economical and more suitable materials than those used in the original installations.

Several years earlier, in anticipation of the use of steam above 700 F, in the generation of electric power, some thought had been given to the reaction between steel and high-temperature steam. Laboratory-type studies were begun in 1927 that demonstrated the trend of the reaction between plain-carbon and high-alloy steel and steam at about 1100 F (3). These studies were not comprehensive enough to permit the data obtained to be used in engineering design, and moreover, by 1934, other alloys, especially low-alloy steels, were offered for high-temperature service. With the upward trend in the temperature of steam used in the generation of electricity, it became desirable, not only to examine the new alloys offered for high-temperature service and to evaluate them from a corrosion-resistance standpoint, but also to obtain data that would enable the usefulness of these alloys over long periods of time to be estimated.

Facilities were available for carrying out a comprehensive examination of this steel-steam reaction under what were practically power-plant operating conditions. Accordingly, a program of investigation was discussed with an interested steel manufacturer, the purpose of which was to determine what the effect of high-temperature steam would be on a group of low-alloy materials then being used or proposed for use in high-temperature equipment. The specific object was to determine the rate of weight loss over an approximately 2-year period and all materials would be tested in an unstressed condition.

Information then available gave only the total weight lost for samples exposed to furnace gases or air for short periods of time. Such data gave no indication of what rate of metal loss could be expected over a period of years, or was there any reason to believe that metal losses as the result of oxidation in furnace gases or air would be of the same order of magnitude as losses resulting from corrosion in a steam atmosphere.

At the time this program was being considered, A. A. Potter, H. L. Solberg, and G. A. Hawkins (4) started a similar investigation at Purdue University, utilizing high-temperature high-pressure steam equipment available in their laboratory, in which they planned to obtain fundamental engineering data related to the steel-steam reaction. The two investigations had as their objective the determination of the rate of weight loss of materials subjected to the action of high-temperature steam. They differed, however, in one important respect. The Detroit Edison Company's tests were to be conducted under average steam-power-plant conditions of fluctuating steam temperature and intermittent operation, whereas those at Purdue University were to be conducted under precise laboratory control for much shorter continuous-exposure periods.

The initial group of nine materials, with which the authors'

tests were begun, comprised steels suitable for superheater and piping use and were subjected to 1100 F steam. Additional materials were added during the course of the investigation, which continued for 5 years, from 1937 to 1942; and the scope of the work was enlarged by subjecting some of the materials to 925 F steam. All materials are described elsewhere in this paper.

The corrosion results, some of which were obtained during exposure periods up to 16,000 hr at 1100 F, show that in the case of steels of low alloy content, there is a definite retardation in the rate of metal loss with increase in the exposure period. The behavior of the carbon steels is entirely different, however; with continued exposure, the loss due to corrosion approaches a straight-line function. The results of the 925 F exposure tests do not indicate the marked differences between the alloy steels and the carbon steels that were evident in the tests at 1100 F. In the case of most of the materials tested at 925 F the losses were so small that accurate weight-loss determinations could not be made.

The results of this work agree with those published by Solberg, Hawkins, and Potter (5) for 2000-hr exposure in that the same rate-of-loss trends are shown for similar materials tested at the same temperatures, although the magnitude of the weight losses does not correspond because of the difference in testing procedure. Moreover, these results assume added significance because of the further findings of Solberg, Potter, Hawkins, and Agnew (6) that stress does not influence the corrosion rate of steels in steam at high temperatures. The information should be of value in design problems, inasmuch as the materials were tested under actual operating conditions of temperature variations and for sufficiently long time periods to establish definitely the trend of corrosion of a number of the materials studied.

Materials Investigated

The material studied in this investigation covered a variety of alloys that could be used for power-plant service, such as in superheater tubing, turbine-shell castings, turbine buckets, valves, and miscellaneous high-temperature equipment, such as flow nozzles, thermometer wells, and so forth. Included were both rolled and cast products. All samples were installed inside an experimental high-temperature steam line. In all, 46 separate materials were tested, varying in composition from relatively pure nickel through nickel-copper alloys, chrome-nickel stainless steels, medium- and

low-alloy steels to plain-carbon steels, and alloy cast irons. The materials included 9 nonferrous alloys, 12 stainless steels, 17 medium- and low-alloy steels, 4 carbon steels, and 4 alloy cast irons.

Table 1 gives a tabulation of the materials and their chemical composition. This table includes information concerning the structural condition of the materials, that is, whether cast or rolled, the heat-treatment, the temperature at which they were tested, and the total hours of exposure.

Test Apparatus

The test apparatus consisted of an experimental high-temperature steam line supplied with steam from a separately fired superheater of the radiant type, installed in 1929 as experimental equipment at the Trenton Channel Power House. Station steam was supplied to the superheater at 380 psi and 700 F, and it was capable of superheating to 1100 F 6000 lb per hr of steam which passed into a 65-ft experimental section of $5^1/_2$-in-OD tubing. A schematic view of the superheater and piping is shown in Fig. 1. Advantage was taken of the various flanged joints in this piping system to insert test cages holding the specimens where they were subjected to the action of high-temperature steam.

The temperature of steam leaving the superheater was so controlled that at joint *B* Fig. 1 its temperature was 1100 F ±50 F, as indicated by a thermocouple installed at that point. The specimens tested at 1100 F were placed in the steam line between the outlet joint *A* and joint *B*. At joint *C* the temperature was reduced so that the temperature of the steam, as measured by a thermocouple adjacent to joint *D* was 925 F ±20 F. The specimens for test at 925 F were placed in the steam line between joints *C* and *D*. The steam velocities in the two sections of the steam line were low, varying from approximately 8 fps in the 1100 F section to approximately 6 fps in the 925 F section. At joint *E* the steam temperature was further reduced to 700 F at which temperature the steam was used in a turbine.

Testing Procedure

Corrosion-test specimens and specimens used for initial-weight determinations were made from each material, according to the detail shown in Figs. 2 and 3, respectively. In the preparation of these specimens, each was given a ground finish and every precaution was taken to insure that the surfaces of all specimens were uniform and that the dimensional variations were small. These precautions were necessary since the weight loss of the specimens after exposure was determined by a comparison of the weight of a selected portion of each, after descaling, with the weight of an initial-weight specimen, 1 in. long, similar to that shown in Fig. 3. The diameter of each test specimen was carefully measured and its weight per unit length was determined by reference to the weight and diameter of the initial-weight specimens, which as noted was 1 in. in length.

The specimens were assembled into test cages made according to the detail shown in Figs. 4 and 5. The materials were tested in groups made up of individual cages welded together with short spacer rods. Each such group was placed in the steam line and held in place by tack-welding. At the conclusion of exposure periods of approximately 4000 hr, the group was withdrawn from the steam line, one cage detached, and the remaining cages replaced in the steam line for continued test.

When, at the conclusion of exposure periods, cages or assem-

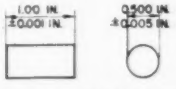

Fig. 3 Specimen for Initial-Weight Determination

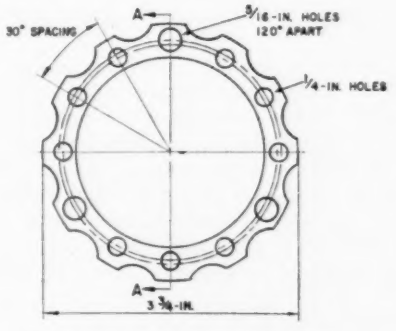

Fig. 4 Detail of Cage Ring

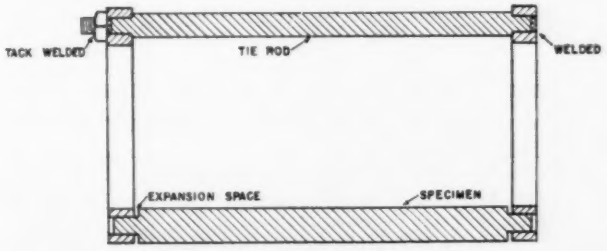

Fig. 5 Cage Assembly, Section A-A

blies of specimens were removed from the steam line, the assembly was taken apart, and the specimens prepared for examination. Two pieces, each approximately $^1/_2$ in. long, one for metallographic examination and the other for hardness determination, were cut from one end of each test specimen. The remaining portion of the specimen, that is, approximately a 5-in. length, was used for weight-loss determinations. In order to insure that the weight per unit length of the weight-loss specimens could be measured with extreme accuracy, the ends of these and of the initial-weight specimens were cut off exactly perpendicular to the longitudinal axis.

The specimens were treated in the following manner in order to determine the weight lost through corrosion.

The weight-loss specimens were first cleaned of corrosion products and then weighed. During the early stages of the investigation, the specimens were descaled with a solution of 100 parts by weight of concentrated hydrochloric acid, 5 parts by weight of stannous chloride, and 2 parts by weight of antimony oxide as inhibitors. Some of the stainless-steel specimens were descaled with concentrated hydrochloric acid containing 1 per cent by weight of quinoline ethiodide as an inhibitor. Later, most of the specimens were descaled electrolytically in a solution of 10 per cent by volume of sulphuric acid with 0.1 per cent by weight of quinoline ethiodide inhibitor. In the electrolytic method, the descaling was done in a lead container that served as the anode, the specimen acting as the cathode. The current was 6v d-c and the current density was about 0.5 amp per sq in. of specimen surface. The weight per unit length of these specimens, after removal of the corrosion products, was then compared with the original unit weights of the specimens.

Hardness readings were made on all the specimens after they were tested as well as on specimens representing the initial condition of all the materials before test. These readings were obtained with the appropriate Rockwell penetrator.

The station steam used in the tests contained no carbon dioxide and less than 0.01 ppm of oxygen. It was considered to be of high purity.

Losses Due to Corrosion

The losses due to corrosion are reported in Table 2, in terms of penetration and as per cent loss in weight, and as penetration only in Figs. 6 and 7.

In reviewing the data based upon the loss in weight, it should be remembered that rather small specimens and small values are being dealt with. In those cases where the materials scaled considerably no difficulty developed in determining the weight lost; but for such materials as did not scale, for example, the stainless steels, the weight losses were very slight and in some instances could not be measured. The relative weight losses of such materials were estimated by comparing the condition of the specimens after test with the condition of other materials of similar composition for which the weight losses resulting from longer exposure periods were known, Table 2 and Fig. 7.

For nine of the materials tested at 1100 F, weight-loss data were obtained after each of three successive exposure periods; for another set of nine materials, weight-loss data were obtained after four exposure periods; and for the last group, containing 19 materials, tested at 1100 F, data were obtained after one exposure period only. Data were obtained for the materials tested at 925 F, after three exposure periods for nine materials, and after one period only for seven materials.

Sufficient data were obtained over these relatively long exposure periods, approximately 4000 hr each, to establish the general trend of the corrosion losses, as is shown in Fig. 8, for 1100 F exposure. Although the curves included are for only 18 of the materials tested, the three general classes of materials investigated, namely, carbon, alloy, and stainless, are represented and their relative rates of corrosion, as established by these tests, are illustrated.

Corrosion at 1100 F. The curves are typical for the ferrous materials tested at 1100 F, in that the high-chromium alloys were the most corrosion resistant. In referring to the 12 per cent chromium steels, it is interesting to note that the free-machining grade sample 19 (type 416) had suffered little surface attack during 16,526 hr of exposure to steam at 1100 F, whereas the other steels in the same class, i.e., sample 17 (type 420) and sample 18 (type 403), had suffered considerable surface pitting. The 18 chromium-8 nickel steel, sample 15 (type 304) was pitted more than the straight-chromium steels.

The 12 per cent chromium-2 per cent molybdenum steel, sample 16, had a higher weight loss than the other samples of the general group in which it would normally be placed, that is, the stainless steels. The higher weight loss of this sample is also shown in Figs. 6 and 7. Improved corrosion resistance in air is reported (7) for 12 per cent chromium alloys containing 1 per cent of molybdenum over that of similar alloys without the molybdenum addition. The results of this test show, however, that in high-temperature steam a 12 per cent chromium alloy containing 2 per cent of molybdenum will scale considerably, whereas a straight 12 per cent chromium steel will exhibit only a slight tendency to scale. Pitting can be expected, however. The behavior of sample 19, which contained 0.30 per cent sulphur, indicates that an increase in the sulphur content of 12 per cent chromium alloys will further improve their corrosion resistance to the extent that pitting may be prevented in high-temperature-steam atmospheres. These tests, however, do not show conclusively that a high sulphur content will improve the corrosion resistance in steam of 12 per cent chromium steels.

Progressive weight losses were not obtained for the nonferrous alloys, samples 1 to 9, inclusive, since only two specimens of each were tested and both specimens were removed from the steam line at the same time. The relative weight losses of these samples in comparison with the ferrous materials tested at the same temperatures and for similar exposure periods are also shown in Fig. 7. The nickel samples 1, 2, and 3 had suffered intergranular attack and the two nonferrous alloys containing a high silicon content, samples 6 and 8, had scaled, sample 6 at 1100 F and sample 8 at 925 F. Furthermore, a layer of copper was found on the surface of both of these alloys after descaling. The high chromium-nickel-ferrous alloys, 10, 11, 12, 13, and 14, together with the chromium stainless steel, sample 19, had the lowest weight losses of the samples tested.

The corrosion losses of the medium- and low-alloy steels did not differ very much in that those steels containing 5 per cent chromium were not greatly superior to those containing 1 per cent chromium; in fact, the losses did not differ greatly from those for 0.50 per cent molybdenum steels. In general, those alloys having silicon contents higher than normal, 0.15 to 0.25 per cent by weight, had approximately the same, and in some cases higher, weight losses than similar alloys of low silicon content. This is contrary to the findings reported for air oxidation, where a high silicon content is beneficial (8).

The highest weight losses were obtained for the carbon steel, 39 (S.A.E. 1010) and 42 (S.A.E. 1035). Sample 40, which was approximately an S.A.E. 1020 steel that had been aluminum-killed had a much lower weight loss when exposed to steam at 1100 F than either the 1010 or the 1035 steels. At 925 F, however, the weight losses of the carbon steels were approximately the same as the weight losses of the low-alloy steels. Materials 5 and 30, which had relatively high aluminum contents, had better corrosion resistance in steam than similar alloys to which only small amounts of aluminum may have been added for deoxidization

TABLE 2 LOSSES RESULTING FROM EXPOSURE TO 925 F AND 1100 F STEAM

purposes. This is in accord with the findings of Houdremont and Bandel (9) who pointed out that aluminum, like chromium, improves corrosion resistance in an atmosphere of high-temperature steam.

In the case of the chromium-molybdenum high-silicon, the chromium-molybdenum, the chromium-molybdenum-titanium, the silicon-molybdenum, and the carbon steels at 1100 F, the outer scale was brittle and tended to flake off, exposing new surfaces. In general the scale was more brittle on those steels having the higher silicon contents, which explains their relatively higher corrosion rates in steam than in air and indicates also that the mechanism of corrosion is different in steam from that in air. This has been reported also by Solberg, Hawkins, and Potter (5).

The 0.50 per cent molybdenum steels, at 1100 F, compared favorably with the 5 per cent chromium - 0.50 per cent molybdenum and the nitrided nitralloy steels. They were far superior to the plain-carbon steels.

At 1100 F, all of the cast-iron samples had approximately the same weight loss irrespective of their alloy content, Fig. 7.

Corrosion at 925 F. At 925 F, the 12 per cent chromium stainless steels were again the least affected. At this temperature there appeared to be no great difference between the 5 per cent chromium - 0.50 per cent molybdenum steel, the 0.50 per cent molybdenum steels, the plain-carbon steels, the high-phosphorus steel, the chromium-molybdenum-silicon steels, the chromium-nickel-molybdenum steel, and the nitrided nitralloy steel, as each had scaled only slightly, Fig. 11. Although the actual weight losses of the nonferrous materials, 7, 8, and 9, tested at 925 F, could only be estimated (see Fig. 7), metallographic examination indicated that they had corroded more than the 12 chromium steels tested at the same temperature.

Surface Characteristics. The weight losses were so slight, in the case of many of the materials tested, particularly at 925 F, that it is better to consider similar materials, for example, the high chromium-nickel stainless steels, as a group. In view of this, the results of the metallographic examinations are important. On that basis a distinction can be made between the samples when no such distinction can be made on the basis of weight-loss measurements. The photomicrographs, Fig. 9, show that sample 19, the free-machining grade of 12 per cent chromium stainless steel, had greater surface stability than the other steels of the same general type. The 18-8 stainless steel, sample 15, had pitted more than any of the 12 per cent chromium steels but the columbium-stabilized 18-8 stainless steel, sample 14, had not pitted. In general, the steels of this class had good surface stability and corrosion resistance in high-temperature steam.

A uniform and adherent scale formed on all the steels at 925 F except the chromium stainless steels, which had pitted slightly at this temperature. Fig. 12 illustrates the surface condition of representative steels at the conclusion of test exposure periods. The scale found on the specimens, exposed to 925 F steam, is shown to be adherent, Fig. 12 (*a*), whereas in the case of similar steels exposed to 1100 F steam, Fig. 12 (*b*), much of the scale, especially the outer layers, had flaked off. Fig. 12 (*c*) illustrates typical adherent scales formed at 1100 F.

This apparent greater adherence of the scale at 925 F than at 1100 F is one reason for less severe corrosion at the lower tempera-

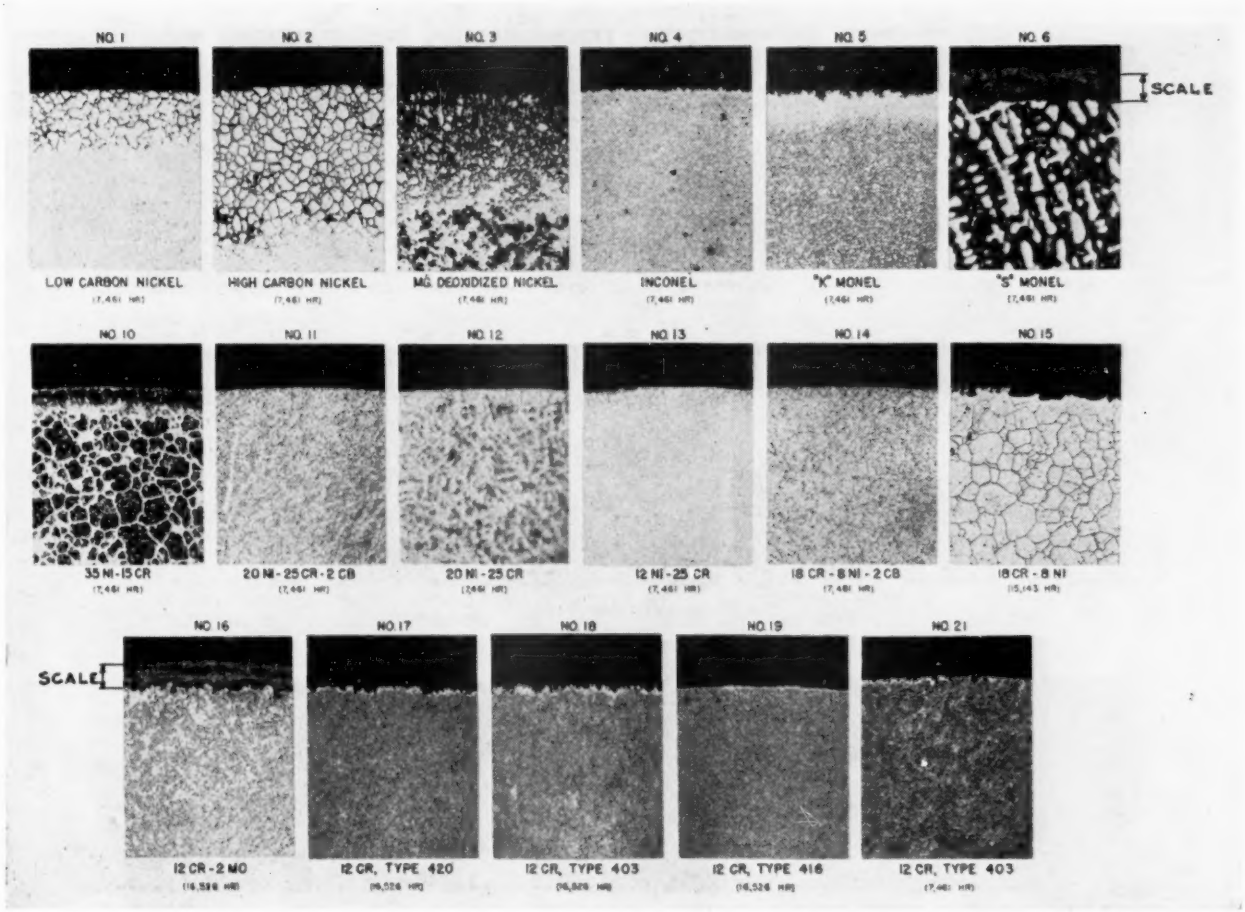

FIG. 9 PHOTOMICROGRAPHS SHOWING EFFECT OF 1100 F STEAM ON METALS

ture. The greater reaction rate between steam and the materials at 1100 F than at 925 F is a further reason for the difference in corrosion at the two temperatures.

For certain of the steels tested, the scale formed in distinct layers and tended to flake off as a result of temperature changes when the superheater was cooled to room temperature. This may offer an explanation for the relatively high weight loss of these samples in spite of their alloy content. The scale on the carbon steels, except sample 40, formed in thick layers. The scale on certain of the samples was tight and adherent at 1100 F, in spite of temperature variation.

The ability of a metal to maintain an adherent protective scale during high-temperature service is important and apparently can be controlled by using or limiting certain elements in an alloy; as, for example, 0.50 per cent of molybdenum added to a plain-carbon steel greatly improves the corrosion resistance in steam at 1100 F, but 2 per cent of molybdenum added to a 12 per cent chromium steel lowers the corrosion resistance of that steel. Silicon also can be considered in the same way, in that a high silicon content does not improve the corrosion resistance of steels in steam as it does in air.

Hardness. The hardness of all materials tested is given in Table 3. The hardness of most of the nonferrous alloys was reduced by exposure at 1100 F, but at 925 F two of the materials, 7 and 9, increased in hardness owing to the fact that they were precipitation-hardening alloys. Increases in hardness after 1100 F exposure also occurred in several of the stainless steels, namely, 10, 12, 13, 14, and 15.

In general the hardness of the low-alloy, medium alloy, and plain-carbon steels was reduced through exposure to the high-temperature-steam atmosphere. In some instances, however, as shown in Table 3, practically no change occurred. This may be attributed to the heat-treatment that the materials had received.

Indications of slight precipitation reactions were shown by the hardness changes of steels 22, 35, and 37, and hardness increases were found for three of the cast irons, 43, 44, and 46.

CONCLUDING COMMENT

Although this investigation has been comprehensive in that in it were included a fairly large number of different materials in the several classes of metals proposed for high-temperature service, the conclusions drawn from the results must be qualified by reason of the fact that in many instances only one specimen was examined for a given material at any one temperature and exposure period. To have done otherwise would have provided many more data, but would have required much larger quantities of material and an enormously greater expenditure of man-hours than it appeared could be justified at the time of the inception of the work.

In summarizing the results of this investigation, the following statements can be made:

1 In general, ferrous alloys containing high percentages of chromium alone are corrosion-resistant in steam at 1100 F.

2 Ferrous alloys containing high percentages of chromium and nickel are corrosion-resistant in steam at 1100 F.

3 Nonferrous alloys containing high percentages of nickel

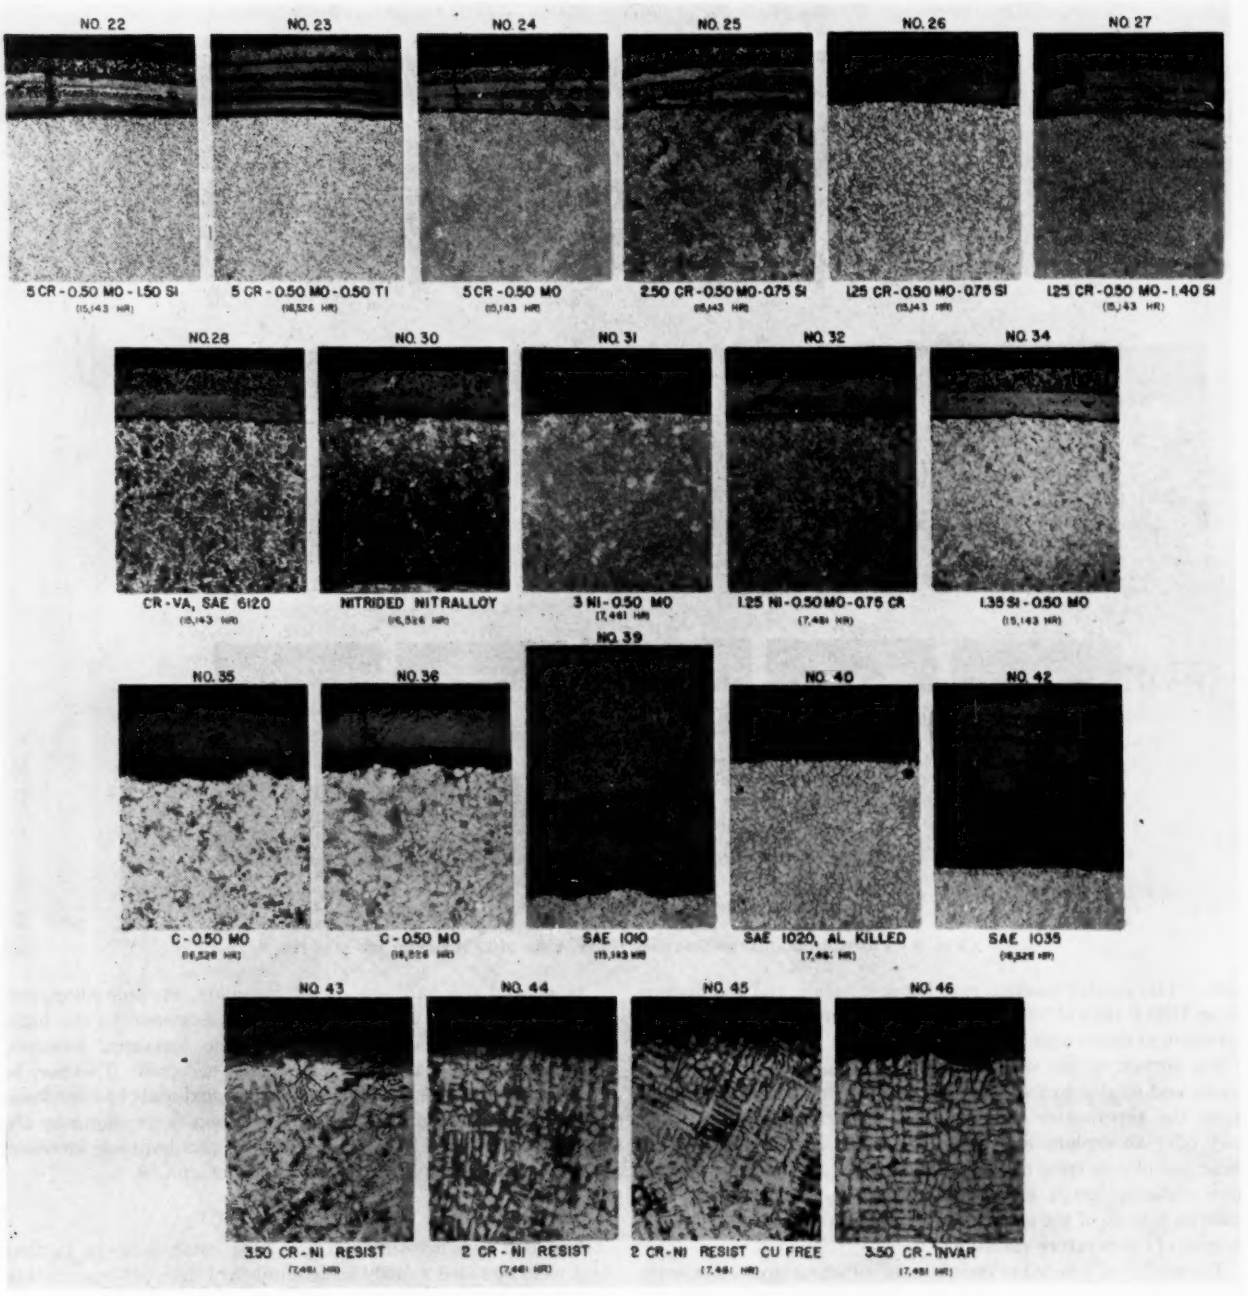

FIG. 10 PHOTOMICROGRAPHS SHOWING EFFECT OF 1100 F STEAM ON METALS

and copper that were tested in either 925 F or 1100 F steam can be expected to corrode in steam at those temperatures.

4 Although significant differences exist between the corrosion rates of carbon steels and medium- or low-alloy steels at 1100 F, at 925 F only a slight difference exists.

5 At both 925 and 1100 F, many steels that have a relatively low alloy content (0.5 molybdenum, samples 35, 36, 37, and 38) compare favorably in corrosion resistance with steels of medium alloy contents (5 chromium, samples 22, 23, and 24).

6 The formation and maintenance of an adherent scale materially increases the corrosion resistance of materials exposed to high-temperature steam.

7 The trends in the reaction between steam at high temperatures and the various steels for which weight-loss rates were determined, the authors believe, have been satisfactorily demonstrated, and on the basis of these trends the user of such steels may be assured that their rates of corrosion in steam atmospheres do not continue to increase. They flatten out and, as has been shown in the case of many of the low-alloy steels, the rates tend to be materially reduced after 15,000 to 16,000 hr at 1100 F. Some reasons for this have been suggested, but the exact mechanism which underlies these reasons has not been fully explored.

ACKNOWLEDGMENT

The authors wish to acknowledge the co-operation from the Steel and Tube Division of the Timken Roller Bearing Company, the Lunkenheimer Company, the National Tube Company, the International Nickel Company, and the General Electric Company. These companies supplied most of the materials studied. Acknowledgment is made also of the co-operation of the Climax Molybdenum Company in permitting the use of its laboratory equipment for cutting the specimens after each exposure period.

The authors are indebted also to their associates in the company who worked on this study and assisted in the many activities incidental to its progress.

Discussion

E. N. Skinner,[4] Jr., and J. T. Eash.[4] Through their extensive study of the corrosion of metals and alloys by high-temperature steam, the authors have obtained data undoubtedly of considerable practical worth to those concerned with power-plant design, as well as valuable information with respect to the little understood question of high-temperature corrosion.

With regard to their results on the three samples of malleable nickel, it may be useful to state here that experience has made it apparent that nickel which is used at temperatures between 750 and 1400 F should be low in carbon. In this temperature range, it has been found that, regardless of the atmosphere, nickel containing carbon may become embrittled with time due to an intergranular precipitation of graphite. In any application involving the use of wrought nickel at these temperatures, the commercial carbon-free nickel which contains a maximum of 0.02 per cent carbon should be specified.

The results of some laboratory tests that we have conducted on the oxidation of nickel in tap-water steam suggest that the presence of minor quantities of residual elements associated with the production of malleable nickel for widely diverse fields of application has a marked effect on its oxidation resistance in steam. Carbon is particularly harmful in promoting rapid intergranular corrosion such as found by the authors.

Our tests indicate, in addition, that a nickel which does not contain small amounts of residual elements has a low rate of oxidation in steam. Such a product is found in electroplated nickel. Specimens of this type of nickel exposed at 1100 F for 600 hr oxidized at approximately one seventh the rate of a wrought nickel containing about 0.08 per cent carbon; furthermore, this electroplated nickel was completely free from the intergranular attack noted by the authors.

The practical value of electro-nickel in steam applications is a matter which designers of equipment may wish to consider.

H. L. Solberg,[5] G. A. Hawkins,[6] and J. T. Agnew.[7] Through the courtesy of The Detroit Edison Company and the authors the Engineering Experiment Station of Purdue University has been provided with copies of progress reports covering the extensive high-temperature corrosion studies which have been carried on by the company over the past several years. The writers have greatly appreciated the fine spirit of co-operation which has made this information available to us, and wish to congratulate the authors on the excellent job they have done in condensing the contents of these numerous and extensive reports into this paper.

The writers reported[8] in an earlier paper upon certain tests which were carried on with steam at 1200 F, and with the specimens subjected to sharp fluctuations in temperature, in order to determine the resistance of the scales formed on the various alloy steels to spalling under fluctuating-temperature conditions. It was found that, in general, as the chromium content was increased to 4–6 per cent, the scale which was formed became more dense and brittle. The addition of either silicon or aluminum in more than normal amounts tended to aggravate the tendency of the scales to spall under temperature fluctuations. These results are confirmed by The Detroit Edison Company tests. Steels containing more than 7 per cent of chromium formed a tightly adherent thin scale which showed no tendency to spall under the test conditions.

Tests with specimens of various shapes indicated that the spalling action of low-chrome steels was severe on the outside of bars and on flat surfaces but was negligible on the inside surfaces of a tube section of 1-in-ID tubing. It is probable that the scale which is formed on a concave surface is in compression and, consequently, resists spalling caused by temperature fluctuation and furnishes better protection than does the scale which is formed on the outside of bar stock. It is, therefore, possible that the long-time corrosion rates determined in The Detroit Edison tests on $^1/_2$-in. round bars are higher than those which would be encountered in superheater tubing in which the shape of the tube might tend to hold the scale in place.

The Detroit Edison tests show a marked reduction in the corrosion rate of carbon-moly steel, as compared with that of low-carbon steel. The results obtained at Purdue University with a fairly large number of specimens of each type of steel do not indicate a very significant difference in the corrosion rates of these steels. Both cast and rolled specimens were tested at temperatures of 1100 F and higher, under conditions of steady as well as fluctuating temperatures for periods of time which were shorter than those employed by The Detroit Edison Company. Table 5 of this discussion has been compiled from previously published data[8] and summarizes some of these results. All specimens were given the heat-treatment recommended by the producers of the steels used in these tests.

F. N. Speller.[9] The experimental data from the 5-year period of testing by The Detroit Edison Company is a welcome addition to our limited knowledge of the corrosion of metals in steam at 925 and 1100 F. It would be useful to know whether the corrosion found is uniform or localized in the form of pitting. Considering the relative cost, the favorable corrosion rate of 0.50 molybdenum plus 1 per cent chromium steels is encouraging. In 1933, we published data showing the favorable physical and corrosion-resistant properties of 3 per cent Cr compared with 5 per cent Cr steels. For oil-cracking tubes at 1100 F, the 2-$^1/_4$ per cent Cr, 1 per cent molybdenum steel has since then shown

very promising results in practice. In fact, experience in high-temperature oil-cracking around 1100 F affords experience on the relative strength of these steels over long periods at elevated temperatures that should be quite useful in the design of high-pressure steam boilers.

Authors' Closure

Respecting the comments of Messrs. Skinner and Eash, we are glad to have an explanation of the intergranular deterioration that was observed in the three samples of malleable nickel. The explanation that this was due to intergranular precipitation of graphite agrees with the results of our tests in that the lesser amount of intergranular deterioration was found in the sample which had the lowest carbon content.

It is interesting also to learn that the corrosion rate of electroplated nickel exposed to 1100 F steam for 600 hr was approximately one seventh that of wrought nickel containing 0.08 per cent carbon. The weight loss for electroplated nickel, as calculated from the factor given by Skinner and Eash in their 600-hr test, i.e., one seventh the value for wrought nickel, would indicate that, although the corrosion rate appeared to compare favorably with that found for the chromium and chromium-nickel stainless steels, on the basis of a 7461-hr test, the corrosion rate of electroplated nickel might not be found to compare so favorably with that for these stainless steels.

The comment of Messrs. Solberg, Hawkins, and Agnew that scale on a concave surface is more protective than on a convex surface and, consequently, the results given in the paper may be somewhat high, as compared with corrosion rates that would be encountered in the inner surface of tubes in service, is probably true. With respect to the relative rates of corrosion instead of the actual rates under service conditions of the 46 different materials, it is felt that, since each material was tested by the same type of specimen, i.e., $\frac{1}{2}$-in-diam bar specimens, the comparative tendency of these materials to corrode and scale has been established. To interpret such data in terms of corrodibility of tube forms in service, will require more such studies as those carried on at Purdue University. There are many applications in power plants, such as turbine buckets, various sections of turbine shells, valve-trim materials, and other uses in which the service conditions would be similar to those under which our tests were made.

In contrast to the Purdue test results, our tests have shown a marked reduction in the corrosion rate of carbon-molybdenum steel as compared with that of carbon steel. Our finding is based upon consistent test results obtained over a period of approximately 16,000 hr of exposure to 1100 F steam, during which time four different specimens of each sample were examined. Our shortest exposure period was approximately 4000 hr, whereas the Purdue results are based upon exposure periods of only 500 hr in 1100 F steam. To compare the test results of the two separate investigations, the shape of the "rate-loss" curve would have to be determined between 0 and 4000 hr of exposure in steam at 1100 F. This point is significant. Furthermore, the metallographic examination made of our test specimens at the conclusion of each 4000-hr exposure period showed a marked difference in the thickness of the scale on carbon steel, as contrasted with carbon-molybdenum steel. The carbon-steel specimens consistently had a much thicker and less adherent scale than the carbon-molybdenum steels. Two different carbon steels and two different carbon-molybdenum steels were each tested at 1100 F. At 1200 F there may be very littly difference in the scaling resistance of carbon steel and carbon-molybdenum steel as shown in Table 4, given in the Purdue comments. At 925 F we found practically no difference between the scaling rate of carbon and carbon-molybdenum steels.

Our test results indicate that carbon content is a significant factor in the corrosion rate of carbon steels exposed to steam at 1100 F. Consistently higher weight losses and thicker scale were found for low-carbon steel than for medium-carbon steel. We did not study the effect of carbon content as related to the corrosion resistance of carbon-molybdenum steel in steam at 1100 F.

Mr. Speller's question concerning whether the corrosion found is uniform or localized in the form of pitting is answered as follows: In general the corrosion found on the carbon steels and the low-and medium-alloy steels was quite uniform. Whenever the surface of the specimens was completely covered with a scale of measurable thickness, which could be seen easily at a magnification of 100 diam in a cross-sectional specimen, we prefer to think of the corrosion as being of a uniform type provided that no intergranular attack has occurred. In the case of the cast materials, considerable surface roughness was observed beneath the scale which is believed to be due to segregation in the cast alloy. Similar materials when tested in the wrought condition did not show such roughening of the surface beneath the scale.

Pitting of the surface as a result of exposure to 1100 F steam was found in the stainless materials, particularly in the 18 Cr-8 Ni without columbium, and in the 12-Cr steels with the exception of Sample 19 which was a Type 416, 12-Cr steel and which had shown very little surface attack after 16,526 hr of exposure. Pitting of the surface was also found in Inconel and "K" monel after 7461 hr of exposure. Intergranular attack at the surface was found in the nickel samples and, as mentioned by Messrs. Skinner and Eash, this was caused by intergranular precipitation of graphite at the test temperature.

No tests were made of 1 per cent chromium, 0.50 per cent molybdenum steels in 1100 F steam. Two steels of that general type were tested but contained a high silicon content and are, therefore, not comparable to such steels with normal silicon. A 1 per cent chromium, 0.50 per cent molybdenum steel was tested in 925 F steam for 13,165 hr. At that temperature its corrosion rate appeared to be about the same as that of 0.50 per cent molybdenum steel and plain-carbon steel, all of which had scaled approximately the same amount. In steam at 1100 F, however, the beneficial effect of 1 per cent of chromium would probably enhance the corrosion resistance of 0.50 per cent molybdenum steels. No tests were made of steel containing $2\frac{1}{4}$ per cent chromium, 1 per cent molybdenum, but from its favorable showing in oil-cracking applications at 1100 F, as reported by Mr. Speller, it probably would be suitable for many steam-power-plant applications.

The Corrosion of Alloy Steels by High-Temperature Steam

By G. A. HAWKINS,[1] J. T. AGNEW,[2] AND H. L. SOLBERG[3]

This paper presents additional test results obtained at the Engineering Experiment Station of Purdue University dealing with the relative resistance to corrosion by steam of unstressed specimens of various alloy steels at temperatures between 1000 F to 1800 F. All of the steels tested, except for the very high chromium-nickel alloys, show rapid corrosion beyond a limiting temperature which increases with chromium content. Data are presented relative to the chemical composition of the scale layers formed during tests at 1500 F and 1800 F.

INASMUCH as steam temperatures in modern power plants and in some of the process industries are approaching and in some cases exceeding those which may be used for the production of hydrogen by reaction between steam and iron, an investigation was undertaken at Purdue University of the corrosion by steam of the various steels which are available for high-temperature service. Apparatus has been constructed and techniques developed for measuring the amount of corrosion on unstressed specimens due to steam temperatures up to approximately 1800 F.

Description of Apparatus

A complete description of the apparatus used in this investigation together with the temperature-control circuit has been published (1).[4] Briefly, steam was passed through a counterflow gas-fired steel-tube superheater, after which it flowed through an electrically heated superheater constructed from 25-20 stainless-steel pipe $^5/_8$ in. OD × $^3/_8$ in. ID. It was then admitted to a reaction chamber made from a piece of 2-in-OD double-extra-heavy 25-20 stainless-steel pipe 10 ft long. A plate was welded over one end of the reaction chamber and was drilled and tapped for the superheater-inlet pipe. The other end of the chamber was threaded and closed with a pipe cap made of 7-Cr steel to facilitate insertion and removal of the test specimens. The reaction chamber was heated externally to the same temperature as the steam by means of two main and two guard heaters constructed from chromel wire. The reaction chamber was suitably insulated. Pyod-type chromel-alumel thermocouples were used to measure the temperatures along the reaction chamber. The steam discharging from the reaction chamber was condensed in a coiled-copper-tube heat exchanger and weighed.

Test Specimens and Testing Procedure

The specimens were machined to a length of 6 in. and a diameter of $^1/_2$ in. After the specimens had been machined, the surfaces were sandblasted in order to obtain identical surface conditions. After sandblasting, the specimens were weighed and placed in small cages made of stainless-steel welding wire and inserted into the reaction chamber, which had been brought up to the desired operating temperature. After remaining in the reaction chamber in contact with flowing steam for the desired length of time, the samples were withdrawn. The outer scale layers were removed mechanically in order to preserve the scale for chemical analysis. All of the remaining scale was removed by making the specimen the cathode in an electrolytic cell containing a 10 per cent solution of sulphuric acid with 1 g per liter of quinoline ethiodide as an inhibitor and with a current density of approximately 1 ampere per sq in. (2). The stripped samples were reweighed and the loss in weight determined by difference was taken as the measure of the amount of corrosion.

Corrosion Results

Samples of S.A.E. 1010, 3 Cr-Moly, 4-6 Cr-Moly, 7 Cr-Moly, 9 Cr-Moly, 12 Cr, 18-8 Cb (Stabilized), 21 Cr, 27 Cr, 25-20, and 25-15-2W steels were subjected to steam temperatures ranging from 1400 F to approximately 1800 F for 500 hr. The results for the various tests are given in Table 1. These data are represented in Fig. 1 by smooth curves drawn through the average of the test points. These curves are based upon the data presented in this paper as well as the results which have been reported in earlier papers (1, 2, 3).

The S.A.E. 1010, 3 Cr-Moly, 4-6 Cr-Moly, 9 Cr-Moly, 12 Cr-Moly, and 18-8 steels show a definite breaking point at a particular temperature. This same fact would probably have been observed for the 21 Cr, 27 Cr, 25-20, and 25-15-2W if the tests had been carried out at high temperatures. Only two points are available for the 7 Cr-Moly steel at the higher temperatures; hence no general curve is presented. The available data on the 7 Cr-Moly steel lie close to the 9 Cr-Moly curve.

An attempt was made to establish a simple single equation which could be used to compute the loss in weight for the steels tested for 500 hr at the various test temperatures. This was not possible due to the fact that the high-chromium steels show little corrosion until a certain temperature is reached above which an abrupt increase in the corrosion rate occurs at higher temperatures, while the low-chromium steels show a gradual increase in the rate of corrosion with increasing temperature. In order to use one equation, it was necessary to employ a very complex relation which would not be satisfactory from an engineering standpoint. As a result, a family of equations was established of the form

$$C = a(x - b)^d \quad [1]$$

wherein the constants, a, b, and d differ for each steel and are given in Table 2. The symbol C is the corrosion or loss in weight as a percentage of the initial weight. The term x is equal to the following

$$x = \frac{t - 1000}{100} \quad [2]$$

where t is the temperature under consideration in degrees F. This family of equations represents the test results within the

CHEMICAL ANALYSIS OF SCALE LAYERS

The steels listed in Table 3 were tested at temperatures in excess of 1700 F for a period of 500 hr.

An extremely thin tightly adhering layer was found on all of the scales next to the parent metal. It was found impossible to remove enough of this inner layer to analyze it.

The scale formed on the 3 Cr-Moly steel consisted of a thick porous and brittle outer layer and a dense brittle middle layer The outer and middle layers were separated mechanically by using a sharp probe. In many cases sections of both layers stuck together. Although the color of the middle and outer layers was

the same, it was very easy to distinguish between the two. The dividing plane between the layers was very sharp, due to the fact that the exposed surfaces of the particles which composed the middle layer reflected ordinary light differently from those contained in the outer layer. Samples of the outer and middle layers were analyzed for Cr, Mo, and Si. The results are given in Table 3.

The 4-6 Cr-Moly showed a scale-layer formation similar to the scales formed on the 3 Cr-Moly steel. The outer layer was very brittle and readily separated from the middle layer. The outer layer of scale formed on the 9 Cr-Moly steel was quite brittle and was easily separated from the adjacent layer. The middle layer was very dense and hard to remove. It was not possible to distinguish the middle layer from a layer next to the parent metal, if such a layer existed. The percentage of chromium in the outer scale layer for the 4-6 Cr-Moly and 9 Cr-Moly steel was larger than for the 3 Cr-Moly steel.

The steels listed in Table 4 were held in a steam atmosphere at 1500 F for 500 hr. From visual observations the scales formed on the 3 Cr-Moly, 4-6 Cr-Moly, and 9 Cr-Moly samples appeared to be quite similar to those formed in the same type of steel specimens tested at 1700 F for 500 hr. The 7 Cr-Moly and 9 Cr-Moly scales were quite similar. The results differ materially from those obtained on the 500-hr test at 1700 F.

The data presented in Tables 3 and 4 indicate that a concentration of chromium, silicon, and molybdenum has occurred in the middle scale layer. The increase in concentration for the middle layer may be clearly brought out by studying the ratio of the percentage of the alloying element in the scale layer to the percentage in the base steel. These data are presented in Tables 5 and 6. For the chromium the relative concentration increase ranged from 1.21 to 2.52, for silicon from 0.96 to 5.48, and for molybdenum from 0.79 to 2.39.

In every case the alloy content in the outer layer is lower than in the middle layer. This agrees with many of the oxidation theories which have been advanced, in that since the outer layer is composed chiefly of iron, the iron diffused through the alloy-rich middle layer.

These results tend to indicate that in all probability the steam-oxidation resistance of the alloy steels tested is due to thin and very dense tightly adhering inner layer of scale and a dense middle layer which contains a higher concentration of the alloying agents than is present in the base steel. An outward diffusion of the alloying agents from the base steel to and into the inner and middle layers must occur. In order to have a steam-corrosion-resisting steel there must be sufficient amounts of the alloying agents to combine with the oxygen diffusing inward to form the dense protective inner and middle layers. These general conclusions are in agreement with those found by White, Clark, and McCollam on air-oxidation tests (4).

It is thus possible that long-time tests would show less difference in the total amount of corrosion for medium- and high-alloy steels than has been found by conducting tests of from 500 to 2000 hr duration.

7 Cr-Moly	1.21	1.25	1.18
9 Cr-Moly	1.37	0.96	1.26

Conclusions

The data obtained on the steels tested together with previously reported data (1, 2, 3) which are graphically presented in Fig. 1 show the effect of temperature on corrosion by high-temperature steam. All of the steels tested except the 25-20, 25-15-2W, 21 Cr, and 27 Cr specimens start to corrode rapidly at some temperature less than 1675 F. After the break occurs the rise in corrosion rate is much more rapid for the steel containing 12 per cent chromium and the 18-8 stainless steel than for the steels containing less chromium. The 25-20 and 25-15-2W steels which were tested at temperatures of 1751 F show no corrosion at the end of 500 hr. The temperature at which rapid corrosion begins increases with the chromium content. The 18-8 Cb steel shows the same tendency toward rapid corrosion above some limiting temperature that the S.A.E. 1010 steel shows at a much lower temperature.

Relatively simple empirical equations have been established to aid in computing the amount of corrosion produced in 500 hr at temperatures within the test range for the various steels tested.

Chemical analysis of the various scale layers produced on the 3 Cr-Moly, 4-6 Cr-Moly, 7 Cr-Moly, and 9 Cr-Moly steels during 500-hr tests at temperatures of 1500 and 1730 F are presented. The chemical analysis of the inner scale layer indicated a build-up in concentration of chromium, silicon, and molybdenum. The diffusion of the alloying agents and the inward diffusing oxygen combine to form the dense protective inner layer.

From the results obtained, the chromium content of a steel is a major factor in controlling the amount of corrosion produced by high-temperature steam.

ACKNOWLEDGMENT

The authors wish to express their appreciation to the members of the A.S.M.E. Special Research Committee on Critical-Pressure Boilers for their valuable assistance during the course of the investigation.

Part of this investigation was made possible through the financial support of the Engineering Foundation, The Babcock & Wilcox Company, The Timken Roller Bearing Company, the General Electric Company, the National Tube Company, The Globe Steel Tubes Company, and The Combustion Engineering Company.

The authors are particularly indebted to Dr. C. L. Clark and The Timken Roller Bearing Company, Steel and Tube Division, for making the chemical analyses of the scales reported in this paper.

Appreciation is also expressed to the various alloy-steel manufacturers who have contributed steel samples from time to time for use in this investigation.

Discussion

R. C. COREY.[5] Since its inception, the work at Purdue University on the corrosion of metals and alloys by high-temperature steam has been followed with considerable interest. No other laboratory studies of this important subject, either here or abroad, have been as comprehensive as the present series, and the authors are to be commended for the excellent data that they have obtained.

It is gratifying to note that the authors conducted their tests for 500 hr. All too frequently one finds data in the literature on the rate of corrosion, intended for general use, but which are based upon extremely short test periods. In a recent article,[6] it was shown that with everything else essentially equal, the corrosion rate varies markedly with the duration of test. It may be argued that regardless of the test period, the relative rate of corrosion of different metals and alloys studied simultaneously under the same conditions will remain the same. Considering, however, that the rate of corrosion of most metals and alloys is greatest initially (except in the unusual case where corrosion increases linearly with time), it is possible that an otherwise satisfactory metal will appear to be unfavorable if the test period is too short.

It is not clear why the authors changed the unit for expressing corrosion from that of penetration, as used in previous reports, to percentage loss of original weight. In order that data of this kind may be compared with those of other investigators, the rate of corrosion is expressed more rationally in terms of the amount of metal lost per unit area in unit time, or as the depth of penetration in unit time. The literature on high-temperature corrosion studies is confusing and difficult to correlate as the result of the use of units which cannot be reduced to a common basis.

If the authors have the data available, it might be of interest to plot the loss of metal against time and thereby determine the specific type of scaling that occurs. Such information would be valuable for interpreting the corrosion mechanism of the various alloys that were studied. Recent papers[7,8] on this subject indicate that scaling may occur linearly, parabolically, or logarithmically with time, depending upon the temperature, conditions, and the metal under study. Thus, the sharp break at a certain temperature noted by the authors for certain of the alloys studied may be the result of recrystallization[9] of the oxide above a certain temperature, which may lead to logarithmic scaling, a factor determined only by the type of plot just mentioned.

The chemical analyses of the scales are of great interest as such data are the first step toward developing a mechanism for corrosion. It is not apparent why the Si increased and the Mo and Cr decreased in amount in the middle oxide layer with increasing chromium content of the alloy at both 1500 F and 1700 F. It is suggested that if possible the authors should have an X-ray diffraction study made of these scales to determine how these elements are distributed, that is, as solid solutions, stoichiometric compounds, or spinels. Such information would afford them valuable supplementary data.

The data of Table 1 of the paper show that Cb-stabilized 18-8 steel loses about 12 per cent of its weight between 1728 F and 1765 F. It might be of interest to study plain 18-8 steel at the same temperature for 500 hr in order to determine if the Cb decreases the corrosion resistance of this alloy.

With reference to the remarks of the authors concerning diffusion of oxygen through the oxide, the following is offered as an alternate explanation: Assuming for the moment that the gas phase diffuses through the oxide to meet and react with metal ions, it is probable that steam and not oxygen, as the authors state, would be involved as it is not until oxidation takes place that oxygen is released, and then it probably combines immediately as an oxide. On the other hand, it is doubtful that a steam molecule could diffuse interstitially through a compact oxide lattice because of the large size of the gas molecule with respect to the interatomic spacing of the lattice. However, if the oxide was porous or fissured the gas could reach the metal ions readily. Also there are cases where a gas like oxygen may be taken into solid solution in an oxide which is deficient in oxygen atoms, i.e., an oxide that is not of stoichiometric composition. The oxide FeO and certain of the spinel type of oxides like $FeO{\cdot}Fe_2O_3$, $FeO{\cdot}Al_2O_3$, and $FeO{\cdot}Cr_2O_3$ are capable of taking a small amount of oxygen into solid solution, but the quantities involved are too small to be significant, thus the rate of scaling probably depends primarily upon the rate at which the iron ions reach the oxide-gas interface.

W. TRINKS.[10] On account of being a furnace engineer, the writer's interest in high temperature begins where the power engineer quits. In furnace work we have learned that water vapor scales iron and steel more rapidly than air does. The writer attributes this phenomenon to dissociation. The professors of thermodynamics tell us that dissociation at the temperature

in question is negligible. They are right, if we limit ourselves to permanent dissociation. They are wrong if we consider instantaneous dissociation. Collision of the molecules causes some dissociation at all temperatures. Ordinarily, the atoms reassociate immediately without leaving any trace of their dissociation; but if a material is present for which oxygen has a greater affinity than it has for hydrogen, it goes after that material, because the oxygen is atomic (in the nascent state) and leaves the unwanted hydrogen to look out for itself.

Water vapor is triatomic and, for that reason is dissociated or cracked more easily than the diatomic oxygen molecule.

The variations in the composition of the scale are what we should expect. Iron oxide has a vapor pressure. Every steel-furnace engineer knows that fact. In a superheater tube the heat comes from the outside. The scale next to the tube is hotter than the scale next to the steam. For that reason the iron oxide gets away from the tube toward the cooler steam. It is a migration which some people call diffusion.

As regards cracking of the scale, we know from the sheet industry that a thin scale adheres and that a thick scale cracks. If we could chromium-plate the inside of the tubes and have the plating stick, then we should have a thin retentive greenish chromium scale which would not crack.

Authors' Closure

The authors are indebted to Messrs. Corey and Trinks for their written discussions and for their excellent comments concerning the mechanism of scale formation.

Mr. Corey has suggested that the data on corrosion be presented in terms of penetration rather than per cent loss in weight. In their earlier reports (1, 2, 3),[11] the authors presented the data in terms of inches of penetration. However, the high-temperature tests reported in this paper produced very thick layers of scale on some of the specimens which were originally 6 in. long and $^1/_2$ in. in diam. This resulted not only in a significant reduction in the diameter of the parent metal during the course of the tests but also produced a shortening of the specimens and a tapering of the parent metal at the ends of the specimens.

Mr. Corey has made some pertinent comments on the effect of time upon the usefulness of corrosion data. The tests which are reported in Table 1 are for 500 hr, and data for shorter periods of time are not available. However, the authors have published data showing the effect of time upon the corrosion of various steels for periods up to 2000 hr at a steam temperature of 1100 F (2).

In conclusion, the authors wish to thank all of those who presented discussions for their interest, comments, and constructive suggestions.

Surface Fatigue of Plastic Materials

Progress Report No. 16 of the A.S.M.E. Special Research Committee on Strength of Gear Teeth

By EARLE BUCKINGHAM,[1] CAMBRIDGE, MASS.

GREATER knowledge of the surface-fatigue characteristics of materials will serve many useful ends. Surface fatigue is a phenomenon largely responsible for one type of wear, commonly known as pitting. Definite information will permit the more intelligent and effective choice of materials for specific service conditions. Again, as noted in our preceding report,[2] if the surface-fatigue characteristics of the materials used are known and the surfaces of a mechanism are carefully watched, dynamic loads that cause surface failure can be detected before any harm is done to any other part of the mechanism, and a reasonably close measure of their intensity can be made from the condition and appearance of the surface failure of the specific part. Thus such information will give us a tool, or weighing scale, by which to measure the intensity of existing loads on all types of mechanisms in actual operation, and also to make possible more accurate comparisons between many laboratory test results and actual service conditions.

A special testing machine, shown in Fig. 1, has been built, and tests have been run almost continuously during the past 6 years. In brief, the testing machine consists of two shafts running in plain bearings, one mounted in a heavy fixed frame and the other mounted in a substantial swinging frame. The test rolls, with a maximum face width of one inch and from 2.200 in. to 4.00 in. in diameter, are mounted on the shafts. A load is set up between them by a calibrated spring acting against the swinging frame. Revolution counters are connected to each shaft. Gears may be mounted on the ends of the shafts in such a manner as to obtain any desired amount of slipping or rubbing between the two test rolls. Many of the tests under rolling conditions are run without gears, the rolls driving each other by friction. The majority of tests to date have been made under rolling conditions only.

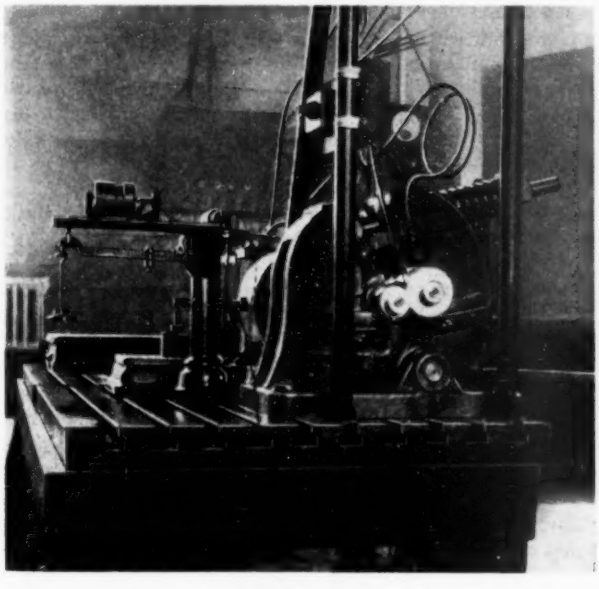

FIG. 1 TESTING MACHINE

Plain bearings were used to avoid the possible dynamic effects of ball or roller bearings. An oil pump provides oil for the bearings and the gears. The testing machine is driven by a small Sprague dynamometer, and records are kept of the torque input during the runs.

The physical properties and the structure of the materials under test appear to have a pronounced influence on the nature of the surface failure. The following is an attempt to put into words a detailed account of the several phenomena that occur concurrently under test conditions of rolling contact. Considering only the plastic materials, the following have been observed.

PLASTIC FLOW OF SURFACE LAMINA AND WORK-HARDENING

The action of one roll upon the other carries a plastic and elastic wave ahead of the contact area between them, setting up conditions quite similar in many respects to the conditions existing when cold-rolling metals. This action cold-works the surface lamina, increasing its hardness and raising the physical properties of the surface of the material. This action appears to be progressive, tests indicating that the depth of this cold-working (which might well be called "mechanical case-hardening") increases with the number of repetitions of stress up to a maximum depth, this maximum depth probably depending upon the pressure. The hardness also increases with the number of repetitions of stress, as well as with increase of load; but depth of penetration appears to depend mostly upon the number of repetitions of load.

This increase of surface hardness has been observed on practically all samples of plastic materials which have been tested. Special tests to study this phenomenon were made by E. L. Bartholomew, Jr., in 1937, using rolls of stainless steel (18–8 steel). The three following tests were run on rolls of 2.3 in. diam, 1 in. face width, against a hardened and ground steel roll of the same size.

Test no.	Load, lb	Number of repetitions of stress	Maximum specific compressive stress, psi	Maximum shear stress, psi
110	2362	500000	146000	44400
111	2362	2069000	146000	44400
112	3150	4940000	184000	56000

The stresses are computed as though loaded under static conditions. Photoelastic tests indicate that, under the combined stress conditions existing in rolling contact, the stress distribution is changed and that the stresses are greater than those existing under static conditions of simple radial loading. In the absence

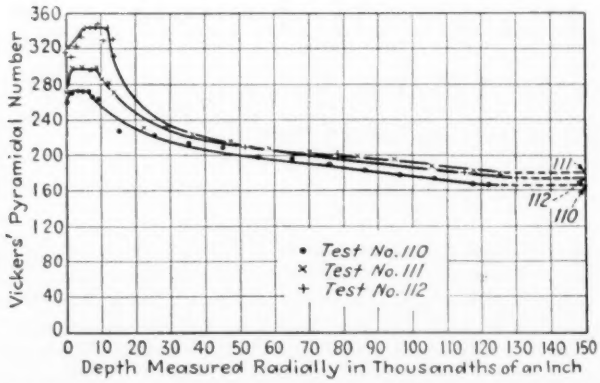

FIG. 2 RESULTS OF TESTS TO DETERMINE EFFECT OF MINIMUM TORQUE CONDITIONS

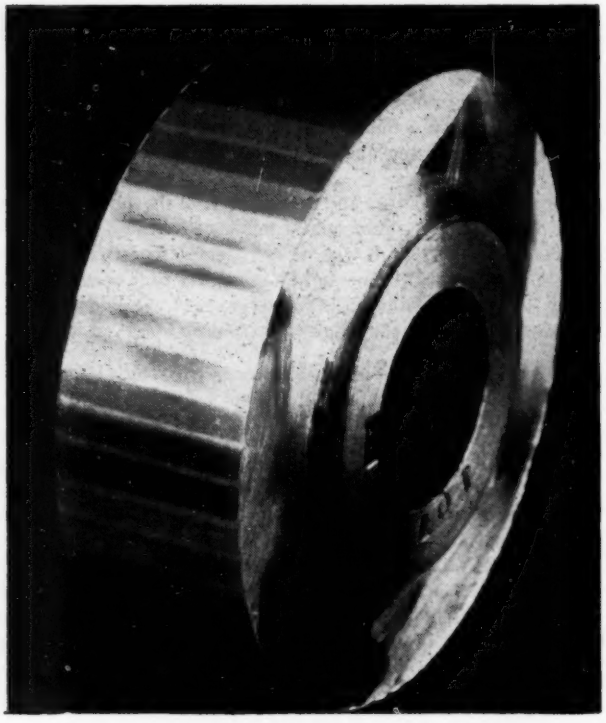

FIG. 3 TEST ROLL NO. 109, CARBON MACHINE STEEL
(3.30-in-diam roll, 0.50 carbon steel, with 8 per cent sliding, 1940-lb load, 67,800 cycles.)

of more exact methods, conditions are compared on the basis of static radial loading only.

On several tests, it has been noticed that the input torque tended to decrease to a minimum as the test progressed, and then to rise slightly after a long period of running under minimum torque conditions. This increase of torque takes place before any indication of destructive pitting can be detected by an examination of the unetched surface. Destructive pitting then occurs in from one or more million cycles after the increase of torque has been detected. Test No. 112 was run until the torque was observed to rise from a minimum of about 1.90 to 2.06 lb at a radius of 1 ft. The results of these tests are plotted in Fig. 2, showing the Vickers hardness numbers against the depth in thousandths of an inch below the surface. The dotted lines at the ends of the graphs show the hardness of the core.

It will be noted that the maximum-hardness reading is obtained at a distance of a few thousandths of an inch below the surface; also, that the depth of maximum hardness is greater for test No. 111 than for test No. 110. It is possible that there is a tendency for the surface material to start to disintegrate, perhaps because of the reversed bending action on the surface as the elastic wave travels ahead of the contact. Photomicrographs taken just below the surface show slip lines, indicative of cold-working. In that of test No. 112, the structure had a semblance of having been more severely worked than either of the other two samples. The grains had the appearance of having shattered in this case. The structure as a whole showed a general precipitation at the grain boundaries and many slip planes.

With very plastic materials, such as soft steel and brass, under heavy loads, this plastic flow of the surface material results in definite waves or corrugations on the surface, much the same as may be found on gravel roads, particularly on the uphill grades. One possible explanation is that when the plastic flow has hardened the material sufficiently, the plastic flow is stopped or reduced at that point; then the rolls ride over and start to build up another wave. Sliding accentuates this condition greatly. Similar waves or corrugations are often found on railroad rails, particularly on curves where sliding between the wheel and rail is greater than on straight stretches.

Fig. 3 shows a 3.3-in-diam test roll of 0.50 carbon machine steel (substantially S.A.E.-1050) which was run with a hardened-steel roll of 2.2 in. diam under a load of 1940 lb for 67,800 cycles. The hardness of the core material was 77 Rockwell B; that of the crest of the waves 89 Rockwell B, and that of the trough of the wave 86 Rockwell B. The pitch diameters of the gears used on the ends of the shafts were 3.20 in. and 2.30 in., thus introducing a relative sliding action between the rolls of slightly less than 8 per cent. Another sample of the same material, 3.5 in. diam, was run with a 2.3-in-diam roll of hardened steel, with rolling action only, under a test load of 3500 lb for 3,000,000 cycles without destructive pitting or waves becoming apparent on the surface.

It is believed that the change in torque observed as the test progresses is some measure of the work done in the plastic deformation of the test samples. For example, on test No. 112, the initial scale load (at a radius of one foot) shortly after the test was started was 3.5 lb. After about one hour, it had fallen to 2.30 lb. After 24 hours continuous running, it had fallen to 2.25 lb. Then it showed a continuous decrease to 1.9 lb at the end of about four million cycles before it started to rise again to 2.06 lb when the test was stopped for examination of the structure of the surface material. The first reduction of from 3.5 lb to 2.25 lb was largely the influence of the warming up of the testing machine. The further reduction of torque is believed to be a measure of the plastic working. When the torque has reached a minimum, and continues there without further change, it is felt that this is reliable evidence that the material has been cold-worked to its limit under the specific test conditions, and that any deformations, other than those resulting from failure of the material, are elastic ones only.

INFLUENCE OF ELASTIC DEFORMATION

At the same time that the surface lamina is being cold-worked by the plastic flow, and even after the surface has been cold-worked to the limit, the elastic wave traveling ahead of the contact imposes reversed bending conditions on this surface lamina. The result appears to be, in many cases, the development of microscopic cracks at right angles to the direction of rolling. Microscopic examination of the stainless-steel samples showed evidence, as already noted, of disintegration of the surface material at the grain boundaries.

Incidentally, the number of cycles of stress required to establish the surface-endurance limits is very much greater than the number of cycles required to establish the flexural or bend-

ing endurance limit. Where, in general, from one to five million cycles will establish the flexural endurance limit of the softer steels, from twenty to thirty million cycles appear to be necessary to establish the surface-endurance limit.

In some cases, tests have been run to twenty-five or thirty million cycles without any surface indications (without etching) of destructive pitting, and the test has then been stopped. To make sure that the material is still sound, a light lathe cut has been made on the surface. In some cases, the material has crumbled away in front of the cutting tool, showing the disintegration of the surface material, although it was not evident from a careful examination of the surface. In other cases, a clean chip was obtained, which indicated that the surface material was still sound, yet the appearance of the surfaces which gave either types of chip conditions appeared to be the same. In all cases where a chip has been taken on the surface of rolls which have failed by destructive pitting, the material crumbled away in front of the cutting tool.

In all cases where the loads are appreciable, whether the stresses are above or below the surface-endurance limits of the material, small pits are evident on the surface. These are shallow, possibly up to 0.005 in. deep at most, generally much less, and the shapes appear to depend upon the structure of the material. Some are microscopic, only a few thousandths of an inch across; others are one sixteenth of an inch or more, and of irregular shapes. This we have called "incipient pitting." Various explanations have been suggested to account for this phenomenon. Dr. Stewart Way[3] ascribes it to the formation of microscopic surface cracks followed by the penetration of oil which lifts these small sections out because of the hydrostatic pressure developed at the region of contact. It has also been called "corrective pitting" and ascribed to the high local pressures developed on the ridges or peaks of surface irregularities left by the cutting tool. It has also been suggested that the plastic flow of the surface lamina builds up local shearing stresses that shear these particles out after the surface cracks appear. Possibly any or all of these explanations may be true, depending upon the conditions and nature of the material. At all events, this incipient pitting does not appear to be the cause of any great concern. If the loads are below the surface-endurance limits, this incipient pitting appears to progress to a certain extent and then to cease. It is our belief that the elastic wave traveling ahead of the contact is a contributing factor to this phenomenon.

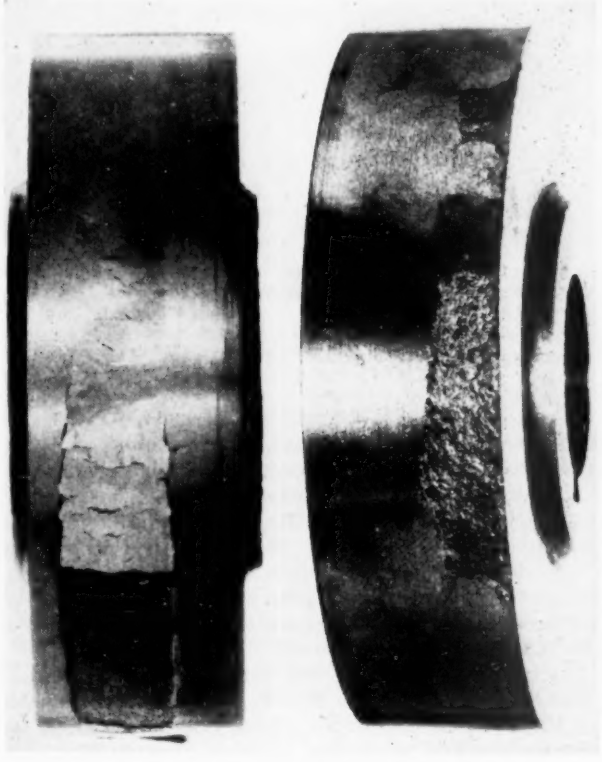

FIG. 4 BLISTER IN BRASS TEST ROLL RUNNING WITH HARDENED-STEEL ROLL
(Brass roll, 3.5 in. diam; 3500-lb load; 305,000 cycles. Thickness of flake, 0.018–0.021 in.)

FIG. 5 SURFACE FAILURE OF NICKEL-CAST-IRON TEST ROLL
(Test No. 23: 4.00-in-diam roll; 3500-lb load; 406,000 cycles.)

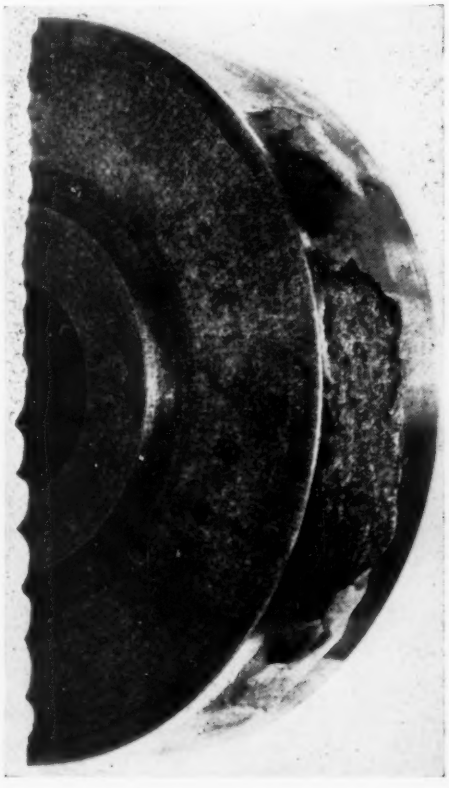

FIG. 6 HEAT-TREATED NICKEL-CAST-IRON ROLL AFTER RUN OF 400,000 CYCLES UNDER 3435-LB LOAD
(Test No. 34: 3.80-in-diam roll; thickness of flake, 0.033–0.036 in.)

DESTRUCTIVE PITTING

Simultaneously with the foregoing phenomena, and probably with many others not yet observed, shear stresses are repeatedly imposed upon the material below the surface. When the loads imposed develop stresses beyond the surface-endurance limits of the material, particles or flakes will be sheared out of the surface of the material; and thus far in these tests, with very few exceptions, the thickness of these flakes or the depth of the pits has been equal to or greater than the depth to the point of maximum shear.

In the case of a phenolic laminated test roll (bakelite) of 4 in. diam running with a 2.3-in-diam hardened-steel roll under a load of 1720 lb, both rolls of 1 in. face width, at the end of 107,000 cycles of the bakelite roll, a blister appeared on the surface with

FIG. 8 CHROME-NICKEL-CAST-IRON ROLL AFTER RUN OF 13,090,000 CYCLES AT 1500 LB LOAD
(Test No. 21: 3.70-in-diam roll.)

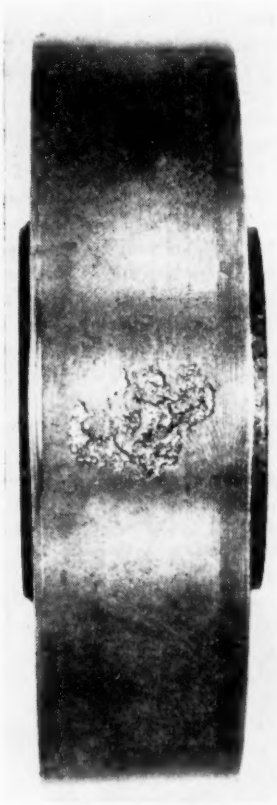

FIG. 9 PHOSPHOR-BRONZE ROLL AFTER RUN OF 1,125,000 CYCLES UNDER 3500 LB TEST LOAD
(Test No. 26: 4-in-diam roll.)

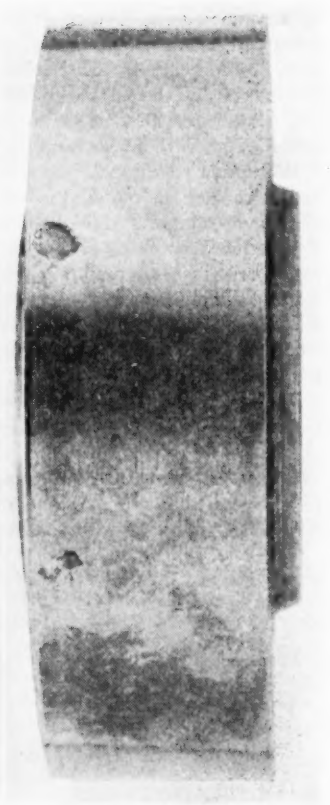

FIG. 10 MACHINE-STEEL ROLL AFTER RUN OF 808,000 CYCLES UNDER 4750 LB LOAD
(Test No. 103: 3.50-in-diam roll, 0.20 carbon steel, 4750-lb load, 808,000 cycles.)

no cracks or other signs of failure on the surface. When the sample was split to examine the blister, a crack about one quarter of an inch long about 0.15 in. below the surface was found to have developed under the blister. In addition, a circular band of the typical dark-brown color of overheated phenolic resins, about 0.030 in. wide and 0.150 in. below the surface, was present, running entirely around and concentric with the surface. A similar dark-brown band of about one half this width was also observed, extending from the surface to slightly below it. Here, the material itself made an automatic record of the heat concentration built up by the internal friction created by the stresses imposed. The testing of these materials is thus further complicated by these thermal conditions. The material has high internal friction, low heat conductivity, and appreciable loss of strength at higher temperatures. Thus in the case of a test roll of this material, 2.3 in. diam, running with a hardened-steel roll of the same diameter, under a test load of 1181 lb running at 950 rpm, the test roll blistered after 7000 cycles. Another roll of the same size and material, under the same test load, running at 350 rpm, blistered after 122,000 cycles.

As noted in Progress Report No. 15,[2] on a brass sample, a blister of similar character to that on the bakelite extended around nearly three quarters of the circumference. This roll is shown in Fig. 4. The brass roll was 3.50 in. diam running with a hardened-steel roll 2.30 in. diam under a load of 3500 lb. The failure occurred at the end of 305,000 cycles; the thickness of flake varied from 0.018 to 0.021 in. The surface hardness before test was 51 Rockwell B and after the test was 87 Rockwell B.

On the softer and more plastic cast-iron alloys, large flakes sheared out of the surface, some one quarter of an inch wide and as much as one inch in length. On the harder heat-treated cast-iron alloys, these flakes were sometimes as small as one eighth of an inch and of irregular shape. These flakes varied in thickness from about 0.010 in. to 0.035 in., depending largely upon the intensity of the load and the number of cycles. Fig. 5 shows the failure of the surface of a 4-in-diam test roll of nickel cast iron, running with a 2.30-in-diam hardened-steel roll under a load of 3500 lb, at the end of 406,000 cycles.

Unless otherwise noted, all tests were run against a hardened-steel roll of 2.3 in. diam. Fig. 6 shows a heat-treated nickel-cast-iron roll, 341 Bhn, 3.80 in. diam, after a run of 400,000 cycles under a load of 3435 lb. The flakes measured from 0.033 to 0.036 in. in thickness.

Fig. 7 shows a chrome-nickel-cast-iron roll, 3.7 in. diam, after a run of 661,000 cycles under a load of 2500 lb. Fig. 8 shows another roll of the same size and material after a run of 13,090,000 cycles under a load of 1500 lb.

Fig. 9 is a phosphor-bronze roll, 4 in. diam, after a run of 1,125,000 cycles under a load of 3500 lb.

Fig. 10 illustrates a machine-steel roll (substantially S.A.E. 1020), 3.5 in. diam, after a run of 808,000 cycles under a load of 4750 lb. The original hardness was 22 Rockwell C, and the surface hardness at the end of the test had increased to 32 Rockwell C.

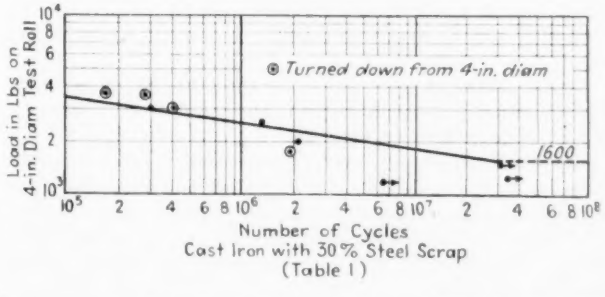
These illustrations show some of the different types of destructive pitting; on some, the shallow cavities left by the incipient pitting may be seen. There does not appear to be any con-

nection between the incipient pitting and the destructive pitting.

The exact sequence of the different phenomena is a matter of question. Probably in some cases a crack may start under the surface in the region of high shear stresses before the disintegration of the surface material progresses far. This appears to be the case with the phenolic-laminated materials and brass. In other cases, the reverse may be true. Again, both types of failure may progress together. Probably the specific physical characteristics of the materials influence these conditions.

Tests on Cast-Iron Alloys

The most extensive series of tests to date has been on several cast-iron alloys. All of these tests were with rolls, 1 in. face width and running with a hardened-steel roll, 2.30 in. diam, unless otherwise noted. The first test rolls were 4 in. diam and were then turned down after one test and used again in a succeeding test. Here it was noted that the surface material crumbled away ahead of the cutting edge of the tool, so the diameter was reduced until the nature of the chip indicated sound material. The results of some of these tests indicated that the properties of the material might be changing as the diameter was reduced more and more from the original size. Therefore, on later tests, the rolls were cast to a size to finish 2.3 in. diameter. The smaller rolls were used to permit higher speeds of the test disks within the same range of surface velocities as before, to save time, particularly after it became evident that the tests must run to thirty million cycles or more to establish the surface-endurance limits of these materials.



The following tables give representative test results. The actual test data are given first, followed by the equivalent load (based upon static stress conditions) on a 4-in-diam test roll, and the equivalent Brinell hardness number for purposes of comparison.

Semisteel. Table 1 gives the test results on gray iron with

30 per cent steel scrap, sometimes known as "semisteel." The chemical analysis of a sample of this material is as follows: Silicon, 1.84; sulphur, 0.136; manganese, 0.65; phosphorus, 0.387; total carbon, 3.25; graphite, 2.80; combined carbon, 0.45.

The results of tests of the physical properties of this material were as follows:

	As cast	Heat-treated
Ultimate strength, psi	35200	45950
Elastic limit, psi	15000	35750
Brinell hardness number	223	255
Flexural endurance limit	21000	25000

The heat-treatment (tests Nos. 18 and 32) was as follows: Heat to 1500 F, and quench in oil; draw to 950–1000 F.

After some tests, the surface was so thoroughly destroyed that no reliable hardness measurements could be made. In many cases, the flakes were so broken that no measurement of their thickness could be made.

The surfaces were turned on the samples that did not fail, and the nature of the chips indicated sound material.

As none of the samples under rolling contact failed after 30,000,000 cycles, the intersection of the line representing the load against the number of cycles on a logarithmic chart with the 30,000,000-cycle point has been used to estimate the surface-endurance limit. Thus, the surface-endurance limit of this material has been estimated as between 1500 and 1600 lb load on a 4-in-diam test roll of 1 in. face width in rolling contact with a hardened-steel roll of 2.30 in. diam. The equivalent maximum specific compressive stress, on the basis of static-stress conditions of load, is equal to 87,500 psi.

alloyed with nickel, with the rolls as cast. The chemical analysis of a sample of this material is as follows: Silicon, 1.42; sulphur, 0.117; manganese, 0.37; phosphorus, 0.448; total carbon, 3.36; graphite, 2.50; combined carbon, 0.86; nickel, 1.52.

The results of tests on physical properties tested were as follows:

Ultimate strength, psi	35400
Elastic limit, psi	12600
Brinell hardness number	217
Flexural endurance limit, psi	16000

The roll used for test No. 53 did not fail. The surface could be turned after test and the nature of the chips indicated sound material.

On the early tests, the rolls were turned down after previous tests. The results seemed to indicate a possible change in the material away from the original cast surface. Some of the tests were repeated with rolls cast to finish 4.00 in. and 2.300 in. diam. The results showed longer life. The tests were not continued further because heat-treated rolls appeared to give much better results. The surface-endurance limit under the rolling-test conditions

* TURNED DOWN FROM ORIGINAL 4" DIAMETER AFTER EARLIER TESTS.

was estimated at about 1000 lb load on the 4.0-in-diam roll. The equivalent maximum specific compressive stress was about 69,200 psi.

Two tests were conducted, introducing about 9 per cent sliding by using a 2.40-in-diam hardened-steel roll, and a 2.20-in-diam nickel-cast-iron roll with gears of 2.3 in. pitch diam on the end of each shaft. These results are given in Table 2B.

The roll used for test No. 141 did not fail. The turned surface indicated sound material. The surface endurance limit with about 9 per cent sliding appears to be about the same as for rolling action, although it appears to fail sooner with test loads greater than the endurance-limit loads.

Another series of tests was made with this nickel cast iron heat-treated as follows: Heat to 1500 F, and quench in oil; draw to 980 F.

The physical properties tested as follows:

Ultimate strength, psi	41700
Elastic limit, psi	24000
Brinell hardness number	246

Table 2C gives the results of rolling tests on this heat-treated material.

* TURNED DOWN FROM ORIGINAL 4" DIAMETER AFTER EARLIER TESTS

The tests on these heat-treated rolls, which were turned down from earlier tests, seemed to indicate that the material nearer the original cast surface was better than that away from it, much the same as in the case of the materials as cast. These tests were not continued further because a more effective heat-treatment for this material had been developed. The surface-endurance limit of this heat-treated material under rolling action is estimated at about 1200 lb load on a 4-in-diam test roll. The equivalent maximum specific compressive stress is equal to about 75,800 psi.

Another series of tests were made with this nickel cast iron, heat-treated as before, but drawn to about 350 Bhn. The results of these tests are given in Table 2D.

These tests were not continued further because a more effective heat-treatment had been developed for this material. The surface endurance limit under rolling action was estimated to be about 1400 lb test load on a 4-in-diam test roll. The equivalent maximum specific compressive stress is equal to about 81,900 psi.

Another series of tests was made with this nickel cast iron, heat-treated as before, but drawn to about 400 Bhn. The results of these tests are given in Table 2E.

The surface endurance limit under rolling contact was estimated to be about 1400 lb test load on a 4-in-diam roll. The equivalent maximum specific compressive stress is equal to 81,900 psi. When the test points are plotted, they group together with those of the tests on this same material heat-treated to 350 Bhn.

While the foregoing tests on heat-treated nickel cast iron were being made, experiments were being conducted by the company

supplying the material on different heat-treatments. The following heat-treatment was developed which changed the structure of the material, particularly the form and dispersion of the graphite, which gave much higher physical properties to the material (patents have been applied for on this heat-treatment): Heat to 1500 F and hold until thoroughly heated; quench to 650 F and hold until heat is uniform; cool in boiling soda water. On the test rolls, the parts are held about 30 min.

This interrupted-quench treatment gave the following properties to a test sample:

Ultimate strength, psi	46500
Elastic limit, psi	25000
Brinell hardness number	287
Flexural endurance limit, psi	19000

The results of the tests for surface endurance are given in Table 2F.

Rolls used on tests Nos. 122 and 123 did not fail; the surface being turned after test showed sound material.

Test No. 121, being out of line with the others, led to suspicion of the material. A microscopic examination disclosed an improper structure, believed to be evidence of too short a time of heat-treatment. Untested rolls, later used on tests Nos. 122, 123, and 124 were also examined and found to be of the same improper structure. These rolls were heat-treated again, and test No. 124 gave results beyond the average, a possible indication that the double heat-treatment improved the material still further. The surface-endurance limit under rolling action is estimated to be about 2400 lb on a 4-in-diam test roll. The equivalent maximum specific compressive stress is equal to 107,300 psi.

Three additional tests were made, introducing about 9 per cent sliding by using a 2.4-in-diam hardened-steel roll and a 2.2-in-diam nickel-cast-iron roll, with gears of 2.30 in. diam on each shaft. The results of these tests are given in Table 2G.

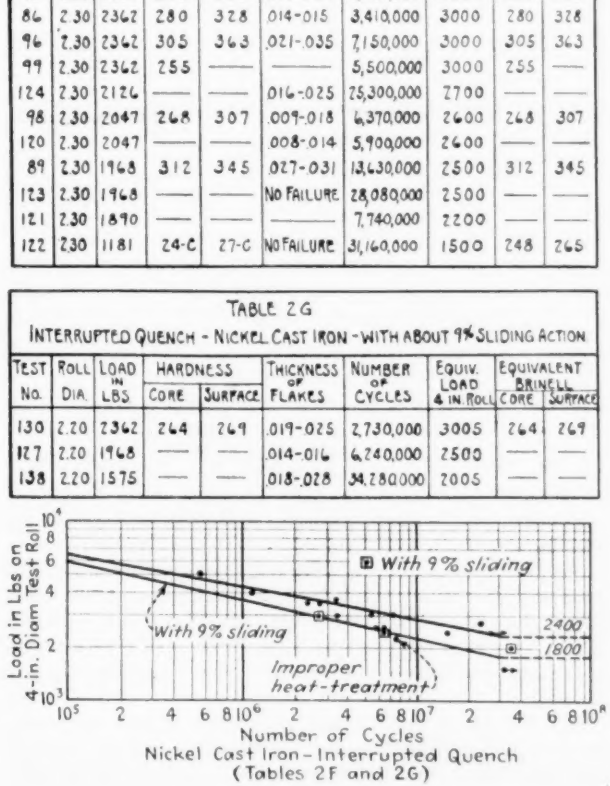
With 9 per cent sliding action, the estimated surface-endurance limit appears to be about 1800 lb on a 4-in-diam test roll. This is about 75 per cent of the value under rolling conditions. The equivalent maximum specific compressive stress is equal to 92,900 psi.

Chrome-Nickel Cast Iron. Table 3 gives the test results on chrome-nickel cast iron. The chemical analysis of a sample of this material is as follows: Silicon, 1.24; sulphur, 0.130; manganese, 0.44; phosphorus, 0.297; total carbon, 3.39; graphite, 2.50; combined carbon, 0.89; nickel, 1.44; chrome, 0.50.

The physical properties of this material tested as follows:

	As cast	Heat-treated
Ultimate strength, psi	39000	44730
Elastic limit, psi	15100	31600
Brinell hardness, Bhn	234	243

The heat-treatment was as follows: Heat to 1500 F; quench in oil; draw to desired hardness.



The heat-treatment employed did not appear to have very

much influence on the surface endurance, which was estimated at about 1100 lb on a 4-in-diam test roll under rolling action.

Molybdenum Cast Iron. Table 4 gives the test results on molybdenum cast iron. The heat-treatment used was the same interrupted quench as was used on the nickel cast iron and reported in Table 2F. The chemical analysis of a sample of this material is as follows: Silicon, 1.77; manganese, 0.59; total carbon, 3.12; molybdenum, 0.66.

The physical properties of this material, heat-treated, are as follows:

Ultimate strength, psi	49000
Elastic limit, psi	22400
Brinell hardness, Bhn	290
Flexural endurance limit, psi	22000

The estimated surface-endurance limit under rolling action on a 4-in-diam test roll was about 1400 lb for material as cast, and about 2700 lb for interrupted quenched material. The equivalent

maximum specific compressive stress for the heat-treated material is equal to 113,700 psi.

Phosphor Bronze. Tests were made on two lots of phosphor gear bronze, both of them being substantially the same as S.A.E. 65 bronze. One lot was cast against a chill, the other was not. Three tests were run with the bronze rolls against heat-treated nickel-cast-iron rolls. The results of these tests are given in Table 5.

The test roll on test No. 56A did not fail. When turned after test, the material crumbled ahead of the cutting tool, showing the disintegration of the surface material. The surface-endurance

limit of material cast against a chill was estimated to be about 1500 lb on the 4-in-diam test roll under rolling action. The equivalent maximum specific compressive stress was equal to 82,800 psi.

The estimated surface-endurance limit for sand-cast material under the same conditions is about 1000 lb; equivalent maximum specific compressive stress, 67,600 psi.

The estimated surface-endurance limit for sand-cast material, running with a cast-iron roll under the same conditions, is about 2000 lb; equivalent maximum specific compressive stress, 83,300 psi.

Another lot of similar material was tested, which was cast in a cast-iron foundry with little regard for the technique of handling bronze. The results are given in Table 5A.

This material was evidently badly overheated when it was melted before pouring. The alloy was obtained in pigs from a reliable bronze company. The differences in original hardness would indicate that the samples, identified by the test numbers, were poured in the following order from the ladle: Nos. 171, 167, 170, 168, 169, 166.

The samples from tests Nos. 166 and 167 were etched, and also broken to examine the fracture. Very large crystals were apparent in No. 167, while they were much smaller in No. 166. On the outside surface, where destructive pitting was present, no crystal structure could be seen, indicating amorphous material where the surface had started to disintegrate. The fractures were in keeping with the porous overheated material. When proper foundry practices are followed, this material should have a surface-endurance limit of over 800 lb on a 4-in-diam test roll under rolling action. The estimated surface-endurance limit on these overheated rolls is about 150 lb.

Summary

Although the complex behavior of plastic materials under the repeated surface stresses set up by rolling and sliding is still far from being understood, and also because the actual intensities of the several stresses, compressive, tensile, and shear, are thus far indeterminate, yet the actual test-load results may be applied safely to design. These tests were started in 1931, and the test results have been successfully applied in the design of cams and their roller followers, and in the design of gears since then. The comparative results between different materials as found in these tests are confirmed by the behavior of these materials in service as elements of automatic machines operating in production. The limiting loads, as determined from these tests, have thus far resulted in designs with no appreciable wear.

For the purpose of setting up a load-diameter-stress factor, we will start from the Hertz equation for the stresses set up between two loaded cylinders in contact. When

s = maximum specific compressive stress, psi
w = load on cylinders, lb per in. of length
r_1 and r_2 = radii of cylinders, in.
E_1 and E_2 = modulus of elasticity of materials

$$s^2 = \frac{0.35w(1/r_1 + 1/r_2)}{(1/E_1 + 1/E_2)}$$

We will now introduce an experimental factor of load and stress concentration, based upon the test values; whence K_1 = experimental load-stress factor for two cylinders

$$K_1 = w(1/r_1 + 1/r_2) \quad \text{(by definition)}$$

and

$$w = K_1/(1/r_1 + 1/r_2)$$

Referring now to Table 1, for the test results on a roll of 4.00 in. diam of semisteel running with a hardened-steel roll of 2.300 in. diam, both with a face of 1.00 in., we have an experimental surface-endurance-limit load of 1600 lb. This gives the following values for use in the foregoing equation:

$$w = 1600 \text{ lb}$$
$$r_1 = 1.150 \text{ in.}$$
$$r_2 = 2.000 \text{ in.}$$

$$K_1 = 1600\ (1/1.150 + 1/2.00) = 2191$$

These factors (K_1) are used to determine the limiting surface loads between two curved surfaces. These limiting loads are the ones which can be carried indefinitely without appreciable wear. (If abrasive particles are present, these values do not apply.) For example, if the minimum radius of curvature of a cam is 4 in., and the cam roll is 2.00 in. diam., the cam being made of semisteel and the roll of hardened steel, then

$$r_1 = 1, \qquad r_2 = 4.00$$

$$w = 2191\ (1/1 + 1/4.00) = 1.25 \times 2191 = 2738 \text{ lb}$$

For involute-spur-gear teeth, where

K = load-stress factor for gear teeth
ϕ = pressure angle
D_1 = pitch diameter of pinion, in.
D_2 = pitch diameter of gear, in.
N_1 = number of teeth in pinion
N_2 = number of teeth in gear
F = face width of gears, in.
W_w = limiting load for wear, lb
Q = ratio factor

$$r_1 = D_1 \sin \phi/2$$
$$r_2 = D_2 \sin \phi/2$$

$$(1/r_1 + 1/r_2) = (2/\sin \phi)\ (1/D_1 + 1/D_2)$$

Let

$$K = s^2 \sin \phi\ (1/E_1 + 1/E_2)/(4 \times 0.35)$$
$$Q = 2N_2/(N_1 + N_2) = 2D_2/(D_1 + D_2)$$
$$W_w = D_1FKQ$$

The value of (K_1) for cylinders is

$$K_1 = w(1/r_1 + 1/r_2) = s^2(1/E_1 + 1/E_2)/0.35$$
$$K/K_1 = \sin \phi/4$$
$$K = K_1 \sin \phi/4$$

Hence, for this combination of semisteel and hardened steel, we have the following:
For $14^1/_2$-deg gears

$$K = (2191 \times 0.25038)/4 = 137$$

For 20-deg gears

$$K = (2191 \times 0.34202)/4 = 187$$

As an example, we will use a pair of 6 DP gears, 20-deg pressure angle, 2 in. face, of 24 and 36 teeth. This gives the following values for the limiting wear-load equation:

$$N_1 = 24 \quad N_2 = 36 \quad D_1 = 4 \quad K = 187 \quad F = 2$$
$$Q = 72/60 = 1.2$$
$$W_w = 4 \times 2 \times 187 \times 1.20 = 1795 \text{ lb}$$

The following values of (K_1) and of (K) have been computed in this manner from the experimental values. Except where noted

Table no.	Material	Cylinder K_1	Gears $14^1/_2$ deg K	Gears 20 deg K
1	Semisteel	2191	137	187
2(*a* and *b*)	Nickel cast iron	1369	85	117
2(*c*)	Nickel iron, heat-treated, 300B	1643	102	140
2(*d* and *e*)	Nickel iron, heat-treated to 350–400	1917	120	163

5	Phosphor bronze, overheated when cast	205	12	17
5	Phosphor bronze, sand cast and nickel iron, interrupted quench	2739	171	234

otherwise, a hardened-steel test roll has been used in contact with the material specified.

Discussion

G. B. WARREN.[4] Professor Buckingham is to be congratulated upon making another fundamental contribution to gear information. The writer hopes that the author will be able to extend the excellent data contained in this paper to a larger variety of steels with different hardness values, since hardened steels are the more common gear materials used in high-duty machines today. Fundamental data of this character are required in order to extend these designs still further, or to design with greater assurance of reliable performance.

Some of the tests reported in the paper were run with sliding between the rollers. A few of the tabulations indicate a significant increase in the tendency to pit with sliding when the member under consideration is running at a slower speed than its mating roller. There is considerable evidence in actual gear performance and in some tests which have been run by Brown-Boveri along similar lines to indicate that the pitting resistance of the higher-speed roller, of two rollers that are rolling and sliding on each other, is greatly increased. The writer would like to discuss this matter briefly and to draw certain conclusions which may have considerable significance in connection with gear design and performance.

While not posing as a gear expert, it so happened that some gear-pitting difficulties in connection with a gear-reduction job were brought to the writer's attention. In posting himself on the subject, some of the principal contributions to the literature which have been made in recent years were obtained from the company library. Four rather outstanding references were found which are to some extent extracted in the Appendix to this discussion.

After studying these, the writer has come to the following conclusions and hypotheses regarding pitting, some of which fit in with previously advanced theories and some are additions thereto, which, so far as he has been able to determine, have not been made before. These are being submitted herewith for critical consideration:

Referring to Fig. 11 of this discussion, based upon the information which the writer has been able to obtain, particularly from reference (1) in the Appendix, it would seem that there are two types of pitting as follows:

1 A large number of usually disconnected small pits as shown at *N* on the dedendum of the gear, that is, below the pitch line. It is understood this is sometimes called "benign" pitting which very frequently occurs on gears in their early stages of operation and which, although somewhat harmful and a source of annoyance to users, may be self-limiting, i.e., it will reach a stable point and not progress further, particularly on soft gears which are not too heavily loaded. It is not clear what is its end point on harder more heavily loaded gears. This is sometimes called "spalling" in the English literature.

2 Pitting, as shown at *O* between the arrows *P-P* directly on the pitch line, is a form of surface failure which, so far as can be ascertained, only occurs on extremely heavily loaded gears. The pits may form connected areas from which the entire surface may be removed, and this form probably leads to ultimate failure.

With respect to type 1 of pitting described, it seems to be the

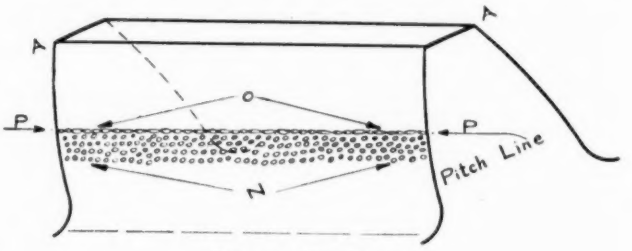

FIG. 11 GEAR PITTING

general consensus of opinion: (*a*) This is a difficulty associated with high pressure between two rolling surfaces; (*b*) it takes place only when sliding is in a direction opposite to the rolling; and (*c*) it will only take place in conjunction with and is due to the action of the lubricant.

As a result of the following analysis, and to the evidence of reference (1) the writer has concluded that this type of pitting is much less prevalent on case-hardened gears than on deep-hardened or unhardened gears, and that it might be entirely eliminated by a treatment which would put the surface of the gear tooth under compression, as is done on case-hardened, induction-hardened, or flame-hardened gears which are not ground subsequently.

Let us consider Figs. 12, 13, and 14, of this discussion, respectively, showing the action of two gear teeth along the line of action *a-b-c*, in successive stages of the tooth contact.

In Fig. 12 is shown the first stage of the contact with the motion from left to right and the lower gear driving the upper with the contact at b_1.

The rolling progresses between the two convex surfaces of the teeth upward as the gear turns. Looking at the point of contact in the case of Fig. 12, the tooth on the upper gear slides on the tooth of the lower gear so that the sliding of the upper gear tooth is downward on the lower gear tooth, away from the pitch line, and in such a way as to put the skin of the lower gear tooth, that is, the driver, in tension due to the frictional forces, and the corresponding section of the upper gear tooth, the driven tooth, in compression.

Considering Fig. 13, when the two teeth have progressed so that the contact is at the point where the line of action a_2-b_2-c_2 goes through the pitch line of the two gears, then we have pure rolling contact and theoretically no sliding.

Let us consider Fig. 14, where the contact is on the upper end of the driving tooth just before it leaves contact with the driven tooth at b_3 on the line of action a_3-b_3-c_3. At this point, the gear teeth are being pulled apart by the instantaneous motion, and the driving tooth is sliding downward along the dedendum surface of the driven surface as shown by the arrow *Z*.

[4] Designing Engineer, Turbine Engineering Division, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

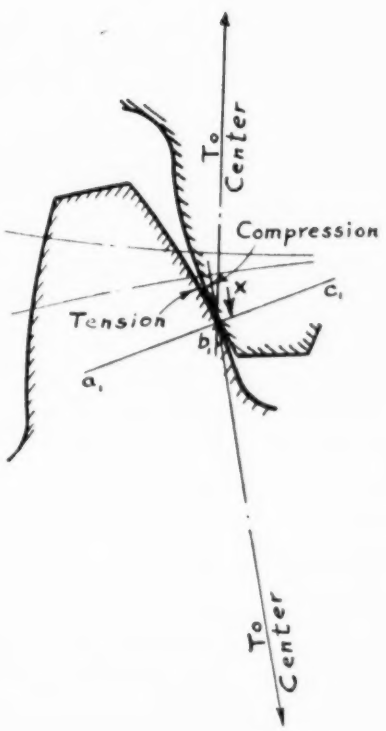

FIG. 12

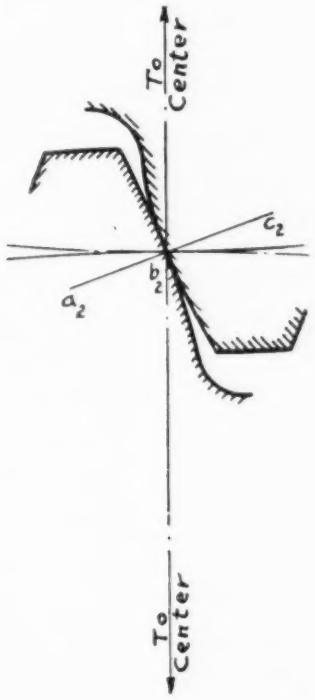

FIG. 13

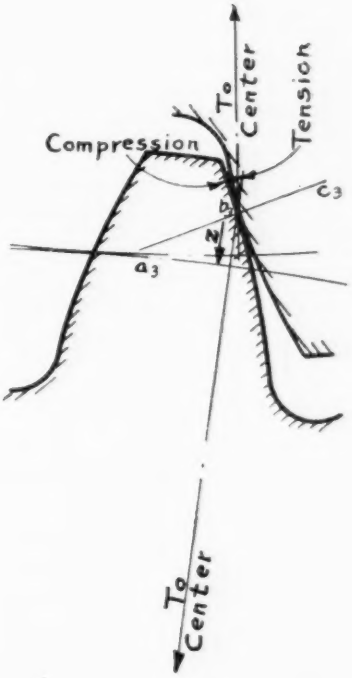

FIG. 14

As stated, the rolling action is progressing upward as the teeth move through the line of action. A careful examination of these three figures will indicate that the addendum, that is, the section of the tooth outside of the pitch line, in each case, is sliding radially on the dedendum portion of the opposite tooth in such a way as to stretch the material of the dedendum ahead of the rolling, and that the oil which has been fed onto the surfaces of the gears is being rolled into this point of contact by the progression of the point of rolling.

This action has been simulated between two rollers, as shown in Fig. 15, by numerous investigators, in which the rollers are

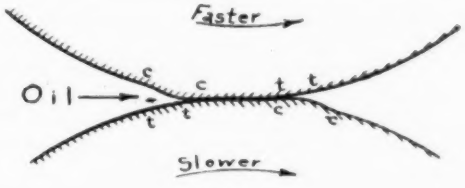

FIG. 15

rolling together in the direction as shown by the arrows but not at the same peripheral speed. If this is done, it can be seen that the traction of the friction parallel to the surface, when the surfaces are forced hard radially together, is such as to produce a tension in the surfaces marked *t-t* and a compression in the portion of the rollers marked *c-c*. The oil is also shown being fed in advance of the rolling point.

Fig. 16 shows an enlarged view of what might be considered as taking place on the surface in which any minute cracks or imperfections on the lower roller would be opened up and correspondingly closed up on the upper roller. The oil would, of course, then be forced into these cracks and raised to very high pressures by its passage under the point of contact, with resulting progressive fatigue failure which would finally lift small pieces of the surface out. This is apparently what happens. Observations show that invariably the pits form on the roller in which the friction of the sliding would produce tension and do not form on the roller in which the sliding would produce compression. This is so marked that even when the upper roller as shown, that is, in this case the higher speed one, is made one half the hardness of the lower roller, the upper roller develops no pits.

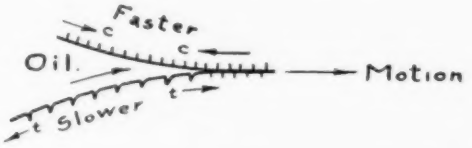

FIG. 16

It would seem that, if the surface could be put in compression to such an extent as to more than offset that which would be formed by the sliding friction, then it might be possible to preclude the formation of this type of pitting on either gear tooth. This is borne out to some extent by the observations that case-hardened gears do not form such pits so readily, although there is good reason to believe that if case-hardened gears are ground there would still be residual surface tension, as evidenced by frequent rejections due to grinding cracks (reference 4). Some tests on induction-hardened rollers which we have made seem to bear this out.

This hypothesis is further evidenced by the fact that on soft gears such pits on the dedendum inside or below the pitch lines, frequently formed during the initial stages of operation, sometimes seem to reach a stable point and do not increase or enlarge from that time on. It would seem as though the formation of a number of pits might permit the escape of the trapped oil, and hence result in a lesser building up of the hydraulic pressure. Also, on soft gears the initial running-in will produce cold work

on the surface and may result in a surface compression stress which would reduce the further formation of these pits.

With respect to type 2 pitting, as shown in Fig. 11 of this discussion, at *O* along the pitch line, the following hypothesis may explain this formation:

Consider the rolling in Figs. 17 and 18, which takes place at the pitch line of the gearing, as shown in Fig. 13. Theoretically, pure rolling is taking place with no sliding. Actually, up to the pitch line, the sliding had been as shown by the arrows in Fig. 17.

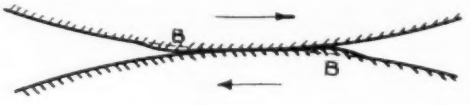

FIG. 17

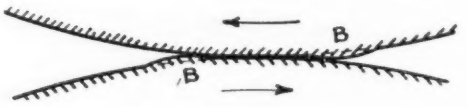

FIG. 18 GEAR PITTING

Immediately when the pitch line is reached and passed, the sliding reverses to the direction of the arrows as shown in Fig. 18. It is quite probable that some bulging of the surface, as shown exaggerated in *B-B* in Figs. 17 and 18, might take place. A more serious situation, however, might exist in the shear forces just below the surface but approximately parallel to the surface due to the tractional or frictional forces existing and to their sudden reversal.

At no other point on the tooth surfaces are these subsurface shear forces reversed through 180 deg in the same material. If the gears are heavy or if the gears and centers are rigid, then this sudden reversal probably takes place along one highly localized line immediately below the surface at the pitch line of both gears. This, it would seem, might easily account for the peculiar types of pits formed at this point, and for the fact that these pits when they are once started seem to progress and run into each other, because, unlike the formation of the other pits, the formation of a few pits would give no relief to the material and would actually increase the pressure on the remaining good surface of the gear.

It is not possible at this time to see any immediate means of remedying this situation.

The Appendix to this discussion contains excerpts from the four references which have been cited and which form the basis for the writer's conclusions.

It is to be hoped that the author or others will extend these roller tests in the near future, including such tests as will prove or disprove the hypotheses presented.

APPENDIX TO DISCUSSION

Reference 1. Excerpts from an article entitled, "Durability of Gears," by H. D. Mansion, which appeared in the *Automobile Engineer*, October, 1941:

Spalling denotes a type of mottled surface failure which appears to consist of a large number of tiny pits extending over a fairly large area, there being no lines in the direction of sliding such as are found in scoring. It has usually been observed on the dedendum of the driven gear teeth and sometimes on the addendum of the driving gear teeth, i.e., mainly during recess in conditions where the oil film is not broken down. Spalling might, in some instances, almost be described as pitting, but the latter term is reserved for the deeper failure to be described.

Pitting is the breaking out from the surface, usually on or near the pitch line, of large flakes, the resultant pits or holes being much deeper than any of the foregoing forms of surface failure. Pitting is generally considered to be a fatigue failure of the surface, though some difference of opinion exists as to the mechanism by which it occurs.

It was now found, in general, that this steel (Ni-Cr-Mo 100-ton oil-hardening steel, type F) would fail by pitting rather than by scuffing. With jet lubrication only, pitting occurred after short periods at loads of 2300 and 2460 lb per in., but with jet and bath lubrication, in a series of 1-hr tests, pitting did not occur until loads of 3830 and 4520 lb per in. were reached.

Of the surface failures which have occurred, two distinct types of pitting have been observed. The direct-hardening steels produce pits which are generally approximately circular and which do not, as a rule, join up with one another. The case-hardening steels, however, appear to become pitted right across the pitch line as though the case had flaked off over that area. It remains to be seen whether this will occur also on gears which are more deeply cased.

Referring in greater detail to the results shown in the tables and dealing first with the 8 D. P. design, it would appear from tables II and III, so far as the irregular nature of these first tentative tests permits of drawing conclusions, that the Ni-Cr-Mo 100-ton oil-hardening steel, when heat-treated in cyanide, in which condition it is virtually case-hardened, has greater resistance both to pitting and to fatigue failure than when simply oil-hardened without cyanide and can consequently carry a higher load without surface failure or breakage.

The incidence of pitting does not appear to be consistently affected by the grinding method used.

Reference 2. Excerpts from an article entitled, "Testing Gear-Wheel Material," which appeared in the *Brown-Boveri Review* for October, 1939:

A new apparatus developed by Brown-Boveri for the testing of gear-wheel material is described in this article. Some results of tests made are given. It is shown that direction of the sliding movement plays a preponderant part in the durability of the material.

Now, in order to reproduce faithfully the conditions pertaining to teeth faces, it is necessary to generate a sliding movement between the rollers. It is not desirable, to this end, simply to cause the shafts to rotate at different speeds. However, it is possible to create a sliding movement even when both shafts have the same number of revolutions, by making the test cylinders of different sizes or by coupling the shafts through eccentric involute gear wheels. The latter is the solution generally adopted in the present tests. It allows of the faithful reproduction on the periphery of one single test cylinder of all the movements occurring between two tooth faces, and thus of determining the behavior of the material by means of a few tests only.

If the sliding and rolling movements of the teeth of a gear wheel are studied, the following results are obtained: The rolling movement on a driving tooth is from root toward tip while on a driven tooth it is from tip toward root. The sliding on a driving tooth is always directed away from the rolling point and on a driven tooth it is directed toward the rolling point. Therefore, on the addendum, the rolling and sliding motions are in the same direction while being opposite on the dedendum.

Contrary to seizing, pitting only appears after a longer testing time. Small particles break out of the roller surface; the appearance of a typical pit is that of a sector of a circle with an angle of 90 to 120 deg. The fracture, being in the center of a sector in formation, penetrates from here at about 15 deg beneath the surface. On the surface, all that is to be seen at first are the two radii as very fine cracks, until finally the crack has advanced so far that the whole wedge now loosened—probably

under the pressure of the lubricating oil forced in—is lifted out of the surface and breaks off in circular shape.

The surface of the fracture is shell-like, and it can be seen that the fracture has advanced progressively as takes place in a fatigue fracture.

The tests show quite clearly that, contrary to seizing, pitting appears exclusively on one of the two test bodies. As is seen in all the illustrations, the pitting only appears on the dedendum arc *a* whereas the addendum arc *b* is always unaffected.

The limitation of pitting to the dedendum arc *a* is very sharply defined indeed. The pitting stops abruptly at rolling point *A*, the limit is sharply defined and coincides with the theoretically determined rolling point, to 0.01 in.

Thus the tests show that the pitting is furthered very much by sliding, but only when the sliding movement is counter to the direction of the rolling movement. The proclivity to pitting is increased to an astonishing degree and the illustrations show some exceptional examples. In one case with a roller of heat-treated chromium-nickel steel having a yield point of about 48 tons per sq in. much pitting appeared on the dedendum arc *a*, while on the other roller of carbon steel with a yield point of about 29 tons per sq in. no pitting occurred at all on the addendum arc *b*. On another roller, the width of the addendum arc *b* was reduced to less than half, and the linear pressure thus more than doubled. Despite this the addendum arc *b* remained intact while the dedendum arc *a* showed marked pitting.

The influence of the viscosity of the lubricating oil is also of interest; the more fluid the lubricating oil the bigger the pit. With transformer oil, big pits of 5 mm diam are formed, while with cylinder oil thep its are hardly bigger than a pinhead. This seems to confirm the view that the lubricating oil forced into the fatigue cracks helps pit formations and finally lifts the loose material from the surface. A heavy cylinder oil will be more likely to detach the material loosened from the lower layer and thus to complete the formation of a pit than a thin transformer oil which can easily escape from the narrowest cracks.

In order to investigate more completely the resistant character of the addendum arc, further tests were carried out with somewhat different apparatus. As said before, it is possible to generate a sliding movement of the two test rollers, one on the other, by imparting uniform running to the shafts but by using test rollers of different sizes. The sliding movement is then the same at every point. With the dimensions chosen here the specific sliding on the smaller test piece was minus 0.29 and on the bigger one plus 0.22. The result of these tests was as follows:

The smaller test pieces were made of carbon steel and of nickel steel with a yield point of 29 and 25 tons per sq in., respectively. The bigger test piece was of chromium-nickel steel with a yield point of 48 tons per sq in. After 3 to 6 hr, pits appeared on the smaller roller. The linear pressure was 1500 lb per in. on this test, the speed being 1000 rpm.

The contrary arrangement, that is, with smaller test pieces of chromium-nickel steel having a yield point of 48 tons per sq in., and the bigger ones of carbon steel and nickel steel having yield points of 29 and 25 tons per sq in., respectively, stood up to 100 running hours without any pitting at all. In order to force deterioration of the addendum arc, the surface of the bigger cylinder was turned down to about half its width and the load increased as much as the safety of the bearings would permit. The linear load was then 3500 lb per in., the stressing, according to the Hertz formula, 70 tons per sq in. After about 100 hr of running, in one case the smaller chromium-nickel roller broke down; in spite of having a yield point of 48 tons per sq in., it could not stand up to the bigger nickel-steel cylinder, having a yield point of only 25 tons per sq in.

We are at a loss, up until today, to furnish a plausible explanation of why the same material should support such exceptionally different stressings according to the direction of the sliding movement. Perhaps subsequent tests will give the answer to this problem.

Reference 3. Excerpts from a paper entitled, "Westinghouse Roller and Gear Pitting Tests," by Dr. Stewart Way, which was presented at the 24th Annual Meeting of the American Gear Manufacturers Association, May 1940:

The investigations being carried on at the Westinghouse Research Laboratories of surface fatigue failures (pitting) are of two types, roller tests and gear tests. Both are more or less indefinitely continuing activities, as new questions about pitting are always arising. Some of the results of the roller tests have been reported previously. (These roller tests were run at the same peripheral speed and were not sliding relatively. —G. B. Warren.)

As a result of these tests there are certain things which can now be put down as fairly definitely known about the formation of surface fatigue cracks on cylindrical surfaces.

We know they originate because of stresses due to surface irregularities rather than because of the theoretical Hertz stress system for smooth cylinders. The theoretical stresses for smooth cylinders do not depend on roughness; on the other hand, pitting strengths depend to a marked degree on roughness. Furthermore, if the pitting cracks were due to the theoretical stress system for smooth cylinders, they would be expected to start at a distance below the surface several times greater than the thickness of the surface layer in which the cracks are observed to start.

We know that it is possible to subject a piece of metal to a range of shearing stresses considerably larger than the shearing endurance range and yet have no failure. Thus the last pair of rollers listed in Table 3 was run 9.4 million cycles at a load of 202,000 psi theoretical compressive stress with no sign of pitting. This loading would give rise to a range of shearing stress plus or minus 50,500 psi on planes parallel to the surface at a depth of 0.0047 in. The shear endurance range of the material was only about plus or minus 30,000 psi, yet when one of these rollers was sectioned there was no evidence of cracks below the surface. The explanation of this is probably that high uniform compression, which exists in the metal below the loaded region, tends to prevent the formation of a fatigue crack at a range of shearing stress that would normally cause a crack.

We know that the growth of surface fatigue cracks to pits is made possible by the action of the oil in the cracks. Pitting cracks which develop in rollers run without oil will not grow to pits. By drilling a small hole (0.006 in. diam) in such a position as to relieve any oil pressure in a growing pitting crack, the growth of the crack can be arrested. The pitting cracks assume a direction that slopes obliquely into the metal; they are roughly in the form of a conical surface so that they meet the surface in the from of a parabola or V, with the vertex of the V being the part that is run over first. It is observed that reversing the direction of rotation after such sloping cracks have formed will stop the growth of the cracks.

When the fatigue cracks form, they may at first slope in various directions. However, there will most likely be some directions more probable than others. All cracks that have been observed in an early stage, both when viewed on the surface and in sections, are oriented in such a way that a perpendicular to the plane of the crack drawn in the outward direction leans in the direction of motion of the contact area. This means that any oil which enters such a crack will tend to be trapped as the crack passes under the loaded region, and a high pressure may be built up in it. A high oil pressure in a crack will produce high tensile stresses at the end of the crack, unless such tension is

canceled by the stresses due to external loads. It is quite possible that a crack, filled with oil, may come under the loaded area so that a high pressure is developed in the oil before the external loads can cause compression stress at the end of the crack to cancel the tension developed by the oil pressure. The crack might then easily be driven further into the metal. If this theory is accepted as a hypothetical picture of what goes on after a surface fatigue crack is formed, it accounts for the observations that oil is necessary for crack growth, that changing the direction of rotation stops crack growth, and that relief of oil pressure in the crack stops its growth.

To study the pitting resistance of gear teeth as influenced by various factors, and to determine what relations exist, if any, between the pitting limits of gear and pinion materials, as determined by roller tests and the pitting strengths of these materials when built into gear teeth, a gear-testing program has been undertaken.

We are here concerned only with the surface compressive stresses, not with the stresses due to tooth bending.

A synopsis of several gear tests shows the following:

The pitting of the gear was confined to the region between the pitch line and the end of one tooth contact.

It is significant that no pitting occurred above the pitch line, although the compressive stresses were slightly higher there.

There was no pitting above the pitch line on the pinion, and nine out of the ten pits were below the pitch line in the region of one-tooth contact.

In reviewing the Brown-Boveri results (2), Dr. Way goes on to say: It was found that negative specific sliding, as occurs in the dedendum region, diminishes pitting resistance, and positive specific sliding increases it (that is the resistance). A carbon steel that pitted at 92,000 psi compressive stress with negative specific sliding carried 140,000 psi without pitting, with positive specific sliding. This finding agrees well with the observation in our gear tests that pitting practically never occurred in the addendum region. It also indicates that negative specific sliding decreases the pitting resistance as compared to that for pure rolling contact.

Future rolling tests with rollers of different ratios and with various amounts of sliding will throw more light on the expected performance of gear teeth.

In a discussion of his article Dr. Way states the following:

On the sketch this is the pitch point and in this region the sliding is in the direction toward the pitch line. It was actually observed in gear tests that pitting was more or less entirely distributed over that whole region below the pitch line and in the region of one-tooth contact, rather than there being any particular tendency for pitting to occur at the pitch line. And since pitting occurred in the region of one-tooth contact where the contact pressure was even lower than it was just above the pitch line, it seems that the sliding, when it is in the direction opposite to the rolling, has the effect of promoting the pitting rather than retarding it, as might be expected, if this view of the oil-film formation is accepted.

You will observe in this region, just above the pitch line, where one pair of teeth was in contact that there was no pitting, while below the pitch line, even though the pitch line where the stresses were much lower than this, there was pitting.

Reference 4. Excerpt from an article entitled, "Peened Surfaces Improve Endurance of Machine Parts," by J. O. Almen, which appeared in *Metal Progress* for February, 1943:

When carburized parts such as bearing races, wrist pins, and gear teeth are ground, we may expect the surface to be stressed in tension.

The residual compressive stress in the carburized layer may be a hazard for members stressed in tension, because the tension stress in the core is equal to the working stress plus the tension stress due to the compressive preload of the case. For members stressed in bending and in torsion the internal compressive stress in the carburized case improves the fatigue strength of the part, except for the thin surface layer which, especially after grinding, is severely stressed in tension. It is, however, a simple matter to convert this thin tension-stressed layer into stress in compression by a suitable peening or rolling operation.

Author's Closure

The Research Committee accepts with thanks Mr. Warren's discussion as a valuable addition to the report. The only comment is in relation to his statement in his fifth paragraph: ".... it would seem that there are two types of pitting as follows:"

This could well be amended to read ".... there appears to be at least two types of *surface* pitting as follows:"

The breakdown of the surface is a very complex process; many different influences are acting and many types of pitting may be present. The author's presentation has been primarily of that type of pitting which results from the subsurface shear stresses. The many surface manifestations of distress deserve much more study, and it is hoped that continued tests, particularly with the harder materials, will shed more light on this phase of the problem.

Simplified Method of Analysis of Reactions Developed by Expansion in a Three-Anchor Piping System

By BORIS LOCHAK,[1] NEW YORK, N. Y.

Existing methods of stress analysis in a three-dimensional piping system fully restrained at three points involve the predetermination of 78 coefficients, and the solution of 12 simultaneous equations. The author proposes a method which reduces the complicated three-anchor problem virtually to a simple two-anchor problem, involving only 21 constant coefficients and the determination of 6 equations. Actually, only routine tabulated computations are required by this method.

THE determination of the reactions set up by expansion in a three-dimensional piping system fully restrained in three points, as illustrated in Fig. 1, is regarded as a complicated problem of pipe stress analysis. The total number of component reactions developed in such a system amounts to 18, as follows:

3 Component moments, and 3 component forces at point *A*
3 Component moments, and 3 component forces at point *B*
3 Component moments, and 3 component forces at point *C*

The 6 reactions at point *C* being equal, with opposite signs, to the sums of the respective reactions at the two other points *A* and *B*, 12 unknowns only remain to be found:

6 unknowns at point *A*
6 unknowns at point *B*

The determination of the 12 unknown reactions requires 12 simultaneous equations which are obtained from the following conditions of equilibrium:

1 There is no rotation in either direction at point *A;* i.e., the summation of the moment areas between the points *A* and *C* alongside the branches I and III is equal to zero. This condition supplies 3 equations.

2 There is no translatory movement of point *A* in either direction, i.e., the summation of the moments about the point *A* of the moment-areas between the points *A* and *C* is equal to zero. This condition supplies 3 more equations.

3 No rotation at point *B:* 3 equations analogous to 1.

4 No movement of point *B:* 3 equations analogous to 2.

The four groups, of 3 equations each, constitute the system of 12 simultaneous equations solving the problem.

Existing Methods. The existing methods of stress analysis, whether it is the slope-deflection method, the moment-area method, or column analogy, all lead to the formulation of 12 equations, and various procedures proposed for the solution of three-anchor problems actually use 12 equations in numerical applications. So does the method published by the M. W. Kellogg Company,[2] in which the constant coefficients appearing in the equations have been given definite, although dissimilar, mathematical expressions.

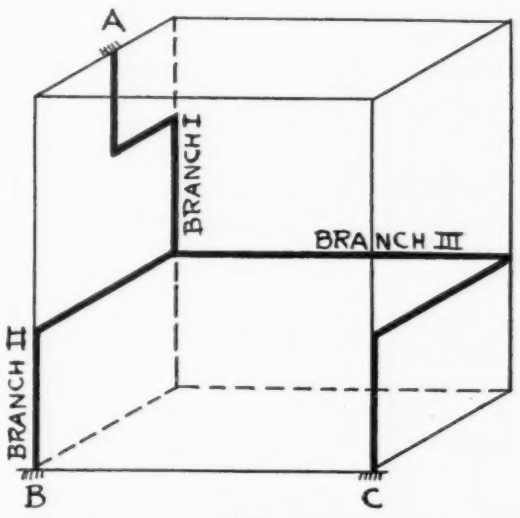

FIG. 1

All these methods involve the predetermination of 78 coefficients, which is exacting work, requiring thorough mathematical training and special skill. They require also the solution of 12 simultaneous equations.

PROPOSED METHOD

The proposed method to be described goes two steps further:

1 The 12 equations have been developed first by the moment-area method, and then reduced to 6 only by means of a quite extensive mathematical transformation which has to be omitted from this paper. In the 6 equations, the moments have been eliminated, and only the 6 unknown component forces appear. The number of constant coefficients has therefore been reduced from 78 to 21. The determinant of the 6 equations is symmetrical about the diagonal, offering therefore a simple solution by using the Kellogg method.[3]

2 By selection of the co-ordinate system, the 21 constant coefficients are given very simple mechanical meanings. These coefficients are either moments of inertia, or products of inertia, elementary notions with which every designer is quite familiar. No mathematics whatsoever is required for the understanding and the use of the method, only routine tabulated computations being necessary.

With these two transformations, the solution of the complicated three-anchor problem becomes practically as simple as the solution of the two-anchor problem by S. W. Spielvogel's well-known method.[3]

Procedure. (*a*) Refer the piping system to a system of axis of co-ordinates centered at point *O*, junction point of the three branches, Fig. 2. Designate the branch *OA*, branch I; branch *OB*, branch II; branch *OC*, branch III. Assume positive directions of co-ordinates, as shown by the arrows, Fig. 2.

(*b*) Project each branch of the piping system on the three co-ordinate planes X-Y, X-Z, Y-Z, Fig. 3.

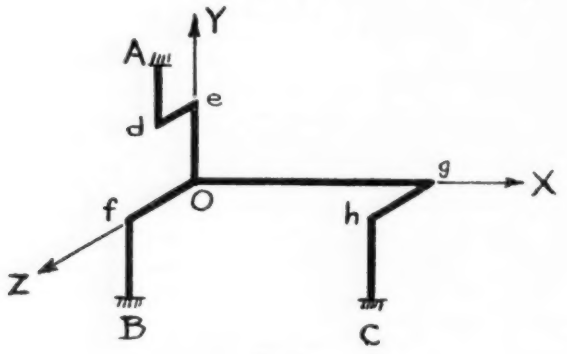

FIG. 2

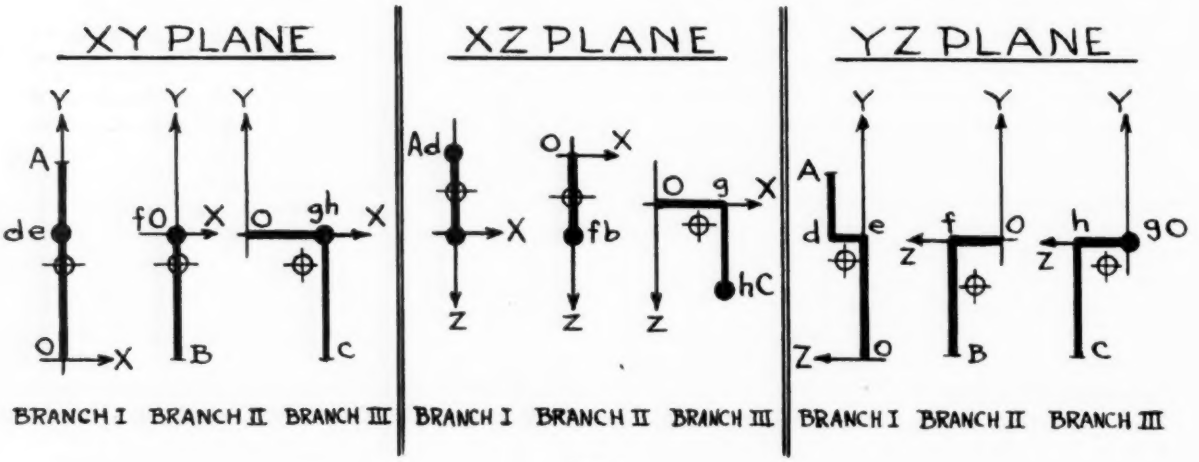

FIG. 3

(*c*) Compute in each projection the elastic centroid of each branch.[4] In doing this (as well as in all the computations hereafter), attribute a stiffness factor equal to 1 to each member projected in a line, and a stiffness factor equal to 1.3 to each branch projected in a point (ratio of EI in bending and GI_p in torsion). The elastic length of every member having a different size, or in general, a different value of EI, shall be corrected in the reversed ratio of the EI values; the stiffer, the shorter. Locate the computed centroids in each projection with reference to the origin (point *O*).

Designate by $(x_1y_1z_1)$ the co-ordinates of the centroid of branch I
Designate by $(x_2y_2z_2)$ the co-ordinates of the centroid of branch II
Designate by $(x_3y_3z_3)$ the co-ordinates of the centroid of branch III

(*d*) Designate also:

By (a, b, c), respectively, the (x, y, z) distances between the centroids of the branches I and III
By (d, e, f), respectively, the (x, y, z) distances between the centroids of the branches II and III

These distances shall be used with their signs as they come out, with reference to the co-ordinate axis centered at *O*. (Refer to their algebraical expressions in the general table of notations, Chart 1.)

(*e*) Compute in each projected plane the K constant[5]

$$K = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3}}$$

where L_1, L_2, L_3 are the developed elastic lengths, respectively, of the branches I, II, and III.

(*f*) Compute the moments and the products of inertia of each branch about its own elastic centroid.[4]

The foregoing computations have to be carried out algebraically with signs as they come out with reference to the axis under consideration.

Setting Up the Equations. The six simultaneous equations are given in Chart 2 in the shape of a determinant. Each coefficient is an algebraical sum of the constants previously computed.

Example 1: The coefficient of X_1 in the first equation is equal to

$$+ [Ix_1 + Ix_3 + K(b^2 + c^2)]$$

(Refer to Chart 1, general table of notations.)

The moments of inertia Ix_1 and Ix_3 are computed in the X-Y and X-Z planes, i.e., about the OX direction.

The term Kb^2, which is also a moment of inertia, is computed in the X-Y plane. *Note:* y term and X axis.

The term Kc^2, also a moment of inertia, is computed in the X-Z plane. *Note:* z term and X axis.

Example 2: The coefficient of Y_1 in the first equation is equal to

$$-[Ixy_1 + Ixy_3 + Kab]$$

The three terms are products of inertia computed in the X-Y plane. *Note:* $a = x$ term, $b = y$ term

Following the numerical example given hereafter, the entire procedure will be clarified.

Computation of Expansion Constants. Release the anchors of branch I and branch II, and let the piping system, anchored at the point *C*, expand freely. Compute the expansion constants as usual with their signs as they come out with reference to the positive direction of the co-ordinate axis.

Computation of Moments. When the 6 equations have been

[4] This can be done in accordance with the basic rules of column analogy, or as explained by S. W. Spielvogel.[3]

[5] The K quantity is an equivalent length. Note the analogy with the expression of the equivalent resistance in electrical network.

solved and the 6 reactions obtained, the moments are easily computed by using the formulas given in Chart 2.

Single-Plane Three-Anchor Problems

Cancel all the z terms, z constants, and z equations. The determinant will be reduced to 4 equations only, and the computations to a surprising simplicity.

Charts 1 and 2 summarize the entire method of analysis of the three-anchor problem.

Numerical Example

The numerical example given in Charts 3, 4, 5, and 6 is taken from M. W. Kellogg's[2] work.

The reactions obtained by Kellogg's method involving the solution of twelve simultaneous equations are (in pounds):

$$X_1 = -4939,\ Y_1 = -6418,\ Z_1 = 2579,\ X_2 = -5515,\ Y_2 = 389,\ Z_2 = 1769$$

The reactions obtained by the method presented involving the solution of six simultaneous equations only are:

$$X_1 = -4937,\ Y_1 = -6468,\ Z_1 = 2600,\ X_2 = -5500,\ Y_2 = 429,\ Z_2 = 1755$$

Acknowledgment

Appreciation is expressed here to Mr. J. Rabinovitz, structural designer, Gibbs & Hill, Inc., for his valuable assistance in the preparation of this paper, especially in working out the charts and the numerical example.

CHART 6

Behavior of Synthetic Phenolic-Resin Adhesives in Plywood Under Alternating Stresses

By A. G. H. DIETZ[1] and HENRY GRINSFELDER[2]

Because plywood is being used in ever-increasing quantities in the construction of aircraft and boats of many types, it is essential to know the effect upon this material of vibrating loads. Hence whether failure occurs in the wood or in the adhesive under repeated stress, what allowable stresses may be applied, and what the fatigue limit may be, are questions which the engineer must be prepared to answer. The present paper gives the results of a research program covering the behavior of plywood and laminated wood bonded with synthetic phenolic-resin adhesives, undergoing alternating stress, in the unweathered and weathered conditions, and at high and low temperatures. This is a continuation of a previous report,[3] which presented some findings with respect to fatigue behavior of plywood and laminated wood under alternating stresses.

Introduction

PLYWOOD is being employed in increasing quantities in aircraft and seacraft, in both of which it is subjected to vibrating loads. It is important for engineers to know whether or not the wood or the adhesive is likely to fail under repeated stress, what behavior should be expected of both wood and adhesive, what allowable stresses can be employed, and what the fatigue limit may be. Should the bond show a tendency to weaken, it is desirable to know the extent of the loss in strength. It should be known whether or not there is any loss of stiffness under alternating stress. In this paper are contained the results of a program of research undertaken to determine

(*a*) The fatigue behavior of plywood and laminated wood under alternating stress.

(*b*) The behavior of the synthetic-resin adhesives used in plywood and laminated wood, under alternating stress.

(*c*) The effect, under alternating stresses, of weathering on the properties of the adhesives used in plywood.

(*d*) The effect, under alternating stresses, of high and low temperatures on the properties of the adhesives used in plywood.

A previous report[3] presented some of the findings with respect to the fatigue behavior of plywood and laminated wood under alternating stresses. In that paper, only item (*a*), that is, the fatigue behavior of plywood and laminated wood as a whole, was reported, but no attempt was made to analyze the effect of alternating shear stresses upon the strength of the glue line. In this paper, items (*b*), (*c*), and (*d*) are reported, that is, the results of investigations into the behavior of the adhesives in plywood under alternating shear stresses. For the sake of completeness, the earlier results are included in this report.

[3] "Behavior of Plywood Under Repeated Stresses," by A. G. H. Dietz and H. Grinsfelder, Trans. A.S.M.E., vol. 65, 1943, pp. 187–191.

Contributed by the Wood Industries Division and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Previous Work

Of the fatigue behavior of plain wood, comparatively little is known, and still less is known about that of plywood. Stanton (1)[4] in 1916 concluded that the endurance limit of spruce was about 27 per cent of the tensile strength, which, in the material he employed, was low (6800 psi). Kommers (2) in 1927 reported tests made at the Forest Products Laboratory, on the basis of which values ranging from 26 to 30 per cent of the static bending strength were assigned Southern white oak, Sitka spruce, and Douglas fir. Schlyter (3) found that Sitka spruce, European spruce, and common European pine had endurance limits 22 to 25 per cent of the static bending strength. Kraemer (4), working with hardwoods (walnut and ash) and softwoods (pine and spruce), found endurance limits ranging from 25 to 33 per cent of the bending strength. He discovered, moreover, that the endurance limit of the heavier woods could in some instances be determined by as few as 20,000 cycles whereas the lighter specimens required several million cycles. Kollmann (5) evaluating the foregoing results, points out that although the endurance limits for wood are relatively low, the ratio of endurance limit to specific gravity may be relatively high compared to the metals used in aircraft. Kraemer (6) investigating plywood bonded with synthetic phenolic-resin film and with casein, found that if the grain of face plies was parallel to the axis of the test piece, the endurance limit was 26 per cent of the tensile strength for resin-bonded and 25 per cent for casein-bonded plywood. If the grain of the face plies was placed at an angle of 45 deg to the axis, the endurance limit for resin-bonded material rose to 52 per cent; for casein-bonded it remained practically the same, or 26 per cent. Failure of the casein-bonded plywood in this instance was caused by exfoliation of the veneers.

Tests on Unweathered Specimens

Materials

Aircraft-quality birch veneer was selected because of its strength and toughness and because it is moderately difficult to bond. The combination of strong wood and somewhat difficult bonding ability consequently was expected to reveal any tendency of the bond to fail under repeated stress.

Adhesives were as follows:

1 Thermosetting phenol-formaldehyde film.

2 Aqueous solution of thermosetting phenolformaldehyde.

3 The same as item 2, but extended with ground walnut shells (Glufil).

[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

4 Aqueous solution of cold-setting urea-formaldehyde.

These were representative of the principal types of synthetic-resin adhesives commonly employed.

Veneers, $^1/_{16}$ in. thick, were laid up and bonded as follows:

1 Phenolic-resin film: Two-ply laminated; three-ply laminated; three-ply plywood.

2 Phenolic-resin, plain aqueous solution: Three-ply plywood.

3 Phenolic-resin, extended aqueous solution: Three-ply plywood.

4 Cold-setting urea resin, plain aqueous solution: Three-ply plywood.

Both laminated and regular plywood construction were investigated in the film-bonded material because differing stress conditions are set up in laminated wood and in plywood. Laminated wood behaves much the same as solid wood, but in plywood with the face grain parallel to the specimen axis, the bending stresses are almost entirely concentrated in the face plies and the shear-stress intensity practically reaches its maximum at the glue line. If the bond were weakened by repeated stress, the behavior of laminated wood and plywood might be expected to differ. Only three-ply plywood was investigated with the other three adhesives because experience with the film-bonded materials indicated that glue-line failure was more apt to occur, if at all, in plywood than in laminated wood.

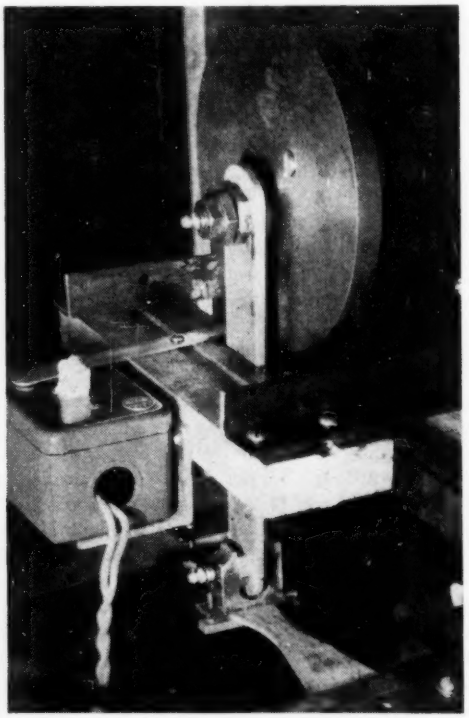

FIG. 1 CANTILEVER-TYPE MACHINE EMPLOYED WITH FATIGUE SPECIMENS

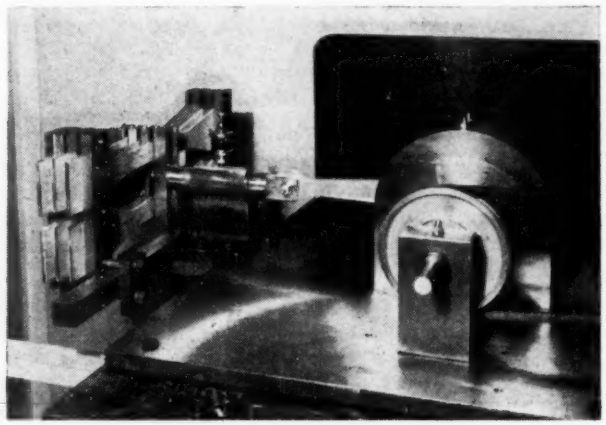

FIG. 2 CANTILEVER-TYPE MACHINE EQUIPPED TO HANDLE SEVERAL SPECIMENS SIMULTANEOUSLY

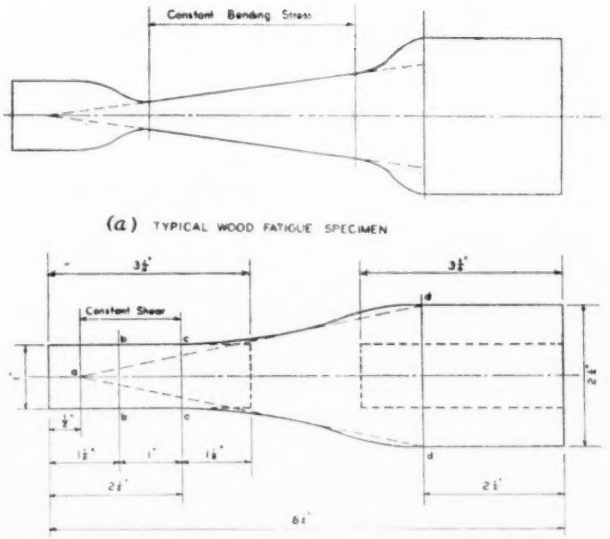

FIG. 3 TYPES OF SPECIMENS TESTED

MACHINES

Cantilever-type machines were employed because these were more adaptable to flat stock than rotating-beam machines, and because both bending and shear stresses are induced in cantilever specimens. In the earlier work, the machines, as shown in Fig. 1, handled one specimen at a time. Because of the large number of specimens involved, however, and because of the length of time required for some of the tests, a machine was constructed which could handle as many as twelve specimens at one time, as illustrated in Fig. 2.

In this apparatus the specimens, in groups of two or four, are clamped between upright pairs of cold-rolled steel plates which are in turn bolted to a heavy horizontal steel bar fastened to the steel base plate supporting the entire apparatus. The free ends of the specimens are forced back and forth by a pusher designed to hold the specimen firmly but to allow the end to deflect freely. The pusher is attached to a driving rod pinned to a connecting rod in turn mounted on an eccentric which forms part of a heavy steel driving wheel. The eccentric can be adjusted to give a throw ranging from zero to $1^1/_2$ in. The driving wheel is mounted in a heavy bronze bearing and is belt-driven by a 1-hp motor. The machine can be run at various speeds, but was generally operated at 1100 to 1300 rpm.

TYPES OF SPECIMENS

Alternating Stress. Two types of specimens were employed as shown in Fig. 3. To study the fatigue behavior of laminated wood and plywood, the shape shown in Fig. 3(*a*) was selected and found generally satisfactory. It provided a considerable

length over which the bending stresses were constant, and still allowed enough taper to prevent splitting in the outer veneers. Tests were run at uniform amplitude, and length was varied in accordance with the stresses desired. A specimen of this kind is shown in Fig. 1. It has failed in the tapered portion.

A different specimen was required to study the behavior of the adhesives under alternating shear stresses. In this instance, the specimen was also designed for flexing as a cantilever and was of such a shape as to provide a constant shear-stress area 1 in. sq at the loaded end while the strength at the supported end was sufficient to avoid overstressing the outermost fibers in bending.

The specimen is illustrated in Fig. 3(*b*). Load was applied at *a*. The specimen was 1 in. wide to point *c* where it was flared as shown to line *d-d*. From *d-d* to the end, the specimen was held in the grips during test. The distance *b-c* was 1 in. and the area *bbcc* was the 1-in-sq area over which uniform alternating shear was induced by the flexing of the specimen. After being run through a given cycle of stress, a glue-line shear test specimen was cut from this portion of the specimen as shown. The far end of the specimen was made long enough to provide sufficient area for rigid clamping and to provide a second glue-line shear test specimen with an unstressed central portion for comparison with the stress specimen.

Five alternating-stress test specimens were cut from each panel, as shown in Fig. 4. From the end of each specimen a third glue-line shear test specimen was cut to provide a second comparative test for the stressed sample. Each panel consequently yielded five "fatigue" specimens, five vibrated glue-line shear specimens, and ten unvibrated glue-line shear specimens.

Glue-Line Shear Test Specimens. As shown in Fig. 3(*a*), glue-line shear test specimens were the standard type commonly employed in the testing of plywood (7). They were tested in a briquette-testing machine equipped with a set of standard glue-line shear-testing jaws. Specimens were loaded at the rate of 600 to 800 lb per min.

Static Controls. To provide standards of comparison, simple static bending specimens 1 in. wide were cut from the panels and tested as center-loaded end-supported beams on spans 20 times the depth of the specimen. From these, modulus-of-rupture values were obtained. In addition, tension test specimens were cut from the same panels as the film-bonded-plywood fatigue specimens, but experience indicated that bending tests provided a better basis of comparison than did tension inasmuch as the alternating-stress tests were essentially bending tests.

Testing Procedure

Fatigue Tests. Each fatigue specimen was first calibrated by clamping the fixed end and loading the free end with dead weights to obtain the load-deflection curve. From this the stress for a given deflection could be calculated. The same procedure was employed for calibrating the alternating-shear test specimens and is illustrated in Fig. 5.

The specimen was clamped rigidly to a heavy table, a hook and pan were hung from the free end of the cantilever, and deflections were read to the nearest thousandth inch on the dial, whose stem rested on a small horizontal plane on top of the hook. The hook hung from the loading point of the specimen and dead weights were supported on the pan directly below the loading point.

After calibration, the fatigue specimen was subjected to alternating stress. In the preliminary runs the motor was stopped at rather frequent intervals and the specimen inspected for extent and type of incipient rupture. After a satisfactory shape and size of test piece had been found, specimens were in general permitted to remain in the machine until failure had occurred.

It was necessary to determine some criterion of failure because a piece which had cracked and was carrying no load might hang on for a considerable number of cycles before parting. Consequently, when a crack had formed completely across the width of the piece so that the cantilever to all intents and purposes was merely hinged at the line of the crack, failure was considered to have occurred. In general, it was found that failure, so defined, followed soon after the first appearance of a fatigue crack.

Fatigue stresses ranged from 90 to 20 per cent of the static moduli of rupture of the controls. Because of the variability of the material, four to six pieces of each length were tested and six to eight lengths were employed.

Alternating-Shear Tests. Alternating-shear test specimens were given the same preliminary calibration as the fatigue test specimens. Since these specimens were not vibrated to destruction, it was possible to recalibrate them after vibration to determine if repeated stress had any effect upon the load-deflection curve,

	50	67	...
10,000,000	86	59	68

that is, if there had been any change in the modulus of elasticity of the plywood.

Tests were run at 100 cycles, 10,000 cycles, 1,000,000 cycles, and 10,000,000 cycles. At each of these cycles, loads were regulated to induce three or four different shear stresses in the glue lines, in order to ascertain if there was any progressive tendency to weaken the adhesive as the shear stress was increased. The highest load applied at any given number of cycles was the highest that could be employed without causing the specimen to fail in bending fatigue. Specimens were made as short as feasible in order to obtain the highest possible shear stresses. Five to fifteen specimens were tested at each combination of cycles, and shear stress to obtain a dependable average. Cycles and stresses are given in Table 1.

Test Results

Fatigue Tests. Fatigue results are summarized in Fig. 6 (*a* to *d*). Fatigue stresses are plotted as ratios of the static moduli of rupture, and numbers of cycles are plotted on a logarithmic scale to bring out the trend. As is to be expected, a considerable amount of scatter is found in spite of the care with which the material was selected and cut. The general trend is apparent, however, and the averages of the plotted points fall fairly close to the indicated straight lines.

The horizontal dotted lines, at approximately 25 per cent of modulus of rupture, represent averages of specimens which had not failed at 1,000,000 to 3,000,000 cycles of stress reversal. In Fig. 6(*c*), the points marked *a*, *b*, *c*, and *d* represent the averages of the most heavily loaded film-bonded specimens employed in the second phase of this research, that is, the alternating-shear specimens. Each of these points represents the average of five to fifteen tests, none of which resulted in failure. Points *c* and *d*, in particular, fall close to the straight line derived from the fatigue tests.

Periodic examination of specimens during the test runs revealed little tendency for the bond to fail or the veneers to separate. After the outer plies had cracked through to the glue line, that is, after failure as previously defined had occurred, delamination did in some instances take place. This tendency was somewhat more prevalent in the plywood than in the laminated material.

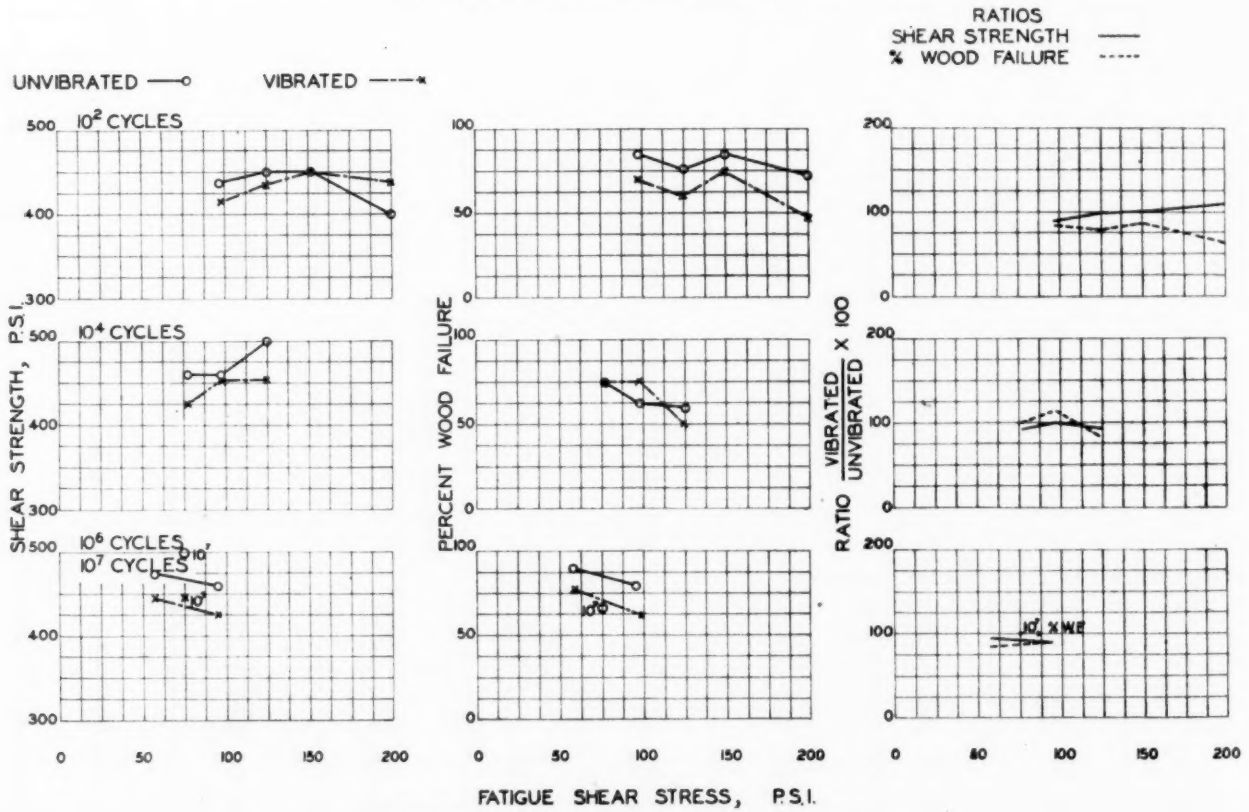

FIG. 9 PHENOL-FORMALDEHYDE SOLUTION, EXTENDED

Alternating-Shear Tests. Results are summarized in Table 2 and in Figs. 7 to 9, inclusive. For each type of adhesive and for each number of cycles of stress, values are given for the average glue-line shear strengths and percentages wood failure of the static controls, the average alternating shear stresses at the glue lines, the average glue-line shear strengths and percentages wood failure after vibration, and the percentage changes in modulus of elasticity.

1 Phenol-formaldehyde film (Table 2, Fig. 7): The most striking feature of the results is that there is no loss in glue-line shear strength after stressing in alternating shear. This is best shown by the ratios of glue-line strength of stressed to unstressed specimens in Fig. 7. The lines lie very close to the 100 per cent mark, in some instances even rising slightly above it. The ratios are strikingly constant in spite of the variation in the actual glue-line strengths of the individual panels. Equally striking is the manner in which the material holds its stiffness. The secondary calibrations show very little change in modulus of elasticity, the largest average for any panel being 6 per cent. A few recalibrations seem to indicate a small increase in stiffness but this is undoubtedly more apparent than real. For all practical purposes, it can be said that there is no significant change in modulus of elasticity under the conditions of alternating stress employed in this research.

No definite trend in percentages wood failure is discernible. At 10,000 cycles, the more heavily vibrated specimens exhibit lower percentages of wood failure relative to the unvibrated controls than do the more lightly vibrated. This is true of the specimens at 1,000,000 cycles. In both instances, however, the lightly vibrated pieces exhibit higher percentages wood failure than do the unvibrated. It does not seem probable that light stressing in alternating shear would actually increase the shear strength, and the trends seemingly indicated by these two sets of specimens are probably more apparent than real. Furthermore, at 100 cycles the material stressed at 146 psi exhibits much higher percentages of wood failure than do the unvibrated controls while that stressed at both 101 and 200 psi is lower, and by nearly the same amount. At 10,000,000 cycles, the vibrated material shows higher percentages wood failure than does the unvibrated. Finally, the variation in percentages wood failure from piece to piece is considerably greater than the variations in the averages from stress to stress or cycle to cycle.

2 Phenol-formaldehyde solution, plain and extended (Table 2, Figs. 8 and 9): In general, the results are similar to those for the film series, in that no great losses in glue-line strength are observed, as shown by the strength ratios of vibrated to unvibrated specimens. This is particularly true at 100 and 10,000 cycles, where the strength-ratio lines hug the 100 per cent line quite closely.

At 1,000,000 cycles both the plain and the extended materials show strength ratios for the vibrated specimens averaging consistently 7 to 9 per cent less than the strength of the unvibrated material. At 10,000,000 cycles, on the other hand, the "plain" vibrated material runs 17 per cent higher than the unvibrated, whereas the "extended" material runs 16 per cent lower. The unvibrated "extended" controls, however, are considerably stronger than the unvibrated "plain" controls.

Table 2 shows that approximately 75 to 80 per cent of the vibrated specimens run lower in glue-line strength than the unvibrated controls, but the diminutions in strength in no instance exceed 16 per cent, and in most instances are less than 10 per cent. This is less than the variation found within a single panel.

Like the strength ratios, the per cent wood-failure ratios are in 75 to 80 per cent of all instances less than 100 per cent, but here the scatter is more marked, as is to be expected. Generally speaking, however, the drops are small and are less than the variation to be found within a single panel.

Quite striking is the consistent behavior of the "extended" adhesive. In not one instance does the glue-line shear strength, either before or after "fatigue" stressing, fall below 400 psi. Percentages wood failure are correspondingly high. Consequently, although the vibrated specimens generally show a diminution of strength properties, the absolute strength values are higher.

Changes in modulus of elasticity are so small as to be insignificant. The majority of the specimens show no change in stiffness after being subjected to vibration, some show an apparent

	Plain	128	95	58
	Extended	125	94	60

increase of 1 or 2 per cent, some a correspondingly small decrease. As a matter of fact, the "extended" adhesive shows more increases than decreases.

TESTS ON WEATHERED SPECIMENS

MATERIALS

Nine plywood panels, similar to those previously described, were exposed to the weather for 6 months, February–July, 1943, on the Florida coast. Three panels were bonded with phenolic-resin film, three with plain phenol-formaldehyde solution, and three with extended phenol-formaldehyde solution. These were fabricated into specimens and tested in alternating shear in the same manner as the unweathered plywood, except that tests were run at the following three temperatures: —70 F, + 70 F (room temperature), + 180 F. This series was designed to ascertain

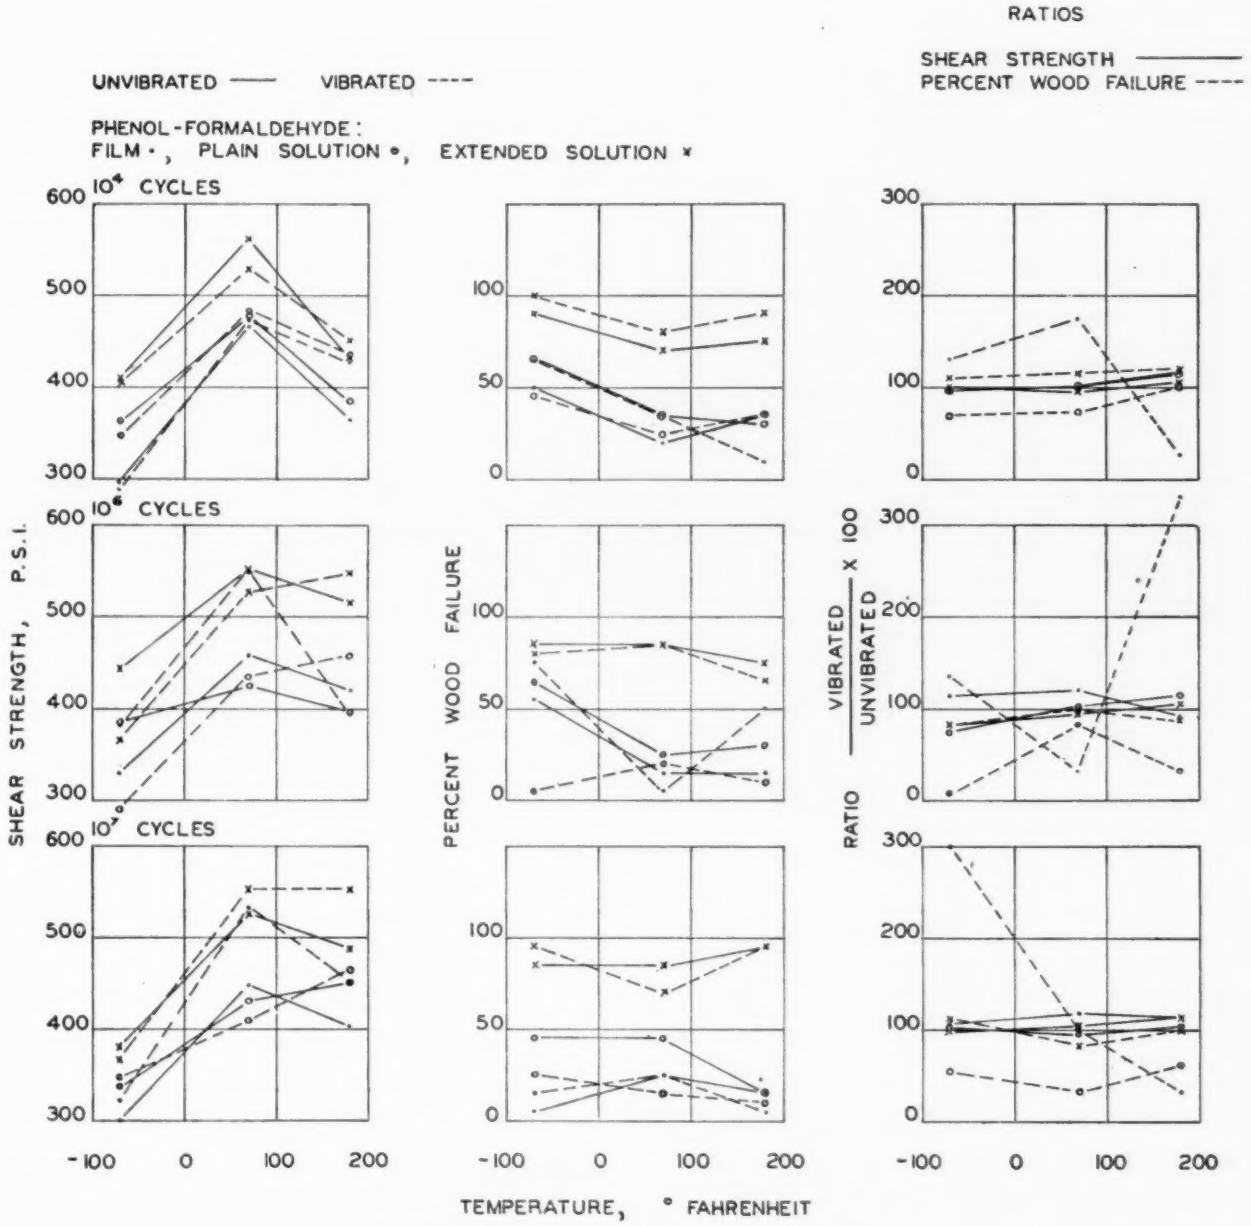

FIG. 13 RESULTS OF TESTS ON WEATHERED PLYWOOD

if weathering, high temperatures, and low temperatures have any effect upon the strength properties of phenolic-resin-bonded plywood. Typical weathered and unweathered panels are shown in Fig. 10.

HIGH-TEMPERATURE TESTS

Vibrating. The pusher and specimen holders of the fatigue machine were surrounded with an insulated cabinet, as shown in Fig. 11, equipped with four 250-w infrared lamps. Lamps were arranged in two parallel-series pairs, and connected to a 110-v a-c main. Power supplied was controlled by two rheostats, one permanently in the line, and another, in parallel with the first, automatically switched in and out by an aluminum-foil-coated thermostat, set to maintain 180 F. Temperature inside the specimens was checked by thermocouples, and the machine was not started until this temperature had risen to +180 F. A small fan maintained air circulation.

Plywood Shear Tests. Small electrical-resistance heating pads, as shown in Fig. 12, were made to be slipped into the standard plywood shear jaws adjacent to the center of the specimen. Pads were designed to heat and to hold the specimen at 180 F. Temperatures were checked by a thermocouple inserted into a small hole drilled in the center ply. Power was controlled by Variac.

LOW-TEMPERATURE TESTS

Vibrating. The fatigue machine was placed in a room maintained at —10 F to —20 F, and the insulated cabinet around the specimens was packed with dry ice. It was found by thermocouple readings that this arrangement permitted average temperatures of —70 F to be maintained in the specimens.

Plywood Shear Tests. Specimens were packed in dry ice, and the shear apparatus was placed in the —10 to —20 F room. Experiment showed that specimens removed from dry ice and placed in the shear tester rose to —70 F during the short time needed to make the tests.

Test Results

Because of the limited material available, tests were run at 10,000 cycles, 1,000,000 cycles, and 10,000,000 cycles only, and at only one shear stress for each number of cycles. Shear stresses were somewhat lower than the maximum values employed with the unweathered material, because weathering had worn away some of the surface plies and thereby reduced the maximum load which the plywood could sustain. Even with the reduced stresses, a few specimens showed incipient wood fatigue failures at the completion of the alternating stress cycles.

Cycles, stresses, and temperatures are summarized in Table 3. Results of all weathered plywood tests are presented in Table 4 and in Fig. 13.

Effect of Weathering. Comparison of Tables 2 and 4 reveals that weathering causes no glue-line strength to be lost at room temperatures. As a matter of fact, all three types of adhesives exhibit higher room-temperature strengths in the weathered than in the unweathered material. This is true of both vibrated and unvibrated specimens. Percentages wood failure in weathered and unweathered, vibrated and unvibrated, material are comparable.

Effect of Temperature. All three adhesives drop off in strength, as a rule, at both low and high temperatures, with the greater diminution occurring at —70 F. Again, this is true of both vibrated and unvibrated material. There is no definite trend in percentages wood failure; individual deviations are much more marked than any average trends.

At —70 F, the plywood shear strength of unvibrated phenolic film drops approximately one third, plain phenolic solution approximately one sixth, and extended phenolic solution approximately one tenth. At +180 F, all three drop approximately one tenth. Vibrated film and extended-resin solution both drop about one third at —70 F, and plain resin solution about one fifth. At +180 F, the vibrated film shows a drop of about one fifth, but the solutions maintain their strength at all but 10^4 cycles (heavy stress, large amplitude).

Effect of Vibration. As in the unweathered material, vibration does not affect the glue-line strength at any of the three temperatures. Generally speaking, the ratios of strengths do not deviate greatly from 100 per cent, with the vibrated material testing stronger, if anything, than the unvibrated. Variations in individual percentage wood failures are much larger than any average trends, so that no general conclusion can be drawn. Although vibration appears to cause a small decrease in modulus of elasticity, the apparent difference is too small to be of practical significance.

Conclusions

Fatigue Specimens. The fatigue tests indicate that, in birch plywood and laminated wood, bonded with thermosetting phenol-formaldehyde film, and in plywood bonded with an aqueous solution of cold-setting urea-formaldehyde resin, at room temperatures (70 to 80 F):

1 Fatigue failures are primarily wood failures.

2 Delamination of the veneers occurs very seldom before the outer plies have given way.

3 Laminated material may be expected to withstand at least 2 000,000 and film-bonded plywood at least 10,000,000 stress reversals without failing, when stressed to 25 per cent or less of the static modulus of rupture.

Alternating Shear Stress. It may be concluded that at room temperature (70 to 80 F):

1 Alternating bending stresses inducing alternating shear stresses up to 200 psi at 100 cycles, up to 125 psi at 10,000 cycles, up to 100 psi at 1,000,000 cycles, and up to 85 psi at 10,000,000 cycles may be expected to decrease the glue-line shear strength of birch plywood not more than an average of 7 to 9 per cent, and the percentages of wood failure by approximately the same amount.

2 Absolute values of strength of phenol-formaldehyde film-bonded plywood and plywood bonded with plain and extended aqueous solutions of phenol formaldehyde may be expected to run within approximately 10 per cent of each other.

3 Vibrations inducing the stresses just given have no discernible effect upon the stiffness (modulus of elasticity) of the material.

Weathering. Weathering has no adverse effect upon the glue-line strength of phenolic-resin-bonded plywood. This is true of percentage wood failure as well, and of both vibrated and unvibrated material.

Temperature. The following may be concluded concerning the effect of temperature:

1 Temperatures as low as —70 F cause a loss in glue-line shear strength in materials bonded with all three phenolic resins. Percentage wood failures do not indicate clearly whether the loss in strength is caused by the effect of cold upon wood or upon resin. Film-bonded material loses approximately one third of its strength; plain-phenolic-solution-bonded material approximately one tenth to one sixth and extended-phenolic-solution-bonded material approximately one tenth to one third in unvibrated and vibrated material, respectively.

2 Temperatures as high as +180 F cause losses in glue-line strength but these are less marked than at low temperatures. All three, unvibrated, drop approximately one tenth. Vibrated film-bonded drops about one fifth, the others show little or no loss in strength.

Acknowledgments

The authors acknowledge their indebtedness to the individuals who assisted in this program, particularly to Mr. Harry Majors, Jr., Instructor in the Department of Mechanical Engineering at the Massachusetts Institute of Technology, and Mr. John D. Barry, Research Assistant, who carried the brunt of the experimental work. Dr. Wm. F. Murray of the Department of Mechanical Engineering was instrumental in devising the testing equipment. Messrs. S. N. Tu, M. Becker, and F. Carroll assisted in the testing.

Maintenance of Hydroelectric Generating Units

By GEORGE H. BRAGG,[1] SAN FRANCISCO, CALIF.

This paper covers the complete overhaul of a 40,000-hp vertical Francis-type hydraulic turbine, operating under 454 ft head to drive a 35,000-kva generator at 257 rpm. Some of the work done was to repair normal wear due to operation over a 20-year period. Other work was of a corrective nature modifying the original design to include improvements found desirable after prolonged operation. Interesting problems were met and solved in some of the work, which involved the handling of heavy parts, and in the use of materials not originally included in the design of the unit.

MODERN hydroelectric generating units usually perform with such reliability that high praise should be given to the manufacturers' engineers who have progressively incorporated improvements in their design and produced machines which often operate continuously year after year without service interruption.

A typical case history usually records only minor annual maintenance work such as repairing the cavitated areas and cleaning the generator windings, etc., all of which may be done in a comparatively short time and without disassembling the unit. But of course there comes a time when a general overhauling is imperative, in which the parts are completely dismantled for careful examination. Then, unusual conditions may be discovered, some of which are due to "wear and tear" while others to "shortcomings" in manufacture.

A good illustration of this is a general overhaul job on a 40,000-hp Francis-turbine-driven unit which had been in continuous operation for almost 20 years. Of course minor repairs had been made on it from time to time but it had not been previously disassembled.

The items of work involving problems of interest were as follows:

(1) Pitting of runner due to cavitation; (2) damaged shaft bushing; (3) shaft packing; (4) worn guide vanes; (5) guide-vane lubrication; (6) runner tip; (7) cavitated liner plates; (8) shaft journals; (9) cavitated relief valve; (10) generator-stator winding.

FIG. 1 PITTED AREAS HAVE BEEN ARC-WELDED BUT NOT FINISHED

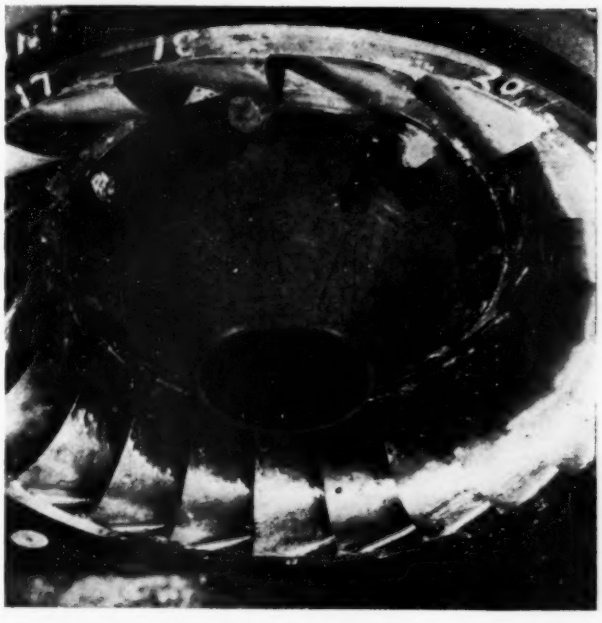

FIG. 2 RUNNER IN PLACE AFTER ALL REPAIRS HAVE BEEN COMPLETED

Pitting of Runner Due to Cavitation. It is rarely possible for a hydraulic-turbine runner to operate over an extended period without pitting of certain areas due to cavitation. The extent and length of time required for pitting to become serious varies greatly but, in general, it is possible to keep it under control by restoring the affected areas by welding at intervals of sufficient frequency to keep the amount of welding at a minimum.

The repair of the pitted areas on the runner vanes required no unusual technique, aside from the precaution to warm the entire casting to 100 C before applying the arc. As no normalizing oven was available to relieve internal strains resulting from localized excessive temperature, the welding was not done continuously in one place but was carried on by skipping from one part to another doing small patches at a time.

In preparing the surface for welding, the spongelike metal is chipped out of the pitted area. The chipping may be as much as $^1/_2$ in. deep in some spots and feather out to the edges of an area which may be 20 or 30 sq in. in extent. With a $^5/_{32}$-in. welding rod a single bead of metal is deposited on a section about $^1/_2$ in. × 2 in., after which the welding is shifted to another blade while the first section cools. When the entire area has been covered with a single bead, it is peened and any slag is chipped off, after which the second layer is added and so on until the required contour is built up. Rotary files applied to the welded surface remove the excess material faster than emery-wheel grinders.

FIG. 3 SHAFT BUSHING WORN BY PACKING

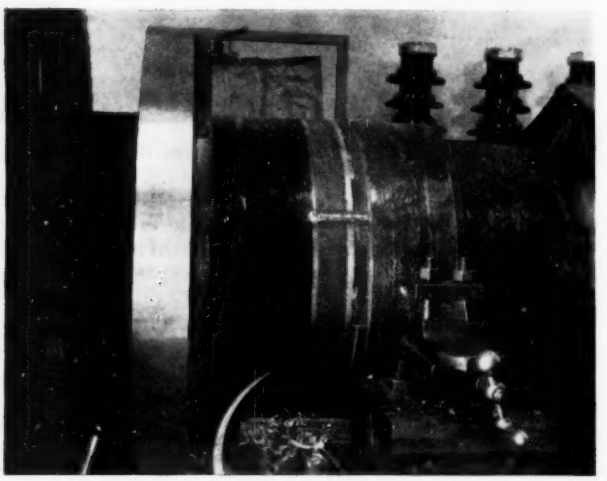

FIG. 5 STAINLESS-STEEL BAND WELDED IN PLACE

However, the surface was finished by emery-wheel grinding, Figs. 1 and 2.

Shaft Bushing. As originally constructed, the turbine shaft was provided with a bushing at the point where the shaft passes through the stuffing box in the turbine head cover. This bushing was about 15 in. long and made from carbon steel $1^1/_2$ in. thick. On account of the flanges on either end of the turbine shaft, it was necessary to make the bushing in halves and join them together by means of special keys having an H-section. Because of the fact that the bushing was made of carbon steel operating submerged in water, deep grooves were found worn into the surface of the metal against which the segmental lignum-vitae packing bore, Figs. 3 to 6, inclusive.

After considering an entirely new bushing made of noncorrosive metal, the cost of which would have been in excess of $800, it was decided not to disturb the worn bushing but to repair it in place.

Accordingly, the turbine shaft, with bushing in place, and weighing approximately 10 tons, was supported horizontally in its own guide bearings on the floor of the powerhouse. A motor-operated worm wheel was bolted to a flange, which revolved the shaft at a proper lathe cutting speed. A compound slide rest with tool post holder was then set in position on T-rail cribbing and a rectangular recess was turned in the bushing, removing all the irregular worn material. The dimensions of the recess are width 4 in., depth $^1/_2$ in.

The ring to fill the recess was made of bar nickel steel which measured 4 in. $\times$ $^5/_8$ in. It was rolled into a circular form of proper diameter, cut into halves, fitted into the recess and secured by welding it circumferentially to the bushing. Both longitudinal joints were then welded thus making a band inserted into the recess.

FIG. 6 STAINLESS-STEEL SURFACE WAS GIVEN A MIRRORLIKE FINISH

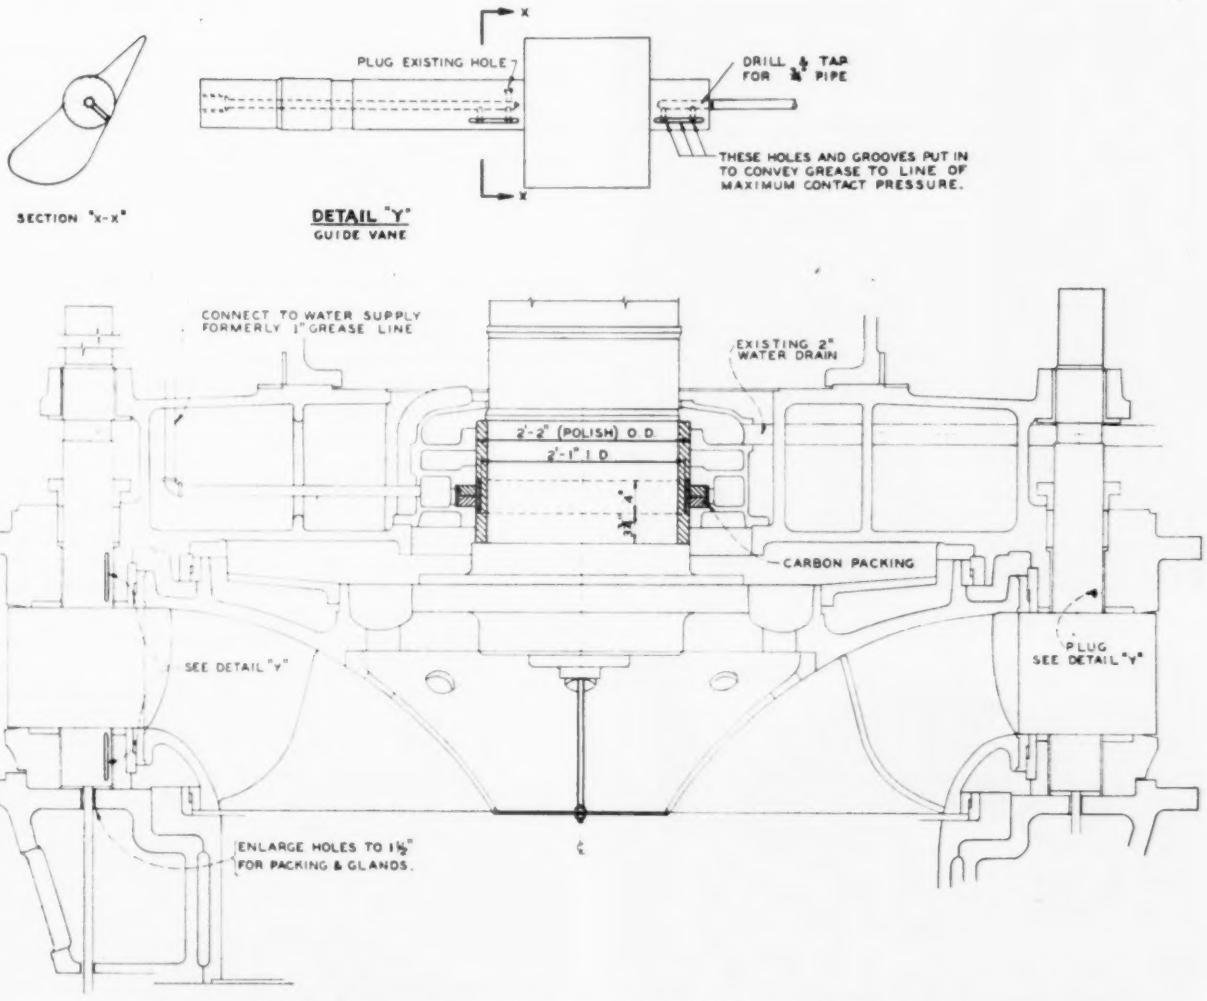

FIG. 7 REPAIR AND RECONSTRUCTION OF 40,000-HP FRANCIS TURBINE

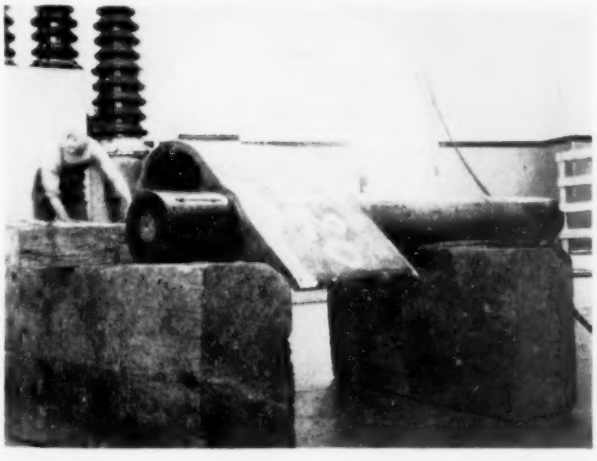

FIG. 8 GUIDE VANE REPAIRED BY ARC-WELDING STEEL TO WORN EDGES

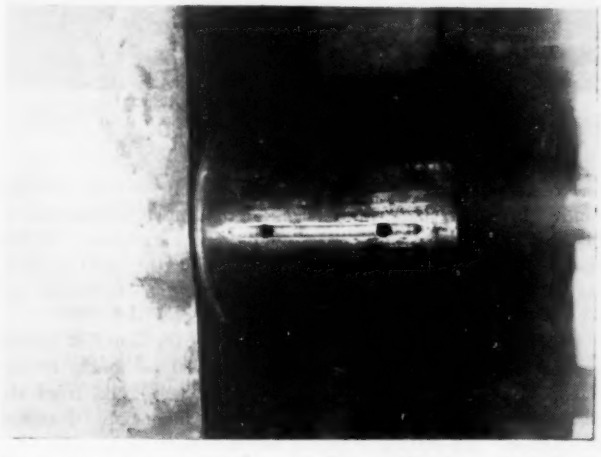

FIG. 9 GUIDE-VANE STEM SHOWING GREASE GROOVE TO LUBRICATE ALONG LINE OF MAXIMUM PRESSURE

The nickel-steel band was then turned, trued, ground, and polished to a mirrorlike finish to minimize the friction and wear on the carbon packing which was installed to replace the lignum-vitae packing.

Shaft Packing. Originally, the shaft packing, serving as a water seal in the turbine head cover, was made of two segmental rings of lignum vitae held in position by means of circular retaining springs. Lignum vitae has certain disadvantages but up to a

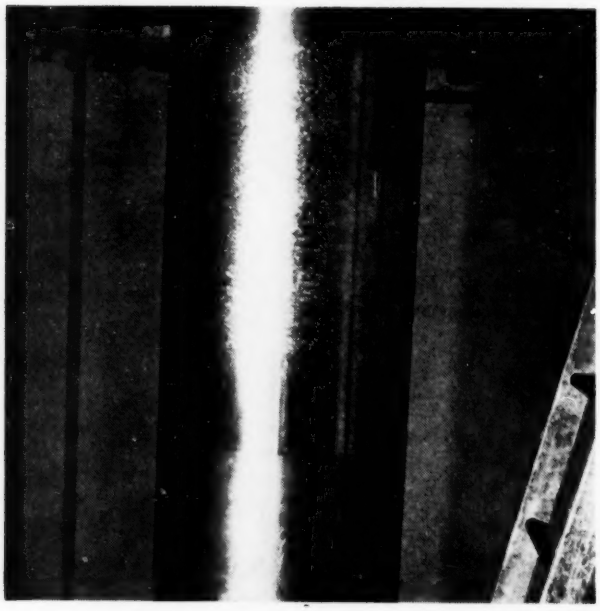

FIG. 10 SHAFT JOURNAL MARRED BY SHAFT CURRENT

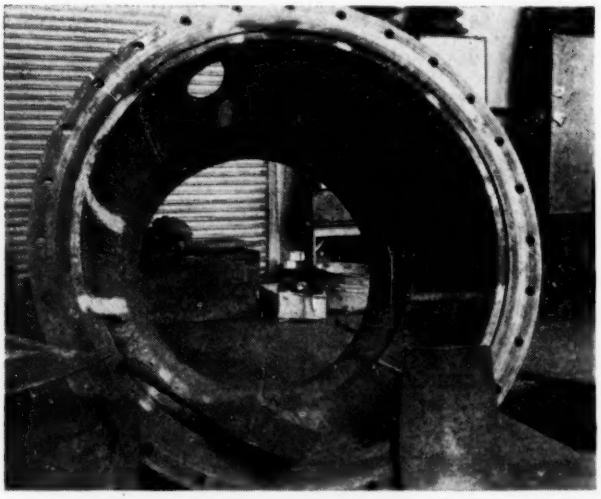

FIG. 12 STEEL PLATES 1/4 IN. THICK PREFORMED AND FITTED TO COVER PITTED SURFACE

few years ago was the best available material for such installations. In recent years, micarta and carbon have become available and offer many advantages over the lignum vitae. In this case, it was decided to use carbon as being the most durable material of the three and the least severe on the metal against which it is pressed, Fig. 7.

The carbon rings were each made of six segments of special carbon having a crushing strength of 20,000 psi and a Brinell hardness of 180 ±. The segments were purchased from the manufacturer in strict accordance with the dimensional drawings submitted. No cutting or fitting was necessary on the job.

Guide Vanes. Ordinarily the most wear on the guide vanes occurs on the edges which are in contact with the throat liner plates, but if some sand is carried by the water, erosion takes place on the streamlined surfaces. In either case, the missing metal may be replaced by arc-welding and the original shape restored by resorting to the manufacturer's methods in fabricating new ones from castings or forgings. Such work can be expertly done by the plant mechanics if a lathe of adequate size to swing the guide vanes is available in the shop, Fig. 8.

Guide-Vane Lubrication. In detailing the guide-vane lubricating system, designers sometimes overlook the fact that the place to exude the grease is between the bearing surfaces which are most intimately in contact for otherwise the lubricant flows in the path of least resistance where it does not serve its purpose.

When upon dismantling the guide vanes the stems are found to be dry and worn where the pressure has been the greatest, the greasing system should be reconstructed by providing a recess on the surface of the stem at top and bottom into which the grease may flow from the central duct to the contact surface between the stem and the bushed bearing. Then if the vanes are moved while the grease is being pumped, the surface will be "wiped" and lubricated without waste, Figs. 7 and 9.

Runner Tip. The runner tip is a separate hollow conical casting attached to the discharge side of the runner, forming a continuation of the upper shroud. The vent holes in the center of the runner were ported within the conical tip and the leakage water from the top side of the runner escaped to the draft tube from the center of the hollow cone.

Notwithstanding close running clearances and a minimum quantity of seal-ring water, a back pressure of 10 psi was built up on top of the runner at full load which subjected the thrust bearing to an additional load of about 75,000 lb.

After analyzing these facts, it was concluded that the rotating conical tip functioned as a centrifugal-pump runner and actually caused the back pressure which retarded the free discharge of the seal-ring water into the draft tube.

Although the thrust bearing had operated at normal tempera-

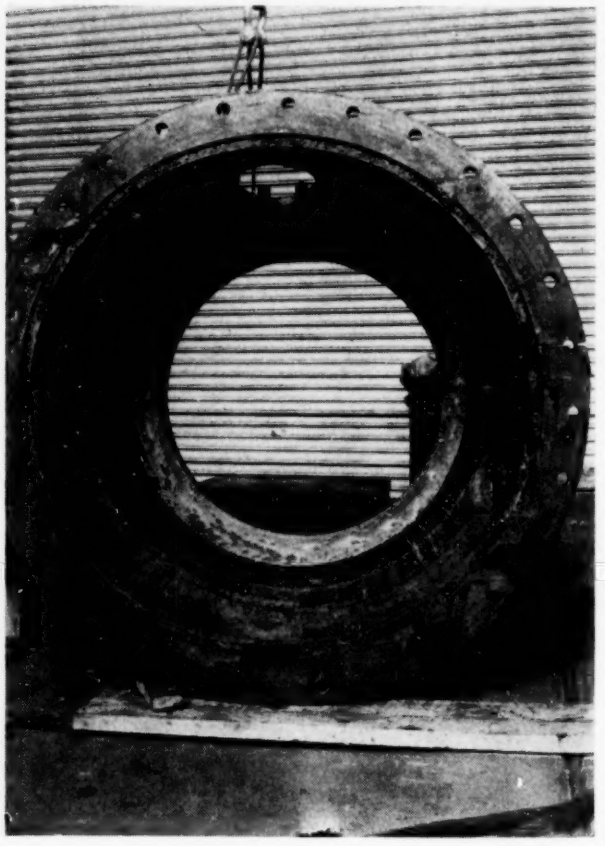

FIG. 11 PITTED BODY OF RELIEF VALVE OF 40,000-HP FRANCIS TURBINE

ture at all times, it was deemed advisable to relieve it of the extra load by providing holes in the tip opposite those in the runner and a plate which closed the center opening. After doing this, the seal-ring water escaped to the draft tube through the drilled holes in the conical tip, and thereafter the pressure above the runner was reduced from 10 psi at full load to a negative value at all loads, Fig. 7.

Liner Plates. Although, as previously stated, the turbine had been in continuous operation for almost 20 years, the seal-ring clearances, contrary to usual experience, had not enlarged appreciably.

When first installed, both upper and lower clearances were 0.030 in., and, when measured prior to taking the unit out of service, the upper one was 0.032 in. and the lower one 0.035 in. This is exceptional and may be explained by the fact that the water carries no sand. The seal rings therefore were not replaced, nor was it necessary to remove the throat liner plates. The slight cavitations in them were arc-welded and the surfaces were refinished by rotary files and emery wheels.

Shaft Journals. It is evident by the appearance of the shaft journal that shaft currents may flow without being detected by the operator. The upper guide bearing was insulated but probably had become short-circuited in some unaccountable manner. Such a condition in a vertical unit is not necessarily serious for the bearing temperature in this instance had not been abnormal at any time. The surface was polished by rubbing it with abrasive

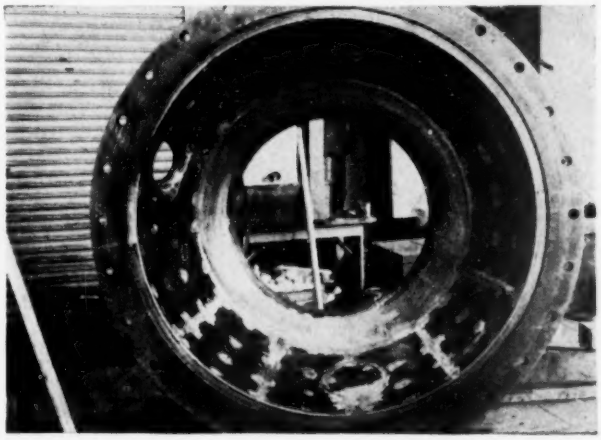

FIG. 13 STEEL PLATES COMPLETELY LINE INNER SURFACE
(Plates were welded along the joints and fastened with patch bolts.)

cloth which lined wooden blocks shaped to fit the journal. The blocks in turn were rotated manually by radial levers. This improved the surface, but of course did not remove the pits, Fig. 10.

Relief Valve. The turbine relief valve invariably pits near the seat rings and, if not allowed to progress too far, effective repairs may be made which will compare favorably with a substitution of new parts for the damaged ones. Irregularities in the bronze seat rings are filled by arc-depositing alloy from a rod having approximately the same composition as that of the parent metal. The contours of the surfaces are restored by filing and grinding according to a template.

The cast-iron body is lined inside by steel plates $^1/_4$ in. thick preformed to fit the curvature of the casting and attached by means of patch bolts. The joints between the plates are welded after all the plates have been attached, and when the surface has been made smooth by grinding, the completed steel surface will be more resistant to pitting than the original cast iron.

Upon reassembling the valve, the seat-ring surfaces are coated with grinding compound and the valve is pressed against the body

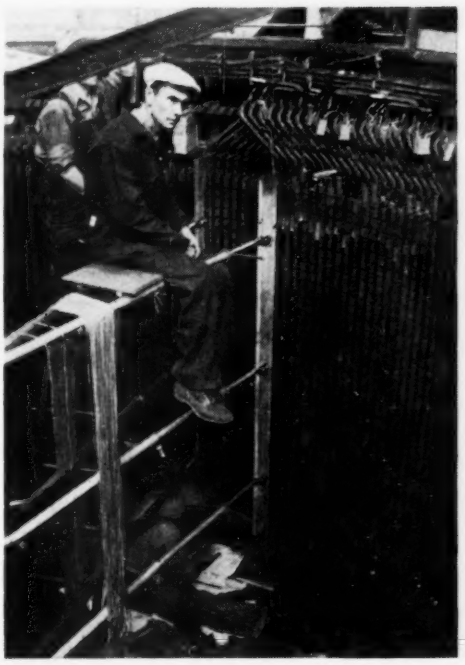

FIG. 14 STRONGBACKS ATTACHED TO SCREW JACKS FORCED COILS INTO SLOTS

seat as if it were in the closed position. It is then oscillated and rotated manually by radial levers, simulating the technique of grinding in automobile-engine valves. The contact eventually becomes perfect and there will be absolutely no leakage, Figs. 11 to 13, inclusive.

Generator Winding. While the turbine was being overhauled by one crew, all the generator-stator coils were removed and replaced with new coils by another crew. As the coils were too heavy to be handled and manipulated safely, mechanical devices for various operations were adopted. Of these a description of the screw jacks which forced the coils into the slots may be of interest. A vertical pipe was rigidly positioned in the center of the stator core. Four screw jacks were then fabricated into radial arms each of which was attached to the center pipe by a ring which allowed the arms to be rotated about the pipe center. A wooden strongback was then attached to the outer extremities of each pair of arms. As the coils were set in place in front of their slots, the strongback was rotated and the jacks adjusted so that pressure throughout the entire length of the straight portion of the coil was uniformly applied until the coil was finally seated in its slot. This device, Fig. 14, definitely avoided any possibility of applying a strain to the mica insulation which might produce a crack that later would break down when the generator was in service.

By restoring each worn part carefully and making improvements where necessary at stated intervals, generating units should maintain their records of continuity of service indefinitely and give reasonable assurance that failures will not occur at inopportune times.

Discussion

P. M. HESS.[2] This paper, dealing with the complete overhaul of a 40,000-hp vertical Francis-type hydraulic turbine operating

[2] Station Superintendent, Safe Harbor Water Power Corporation, Safe Harbor, Pa.

under a head of 454 ft, should be of interest to all companies having hydraulic generating stations. This is particularly true for stations which were built many years ago. During the last 25 years, however, much improvement of design features has been made, and the use of better materials has to a great extent eliminated the need for much of the repair work mentioned in this paper.

Pitting Repairs. Repairs to pitted areas due to cavitation, as described in this paper, are treated along the lines followed by most companies. However, it is of interest to note that rotary files have been used for the rough-grinding, thereby greatly reducing the grinding time which constitutes an appreciable item of expense.

Shaft Repairs. The work of repairing the worn part of the shaft at the packing gland is interesting, but it is believed that this job could have been done satisfactorily by the use of sprayed stainless steel. Recently, information has become available on the use of carbon packing to eliminate most of the wear at this point.

Wicket Gates. Leakage through the guide vanes or wicket gates is of concern to most companies, especially where corrosive or erosive waters are encountered. On the latest designs at Safe Harbor, the contact surfaces are prewelded with stainless steel which thus far is proving well worth the additional investment. On the extremely large units, where complete dismantling of the unit is a major job, it is desirable to weld these corroded contact areas of the gate in place. This job certainly will be a difficult one without warping the surface. It is believed, however, that some attempts should be made to coat these areas with a noncorrosive hard stainless material in place. There is a possibility of applying sprayed stainless steel to the heel part of the gate, but it is doubtful whether or not a sprayed material will adhere properly to the tip.

Shaft Currents. Much discussion is heard concerning damage to bearings from shaft currents, but it is believed that in vertical hydraulic units there are very few cases on record of guide-bearing failures from this cause. It is desirable to insulate at two points in order to provide additional protection and permit testing.

Correcting Pitting From Cavitation. This paper stresses the necessity of complete overhaul after a period of many years' operation but further states that minor repairs in place have been made from time to time. We are of the opinion that, when dealing with propeller-type units, where much damage can be done to the blades in a period of a year or less, very frequent inspections should be made during this early operating period. Local cavitation, which is due to improper shaping of the blades or poor surface conditions, will show its early presence, if not by actual pitting, by the disappearance of the paint or protective coating on the blades. These local conditions can be corrected by grinding ahead of the pitted section to relieve the high spot and reshaping if due to improper shape.

Fig. 15 of this discussion shows a condition of severe pitting resulting from improper shape of the entrance edge of a Kaplan blade after only 6 months of operation. This pitted area could have been corrected by welding with an 18-8 stainless material, but this would not have corrected cavitation. The cavitation or the cause of the pitting was eliminated by reshaping the entrance edge to eliminate the jump of the water. No welding was resorted to, and after 10 years of operation no more pitting has been discovered.

A similar condition is shown in Fig. 16, where the trailing edge was rounded. This rounded surface set up cavitation close enough to the metal so that pitting occurred and continued progressively. The pitting was corrected by making provision for a rectangular trailing edge so that the cavitation which did result existed in the water sufficiently far away from the metal to prevent attack.

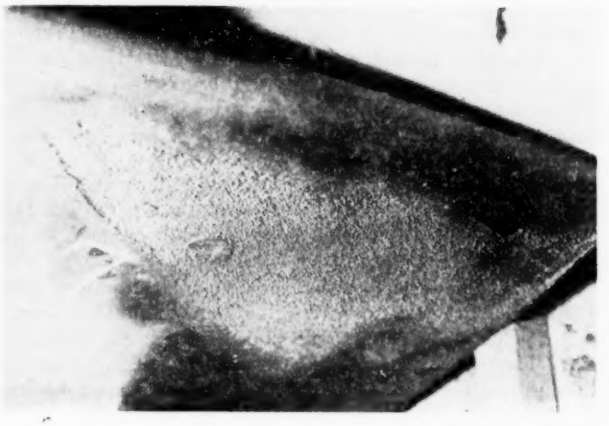

FIG. 15 PITTING ON BOTTOM OF BLADE

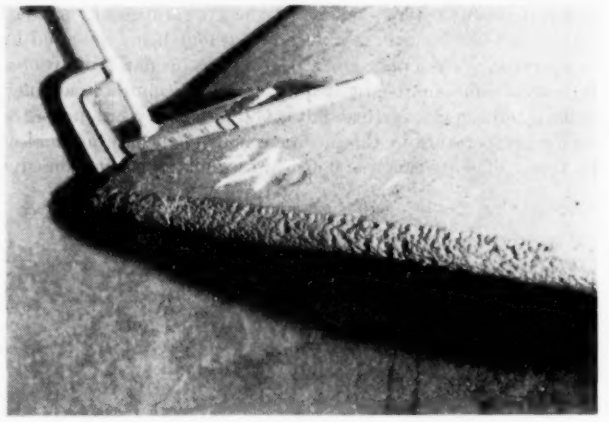

FIG. 16 PITTING ON TRAILING EDGE OF BLADE

FIG. 17 PITTED AREA ON BOTTOM TRAILING SIDE

Fig. 17 shows a condition of pitting at various points due to local cavitation. These areas were corrected by grinding the more or less high section ahead of the pitted area. Here again no weld was required to prevent further pitting.

Recently, one of our newer units showed considerable pitting on the pressure and suction side of the leading edge. Some of this area was prewelded with 18-8 stainless and withstood the attack, but the mild steel pitted rapidly. Investigation showed that a comparatively blunt section of the entrance edge existed,

FIG. 18 PITTING ON UNDER SIDE AND LEADING EDGE OF TURBINE BLADE

causing a tendency for the water to break away from the blade surface. Fig. 18 shows this condition on the suction side of a blade. Here again it would have been possible to combat this pitting by extending the stainless weld over the pitted area; instead, due to the scarcity of stainless welding rod at this time, it was decided to reshape the entrance edge properly. In order to do this, it would have been necessary to grind away practically all of the prewelded stainless steel. Nevertheless, this was done and has almost entirely eliminated the pitting. This is of interest, because pitting, which is shown in Fig. 18, occurred after approximately 1 year of operation, and, after more than a year's additional operation, the reshaped surfaces are still good.

It is therefore suggested that pitting resulting from cavitation should be corrected, if possible, by eliminating the cause, namely, cavitation.

Blade Packing. When the Kaplan units were installed in the Safe Harbor plant, they were many times larger in capacity and dimensions than any units previously built or installed in this country. One problem encountered in the early days was the sealing of the area around the blade journals or shanks to keep the lubricating oil in the hub from leaking outward and the water from leaking inward. A special design, Fig. 19 of this discussion, utilizing a leather packing, was provided for this area, but it never proved entirely satisfactory, growing progressively worse to the point that oil wastage was a considerable factor. Furthermore, it was necessary from time to time to shut the unit down to drain water, which entered at certain loads, from the hub. On the newer designs the water-removal problem has been simplified by the installation of a special pipe within the shaft; also the packing has been redesigned. However, in these units it was extremely difficult to redesign the packing area, and so it was necessary to experiment with different materials and shapes.

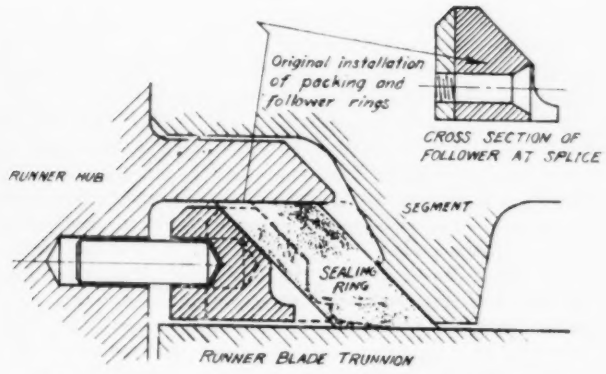

FIG. 19 ORIGINAL RUNNER-BLADE PACKING INSTALLATION

(The dotted lines show how neoprene packing is pressed out of shape and lifted from the trunnion with the original-type installation.)

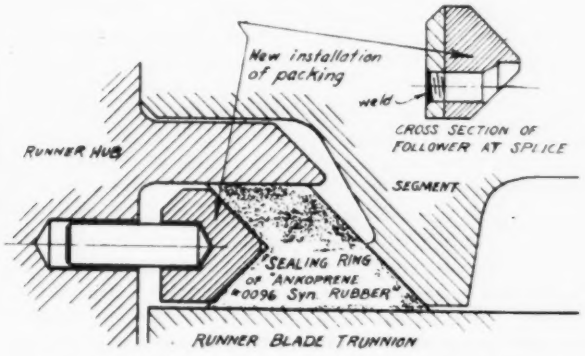

FIG. 20 NEW INSTALLATION OF RUNNER-BLADE PACKING

(Sketch shows how original follower rings were machined.)

After much experimentation, it was found that a neoprene rubber reshaped to the section, as shown in Fig. 20, has practically eliminated any leakage of oil out or water in. It was necessary to secure a neoprene of the proper hardness, because this material has a tendency to become quite hard at freezing temperature and, if made too soft, it will have a tendency to stretch, creep, or swell too much under oil pressure. The neoprene rings shaped similarly to the leather cross section, shown in Fig. 19, were more satisfactory than the leather but did not entirely eliminate all the leakage.

Some of the units have considerable pitting just outside of the sealing ring which caused increased leakage when using the leather. This pitted condition is not as serious when using the neoprene or more pliable material for packing. It has, however, been necessary in several cases to chip, weld, and grind these pitted areas.

The more frequent presentation of similar papers by operating men who are in contact with the equipment in the field is highly desirable, since such information, based upon actual operating experience, has much more value than that to be found in many of the papers which give only opinions without experience.

J. F. ROBERTS.[3] The writer has been greatly interested in the turbines dealt with in this paper, since he spent several months at the plant when it was first started up in 1923. Early in the operation of these units, it was found that there was an unusual vibration which caused a loud humming noise and considerable movement in the exposed parts of the penstocks. The turbines

[3] Manager, Hydraulic Department, Allis-Chalmers Manufacturing Company, Milwaukee, Wis. Mem. A.S.M.E.

themselves operated quite satisfactorily and there appeared to be no unusual vibrations around them.

The penstocks are housed in concrete-lined tunnels underneath the switch structure on the upstream side of the powerhouse, and while they are supported at intervals of 18 to 20 ft, the actual movement of the penstocks in this location and the noise which they produced were quite disturbing.

We feel sure that, in the ensuing 20 years, most other manufacturers have had similar occurrences, and we are not disclosing any professional secrets when we reveal that the cause of these disturbances was in the water wheel itself. We found that the space between the inlet edge of the runner blades and the guide vanes was too small so that, in effect, as each runner blade passed the guide vane, it tended to shut off the flow of water from that opening. This sent a small pressure wave back through the guide-vane opening into the spiral casing, and these pressure waves added together and were transmitted up the penstock. There were 19 runner blades operating at 257 rpm and the pressure waves corresponded exactly to this product, or 4880 vibrations per min. The actual pressure variation was in the neighborhood of $1^1/_2$ psi, or about 0.75 per cent variation on 195 lb static pressure. The difficulty was first eliminated by cutting down the diameter of the runner 5 in. by burning off the inlet edges of the blades. Subsequently, new runners were installed having a smaller inlet diameter and a different number of runner blades, and the results were very satisfactory.

We would be interested in knowing if the author has any records of the change in efficiency of this unit after about 20 years of operation. The original units, as tested by Professor Allen in April, 1925, showed about 90 per cent turbine efficiency. At that time the power company had some venturi connections in the penstock, and they expected to keep a continuous record of the performance of the units. Such records would be interesting to the profession, particularly in view of the rather unusual capacity of these units and the date on which they were installed.

The author mentions the matter of wear on the guide-vane bodies themselves but does not give any figures as to the wear on the guide-vane stems. Apparently the water in the Pit River is extremely clean, as he points out that the runner clearances had not increased appreciably in the 20 years of operation, but some figure on the amount of wear on the guide-vane stems and the bushings would be of interest. The writer has had considerable experience with mountain streams containing silt where the guide-vane stems were worn so badly that they had to be built up by welding and then turned to restore them to the original diameter.

The Pit River units are equipped with 9-ft-diam butterfly valves operating under 450 ft head, the valves having snap rings or piston rings on the disk, in order to give them a tight seal and take up any deflection which occurs in the valve housing under pressure. Originally the leakage on these valves was relatively small, possibly 5 to 10 gpm. It would be interesting if the author could supply information as to how these valves maintained their original tightness.

Illustrations are shown in the paper of the welding on the bottom side of the runner blades which was done to fill in the pitted areas. At the time of the installation of this plant, the question of suction head was not as thoroughly understood as at present, and to our knowledge cavitation tests on model runners had not then been conducted.

The throats of the Pit River No. 1 runners are set about $11^1/_2$ ft above normal tail water. Present practice would require that these units be set down within 4 to 5 ft of the tail water, in order to reduce the sigma value to a figure which is now considered good practice for units of this type.

This powerhouse is located at an altitude of nearly 2900 ft above sea level, and at this altitude perfect vacuum occurs at slightly under 30 ft of water vacuum. With the relatively high draft head which exists, it is not surprising that some pitting has taken place, but the amounts indicated in the paper do not appear excessive in view of the long life of these machines and the operating conditions.

The author's method of correcting the wear in the main-shaft sleeve is interesting and instructive. The use of a high-chrome steel with from12 to 15 per cent chrome is now common practice and appears to give the best results. It stands up considerably better than a nickel-chrome steel. The change in the method of draining the pressure from the upper side of the runner is interesting, and we hope that the results will be available at a later date.

F. H. Rogers.[4] The high-head turbine described in this paper had an excellent record of 20 years of continuous operation before major repairs were required.

The pitting of the runner, as described, occurred on the back of the runner vanes beyond the discharge orifice, which is the usual location for pitting on high-head Francis runners, as it is difficult to guide the water so that it will remain in contact with the back of the vane after the water leaves the orifice formed by the preceding vane.

In recent years, prewelding of the runner vanes has often been done during manufacture to protect the areas where pitting may occur, as determined by past experience. This is now quite general practice in the case of propeller-type runners and has been done in a few cases on high-head Francis runners. The surfaces to be prewelded are cast as depressions about $^1/_8$ in. below the final contour. The initial cost of this work is rather high, and its advisability may be questioned in the case of Francis runners as the actual pitting may not always occur at the protected surfaces.

The cause of pitting in a particular installation may be due to faulty operation as well as to faulty design. The runner is designed for operation under given conditions of horsepower output, total head, and minimum tail-water elevation, as specified by the purchaser. The designer allows some margin over the rated horsepower required to allow for speed regulation, ordinarily from 5 to 10 per cent.

To prevent cavitation, it is necessary that a reasonable absolute pressure exist at all points on the runner vanes. The absolute pressure available is dependent upon the water barometer pressure at the plant site (from 30 to 33 ft, depending upon elevation above sea level). This absolute pressure is reduced by (1) elevation of runner above tail water, (2) regained velocity head of the flowing water, and (3) local pressure drop due to curvature of the vanes, or to the pressure difference required to develop power. All these factors are taken into account by the designer, so that the actual remaining absolute pressure will be from 5 to 10 ft at all points on the vanes.

In actual operation, the turbine may develop a full-load capacity of from 5 to 10 per cent in excess of its rated capacity; the efficiency, however, at this load being somewhat reduced. If the unit is operated at this overload, the discharge will be considerably higher than at the rated output. Under such conditions, the absolute pressure on the runner vanes will be reduced below the value established by the designer and may fall so low as to result in a break in the continuity of the flow causing cavitation and pitting.

This condition is illustrated by the curves in Fig. 21 of this discussion, produced from the actual design of a 60,000-hp turbine operating under a head of 390 ft at a speed of 225 rpm. At the

[4] Manager, I. P. Morris Department, Baldwin-Southwark Division, The Baldwin Locomotive Works, Philadelphia, Pa. Mem. A.S.M.E.

normal rating, the discharge is 1500 cfs. At the elevation of this plant above sea level, the atmospheric pressure minus the water-vapor pressure at 80 F is 31.8 ft. This total absolute pressure at the runner discharge is reduced by the three factors previously mentioned, the values of which as shown are as follows:

		Feet
1	Elevation of tail water (static draft head)	= 5.2
2	Average velocity head regained	= 11.1
3	Local pressure drop	= 9.4
	Total pressure reduction	= 25.7
	Margin in pressure	= 6.1
	Total available pressure	= 31.8

If this unit is operated at full gate, developing 64,500 hp, or 7½ per cent excess power, the efficiency falls to 86 per cent, and

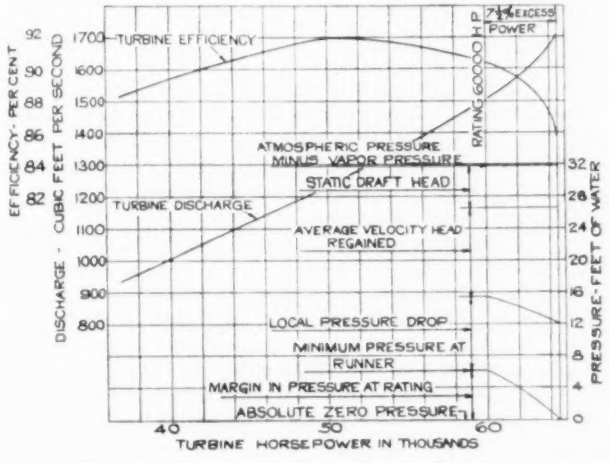

FIG. 21 CAVITATION EFFECT DUE TO OVERLOADS

the discharge increases to 1700 cfs. As both the velocity head regained and the local pressure drop vary as the velocity squared or the discharge squared, it will be noted that these two curves drop rapidly, so that at this output the pressure reduction is made up of the following:

		Feet
1	Elevation above tail water	= 5.2
2	Average velocity head regained	= 14.4
3	Local pressure drop	= 12.2
	Total pressure reduction	= 31.8

Under these conditions all the design margin is lost and only the water-vapor pressure occurs at the vanes, resulting in cavitation and pitting. To avoid this danger it is good practice to furnish the plant operators with charts showing the maximum allowable outputs at various heads and tail-water elevations, based on data furnished by the manufacturer. Under emergency conditions a unit may be operated beyond these limits for a short period of time, recognizing the fact that pitting may occur, the extent of which would be dependent upon the period of operation. The value of this additional output versus the cost of repairs and outage time should be studied carefully by the operating company before permitting such overloading of the unit.

The repair work on the guide vanes, described in the paper, is frequently found in high-head units where abrasive materials are carried by the water. It is now usual practice to preweld the guide vanes at the manufacturer's plant at certain locations for high-head plants where it is known that the water carries silt or other abrasive materials. This is done by welding with stainless steel on the vertical contact lines between the guide vanes, as this hard metal not only preserves the shape of the vanes at the point of highest velocity but also maintains the leakage at the original low value when the guide vanes are closed. This is of considerable value when shutting down a unit and applying the brakes, as it is frequently found that after the guide vanes are worn the leakage in the closed position is so great that the unit cannot be stopped with the brakes and it is necessary to close the main intake valve. Wear at the top and bottom of the guide vanes also increases the leakage at the distributor plates, resulting in loss in efficiency as well as difficulty in shutting down the unit. This portion of the vanes is sometimes protected by welding stainless-steel plates to the top and bottom of the vanes before final machining. This protective work can be done at lower cost in the manufacturer's shop than after wear has occurred in the plant.

Another method of reducing leakage above and below the guide vanes is the use of the so-called "disk guide vanes." In this type, disks are cast with the guide vanes, machined for a close fit in holes bored in the upper and lower distributor plates. These disks reduce the leakage area above and below the guide vanes by the difference between the diameter of the disk and the diameter of the vane shanks.

T. C. STABLEY.[5] The complete overhauling of the 40,000-hp turbine, as outlined in this paper, is more or less typical of Francis-type turbines. Generally, the most common maintenance problems are pitting of runner by cavitation, lack of grease lubrication at crucial points, water-lubricated bearings, wear of shaft or shaft sleeves at bearings and packing glands, and corrosion.

Another more serious condition, which has appeared in recent years and which is confined mainly to cast-iron runners, is that of cracking of blades at the runner crown, beginning at the outflow edge and progressing toward the inflow edge. On this condition very little has been published.

The California Unit. Repairs and modifications to the 40,000-hp turbine were carried out evidently under favorable conditions, in that it was possible to dismantle the entire unit completely. This method is undoubtedly the most satisfactory and should be used where time and costs permit, as it facilitates and insures a more dependable job, especially so when the runner can be positioned for flat welding instead of the usual difficult overhead method.

Considering the capacity and the extraordinarily high head, the runner evidently is made of cast steel, which lends itself readily to the production of a first-class and enduring welding job of the pitted areas with stainless steel.

The most difficult repair method of welding runners is in the overhead position when it is not convenient to dismantle, especially so with cast-iron runners which are the most common type. Great care must be exercised in these welding repairs to re-establish the original contours by grinding. Experience has proved that if only the general curvature of buckets is followed high spots remain, causing severe pitting to appear well beyond the welded section.

Stainless-Steel Welding. We pioneered with welding stainless steel (18-8 and 18 Cr) on cast-iron runners in the overhead position in 1929 and 1930. Since then we have welded ten large runners with excellent results, so that none of the welds indicates any trace of pitting. In some of our early jobs, insufficient attention had been given to contours, resulting in further expansion of pitting beyond the welds.

Shaft Repairs. Like runner repairs, work on shafts can be more readily carried out when dismantled and set up in a lathe, or in some improvised turning rig as described by the author. In recent years, several interesting articles have been published on

[5] Station Superintendent, Pennsylvania Water & Power Company, Holtwood, Pa.

truing or machining vertical shafts in position, because of corroded or worn sections. We have found it necessary to machine 24-in-diam shafts on two vertical 20,000-hp single-runner, 60-cycle units at the water-lubricated, lignum-vitae, guide-bearing section of the main shaft, where split bronze sleeves 62 in. long are attached. Water entered between the shaft and the sleeve, causing considerable corrosion and loss of metal, allowing some clearance between the shaft and the sleeve. With a locally fabricated tool-holding rig, mounted within the bearing barrel, the shaft was trued to clean metal at 13 rpm. In each case this was accomplished by driving the 60-cycle unit as a synchronous motor with a 13,500-hp 25-cycle unit as the generator, on hand control, running at approximately 38 rpm. The two generators were directly connected through temporary cables between the corresponding oil circuit breakers. To compensate for the slightly reduced shaft diameter, the contact ribs of the bronze sleeve were slightly enlarged in the bore, bronze rings fitted and bored to the reduced shaft diameter.

Inhibiting Shaft Corrosion. On previous fittings of shaft and sleeve, the former was liberally coated with thick white lead, which in time was dissolved by the entrance of water. A "No-Ox-Id" preparation was applied on the last fitting and this is expected to be more durable than white lead.

Restoration of Worn Runner Seals. The author states that the runner seals required no attention in 20 years of service, which is an excellent record. The unit surely must have been operating under very favorable conditions, such as the absence of sand, silt, or other abrasives common to rivers, during freshets and floods. We have seven vertical double-runner units (13,500 hp), and three vertical single-runner units (20,000 hp) in the Holtwood plant with from 19 to 33 years of service, in all of which the seals have become considerably enlarged. These enlargements are caused locally by operating conditions that generally do not apply to all hydrostations.

During the winter months, when frazil ice troubles occur, we are obliged to raise the intake screens which allows all trash, timbers, tree stumps, railroad ties, etc., to enter wheel pits for the duration of the ice run, which may last for several days at a time. Many of these obstructions do not pass through runners but become lodged between the buckets causing unbalancing and excessive shaft oscillations. The units frequently operate under these conditions for extended periods before unwatering and removal of obstructions, hence the seals become progressively larger yearly, owing to the runner band rubbing on the distributor ring.

Efficiency losses are a factor to be considered when a number of units are involved; accordingly this year we began reducing these losses on a 13,500-hp unit, by electrically welding a bronze seal band 1 in. wide on the inside of the lower cast-iron distributor ring, thereby restoring the original clearance of $^1/_{16}$ in.

Determining Normal Position of Runner. The inside diameter of the lower distributor of this unit was found to be worn eccentrically. To locate the normal running position of the runner, the unit was rotated as a motor and measurements taken at the seal of the varying clearances around the distributor. It was surprising to learn that the runner band rotated nearly concentric with the shaft. Owing to the great amount of work entailed in dismantling the entire unit, the job was simplified by removal of vanes, unbolting the distributor and raising it 8 in. for the welding job. After welding, the excess metal was ground off and a true circle established by means of a chart showing all dimensions from a circle drawn on the distributor plate through the fulcrum-pin holes.

The following unusual turbine troubles are cited:

Cracked Blades. Several years ago, we were confronted with a major repair problem in that cracks had developed close to the crown at the base of the fillet in two 20,000-hp (53-ft head) cast-iron runners. (Over-all dimensions: Throat diameter 14 ft, height 9 ft.) Fortunately the cracks were discovered in time to prevent disastrous results. Only a brief summary of the job will be given.

All fractures started at the outflow edges of the blades and progressed toward the inflow, varying in length from a minimum of 4 to a maximum of 32 in. and extending through the blades from the pressure to the suction side. The line of juncture at blade and crown is 57 in. long. A survey of the situation revealed that similar troubles had been experienced and corrected elsewhere by welding. After a thorough study of several methods of restoring the runner, it was decided to make repairs by electric welding without dismantling the unit. Briefly, the cast iron was chipped to a width of 3 in. on either side of the cracks, $^3/_8$ in. deep, and generously studded with $^5/_8$- and $^3/_4$-in. steel studs, carefully welded and ground to smooth contours. All upper sections of the outflow edges were chipped off. Steel inserts 16 in. long and 4 in. wide at the top, and tapering to zero at the lower end, were fitted between blades at crown and runner hub and securely welded. The hub, crown, and blades were liberally studded to make a secure bond so as to reinforce the blade and to reduce the likelihood of cracks starting at the outflow edges again.

Elaborate studies were made by means of seven strain gages fixed to the outflow edge of a blade and used in conjunction with an oscilloscope and oscillograph with the unit operating under varying loads, unloading and loading, to determine conditions which might overstress the blades. Since these analyses have involved pioneering work in the measurement field, as well as in the exploration of stresses in a blade under operating conditions, there is naturally some uncertainty in the results of the studies which remain to some extent in an inconclusive stage. Several theories have been advanced as to conditions overstressing blades, i.e., that of the transition period of the rising water column in the draft tube when changing from condenser operation to power generation, due to impact of water column striking rotating blades; another, fluttering of outflow edges of blades, owing to the long cantilever span between crown and shroud ring causing vibration fatigue of metal. Still another theory advanced is the "out-of-step" condition which occurred a number of times on these units and may have produced severe shocks and irregular rotation. It is thought possible that the thrust on the turbine could increase to such an extent as to cause failure between blades and crown.

Runners of the Francis type made of cast steel would be a marked improvement over cast iron owing to added strength, far less likelihood of failure, such as the development of fractures and broken out section of blades, and would have the added advantage of allowing welding repairs to be made readily on the pitted areas by the application of stainless steel on the vulnerable spots.

Runner-Blade Replacement. A year ago we were obliged to perform another unusual piece of mechanical surgery on a 33-year old 13,500-hp vertical double-runner turbine in which a blade had completely broken out of the lower runner between the crown fillet and the shroud ring. The over-all dimensions of the cast-iron runner are throat-ring diameter 10 ft 7 in., height 6 ft. The blade had been previously welded at what was considered a fatigue crack extending approximately one third of the way across the face of the blade slightly below the crown fillet. Fortunately, the broken-out blade was found intact directly outside the draft-tube discharge and was used as a pattern for casting a new steel blade. Forged-steel anchor plates were fitted to crown and shroud ring, and the new blade welded to these plates, making a secure job and restoring the capacity of unit to normal. In order to compensate for the added weight of the new anchor plates, counterweights were secured to the crown and band

on the opposite side to balance the runner. The fitted blade was 60 in. long, 27 in. to 32 in. wide, and weighed 580 lb.

In 1925, the writer presented a similar paper[6] outlining maintenance problems and procedure which mainly concerned early (1907) low-head types of vertical double-runner units, early welding procedure with high-carbon steel, rubber bearings, etc. The general overhauling periods of these old units have been extended by scheduled inspection periods and minor repairs from every 7 years to an average of 12 years. This was accomplished by providing better lubrication, grease retainers, fitting bronze bushings to unbushed moving mechanisms, and the substitution of stainless steel for ordinary steels to eliminate corrosion in the submerged operating mechanism. Reference was made in the present paper to the first use of rubber for bearing linings in vertical hydraulic turbines. The trial was made in the Holtwood Station in 1924, and since that date eight of the ten main, and two exciter, units have been fitted with rubber bearings; numerous similar installations have been made throughout the country. These bearings have given excellent results and long life; in fact, we have found them far superior to lignum vitae and other modern substitute materials.

In 1925, a rubber liner was fitted to a bearing housing for a 16,500-hp vertical unit and has been in continuous service to date. The only modification made was to enlarge the bore slightly to accommodate a new stainless-steel sleeve fitted on the shaft to replace a worn bronze sleeve. We have likewise found that stainless-steel sleeves on the main shaft at bearing locations are far more durable than bronze owing to its resistance to the abrasive actions of sand and silt in the river.

Vertical Thrust Bearings. It may be of interest to mention that Kingsbury thrust bearings for large vertical hydraulic units had their first trial and development in 1912 in the Holtwood Station, and since have had wide application.

E. B. Strowger.[7] The author has described an ingenious method of installing a split bushing on the shaft of a 40,000-hp Francis turbine after it had been in operation for almost 20 years. This record of performance seems to be very good, and the methods used show ingenuity in handling maintenance problems. The method now used in maintaining the shafts of the 5500-hp vertical turbines of The Niagara Falls Power Company, some of which are 40 years old, might be of interest for the record. The 11-in. nickel-steel shafts have worn in the guide bearings and to a greater extent in the stuffing boxes. No provision in the original design was made for a sleeve to take up this wear. Until recently, the shafts were repaired by truing them up at the guide-bearing section and at the packing-gland section by machining to the depth of the grooves worn by the packing and then fitting a split sleeve or band in the recess and welding it together and fastening it in place. The shaft was then finished to the proper dimensions. With this method, as repairs were made, the various shafts kept decreasing in diameter at the bearing and eventually no two shafts had exactly the same diameter at this point.

To overcome the difficulties resulting from this nonuniformity it was decided to try metallizing. In 1939, one of these shafts was built up by metal-spraying over a length of about 4 ft 4 in., which included the section at the lower packing gland, the bearing section, and the section at the upper packing gland. Fig. 22 of this discussion shows the spraying in progress. The diameter was increased from 1/4 in. to about 1 in. above the worn size using stainless steel. The shaft was then machined and placed in service and is still running. An impregnated flax packing was

[6] "Hydraulic Maintenance at Holtwood Plant," by T. C. Stabley, *Mechanical Engineering*, vol. 48, 1926, pp. 341–349.

[7] Hydraulic Engineer, The Niagara Falls Power Company, Niagara Falls, N. Y. Mem. A.S.M.E.

Fig. 22 Metal-Spraying Turbine Shaft

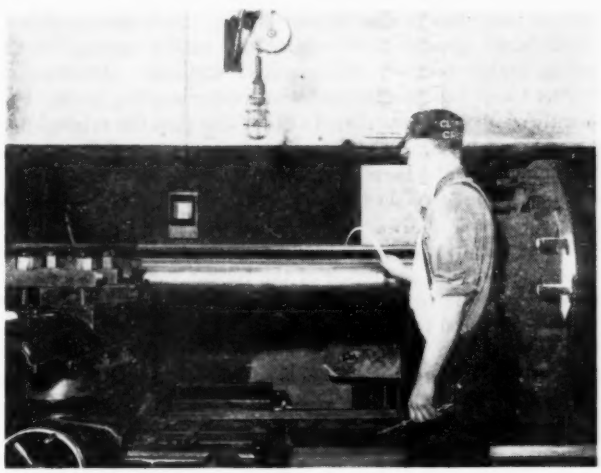

Fig. 23 Completed Shaft Built Up by Metal-Spraying Stainless Steel

used in the packing gland. Fig. 23 shows the completed job.

On this work it was found that while the flax packing was very satisfactory, some of the original U-shaped leather packing rings could not be used because particles of stainless steel would adhere to the leather and the resulting abrasive surface of the metal would quickly wear the leather away. It is therefore necessary in such repair work to make sure that the combination of materials chosen is suitable for the job.

I. M. White.[8] The maintenance time required in connection with the author's modification to the shaft sleeve and the relief-valve body clearly indicates the desirability of taking considerable care in initial purchasing in order to hold turbine outage time to a minimum. For instance, in modern turbine installations a spare split-shaft sleeve is normally ordered at the time of original manufacture. In such cases, the spare sleeve can be completely finished in the manufacturer's shop so as to eliminate any need of special fixtures that might be required should the spare sleeve only be ordered at a later date. Such spare sleeves can be held together with either H-section keys as noted by the author or by special machine screws. Normally, a small notch is

[8] Chief Engineer, The Pelton Water Wheel Company, San Francisco, Calif. Mem. A.S.M.E.

provided at the two joints to permit welding or brazing of the notch at final field assembly. After the welding, the metal can be ground and finished by hand to form a very smooth surface contour. In present-day designs, such sleeves are normally made of stainless steel in order to provide maximum wearing life.

The author has indicated that considerable work was required in the lining of the relief valve in order to overcome cavitation. This excessive repair work and consequent outage of the turbine could have been almost eliminated had the relief valve been made of cast steel at original manufacture. It is probable that the relatively small additional cost of providing initially a cast-steel body would have been offset by the outage time required for the extensive repair.

The change in head cover pressure by modification of the runner tip as discussed by the author has been found to exist on other installations. Several experiments have been conducted in order to determine the best place for venting the upper head cover through the runner. The results of these tests indicate that the author has selected a very desirable location.

Modern practice in connection with the replaceable seats of relief valves indicates a preference for the utilization of 18-8 layer weld on mild steel in place of cast bronze. Such seats cannot be satisfactorily ground as noted by the author because of the galling action between stainless-steel surfaces. However, an excellent seat can be obtained with proper cutting tools. Frequently spare seats are ordered at the same time the original unit is purchased. With such an arrangement, it is possible to install the spare seats and then to recondition the original seats in the machine shop so that they may be returned for use as spares when the need arises.

The author does not specifically mention the type of rod used in connection with the repair of the runner vanes and repair to other cast-steel surfaces. Experience indicates that an 18-8 stainless-steel rod is very satisfactory. This rod provides a surface which has proved of high quality in resistance to cavitation. Another factor that greatly influences the cavitation of the runner

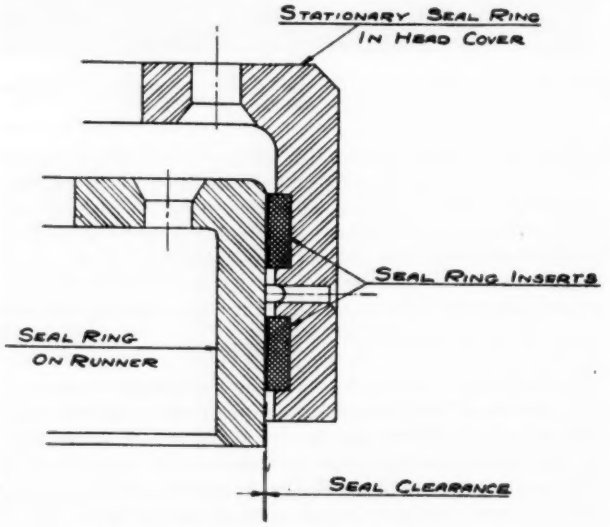

FIG. 24 TYPICAL SEAL-RING CONSTRUCTION

is the actual contour of the runner surfaces upstream from the area experiencing cavitation. It has been found that a very slight high spot upstream will have a tendency to start cavitation, which accelerates as the cavitation becomes more and more severe. It is advisable to take considerable care in inspecting the area upstream of a repaired cavitated area in order to insure that no high points exist which would make the stream of water leave the surface and thereby create cavitation.

The author has stated that the seal rings on the subject turbine showed practically no wear after the 20 years of service. This is indeed unusual and indicates that very clean water undoubtedly passed through the turbine. In many cases, excessive wear of the seals does develop. Consequently, the operating companies desire to make repairs with the minimum of difficulty. Fig. 24 of this discussion indicates a scheme which has proved very satisfactory in providing new seal rings with low outage time required.

The seal-ring inserts indicated are cast in segments and then individually peened into slightly dovetailed grooves. The ends of the segments are joined together by heating with a torch. Seal-ring segments are made of Parsons white brass which has proved to be very desirable from a wearing standpoint. Close clearances can be used without danger of galling between the stationary and moving seal ring, since the Parsons white-brass material has a tendency to wipe clear should contact develop.

The seal-ring inserts can be easily ground in the field to the exact diameter required to suit the runner wearing rings. In many instances, a spare set of rings is ordered with a turbine so that it becomes a very simple matter to make a complete replacement in the field. The worn rings can be repaired at the convenience of the operating personnel.

In addition to the foregoing maintenance points, wear is sometimes experienced in the butterfly-valve seats, guide vanes, liner plates, head cover, and runner throat. In modern turbines, these parts are either made replaceable or provided with replaceable liners so that maintenance work can be accomplished with the minimum of outage time. Special wear plates are sometimes provided in the head covers so that as wear, either from erosion or cavitation, takes place, the plates can be more easily repaired or replaced than the main part itself. Replaceable plate-steel liners are normally installed in the draft tube immediately below the runner. Cavitation frequently occurs at this point and, consequently, a replaceable steel liner is of considerable advantage in maintenance.

During the past several years considerable study has been undertaken by turbine manufacturers concerning cavitation problems. These studies have definitely disclosed that runner and draft-tube cavitation is a function of turbine setting, specific speed, and barometric pressure. As a result, proper operating conditions and unit setting can be established for a new installation so that cavitation and consequent maintenance problems are reduced greatly over what has been the case in the past. Such care in initial selection of units together with proper consideration for spare parts should greatly reduce maintenance problems of present-day turbines in contrast with older turbines.

AUTHOR'S CLOSURE

The discussions presented by various central-station engineers and manufacturers' representatives embrace the practice throughout the United States and contribute much to the scope of the subject.

By keeping the problems of maintenance before designing engineers, progress of improvement in performance of equipment must ensue.

Apparently, there is a gravitation toward the usage of 18-8 stainless steel as an "antidote" to cavitation, erosion, and corrosion. We have all tried various alloys from time to time, but thus far our experience indicates that none offer any advantage over the stainless steels.

Likewise, the metal-spray process has been employed with varying degrees of success. In general, it has been satisfactory on shafts and the like, but it has not done so well on flat surfaces

or shapes upon which the sprayed metal is in the form of a patch.

Packings of various materials and forms have also engaged the attention of maintenance men. No one type, however, is a "panacea" for all conditions. Metallic packings and rawhide seem to be less severe on the shaft or trunnion than others; especially the square-plaited flax.

Mr. J. F. Roberts is probably more intimately acquainted with the units at Pit River No. 1 powerhouse than any one else, for he "lived" with them when their service life was in its "infancy," and so his contribution supplies interesting information which otherwise would have been lacking in the paper.

Supplementing his comments, relating to the runner vibration, a complete revelation of this may be found in a paper by Roy Wilkins.[9] A unique device was employed to record graphically the magnitude and frequency of the vibrations. This is described and some of the records have been reproduced.

The efficiency tests on the Pit River No. 1 units, conducted by Prof. Charles M. Allen, in 1925, have not subsequently been repeated.

[9] "Study of Irregularity of Reaction Francis Turbines," by Roy Wilkins, *Journal of the American Institute of Electrical Engineers*, vol. 42, 1923, pp. 1141–1144.

With seal-ring clearance unchanged, and runner and guide-vane surfaces restored in 1942, the turbine efficiency should be about the same as it was in 1925. It may even be slightly higher, due to the reduction of the load on the Kingsbury thrust bearing, by virtue of the reduction of pressure on the top side of the runner brought about by the vent holes drilled in the runner cone.

The guide-vane stems of the Pit turbines were not worn sufficiently to warrant repairs. This is due to the absence of grit and foreign matter in the water and also to greasing at regular intervals, performed with the vanes in motion.

In answer to Mr. Roberts' inquiry concerning the seat rings of the Pit River No. 1 turbine butterfly valves, the only attention they have had in their 20 years of service is a dressing of the roughened areas by use of a drawfile. They were then readjusted to minimize the leakage.

We have more than twenty-four turbine butterfly valves in service at various hydroplants, varying in size from 36 in. to 9 ft, and operating under heads up to a maximum of 700 ft. Thus far, it has not been necessary to replace the seat rings in any of them. It is our practice to prevent the surfaces from becoming rough or cavitated by arc welding periodically or filing them, or both.

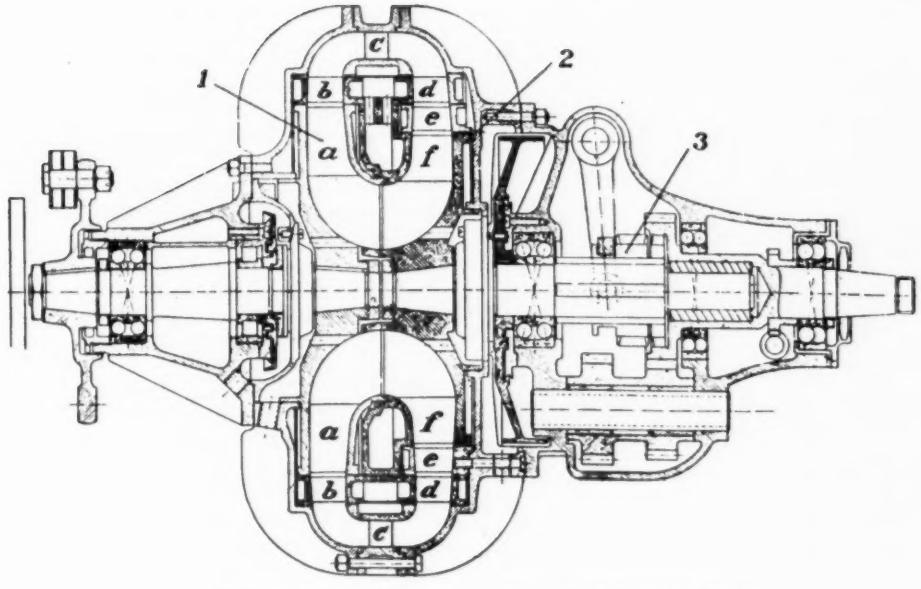

FIG. 1 LYSHOLM-SMITH CONVERTER WITH REVERSE GEAR
(*a*, pump; *b*, *d*, *f*, turbine; *c*, *e*, guide).

Development of the Lysholm-Smith Torque Converter

BY A. LYSHOLM,[1] STOCKHOLM, SWEDEN

The author's experience in the design and construction of hydraulic transmissions for automotive drives goes back over a 15-year period when the outstanding development was the Föttinger transformer, incorporating a coaxial pump impeller and turbine which was used as a speed reducer for ship propellers. Present-day designs of the Lysholm-Smith torque converter employ the Föttinger coaxial arrangement, but with improved multiple-stage turbine blading which enables the torque-speed range to become automatically variable within a wide range of high efficiency. The paper is concerned principally with the theory of the torque converter, details of early experiments in Sweden, and design features of hydraulic drives of various types as now widely applied in the automotive and railroad fields.

ABOUT fifteen years ago the author took up the problem of hydraulic transmission for automotive drives. At that time the Föttinger transformer which incorporates a coaxial pump-impeller and turbine had been used as a speed reducer for ship propellers. According to published information this converter had a very high efficiency at a certain speed ratio, but at other ratios the efficiency dropped off rather rapidly.

With the Lysholm-Smith torque converter which, like all modern hydrodynamic converters incorporates the Föttinger coaxial arrangement, it has been possible to obtain high efficiency as well as a flat efficiency curve, principally by means of improved multiple-stage turbine blading, which enables the torque-speed range to become automatically variable within a wide range of high efficiency. Fig. 1 shows the original test converter which has one pump impeller, three rotating turbine rings and two stationary guide-blade rings. An account will be given of some of the fundamental principles of the torque converter and the experimental work leading to the evolution of the present types, namely, the fixed-blade type, the adjustable-blade type, and the type with direct drive.

THEORY OF THE TORQUE CONVERTER

In a hydraulic gear of the turbine type, the following are the principal normal losses:

1 Friction loss in the pump wheel
2 Carry-over loss between pump and turbine
3 Friction loss in the turbine blading
4 Carry-over losses between the turbine stages
5 Carry-over loss between turbine and pump
6 Leakage losses
7 Rotational losses
8 Mechanical losses
9 Auxiliaries.

A summary of these losses is given in Table 1.

The friction losses in the pump wheel and turbine in the table include all losses due to the flow through the blading, together with the eddy-current losses at the inlet and outlet edges of the blades, but do not include leakage losses. When running at different torque-speed ratios, the blading losses due to varying inlet angles are the most important and account for nearly the total loss at the stalling point and racing speed. Therefore, only these losses will be considered in the following analysis, as this simpli-

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

TABLE 1 BALANCE OF LOSSES

Item	First test converter	Standard bus converter	Standard rail-car converter
1 Friction, pump wheel	3.5	4.5	4.5
3 Friction turbine	2.5	3.0	3.0
6 Leakage	2.5	3.5	3.5
7 Rotation	1.5	1.5	1.5
8 Mechanical	0.5	1.5	1.0
2, (4), (5), (9) Others	0.5	1.0	1.0
Efficiency, per cent	89	85	85.5

fied assumption gives a fairly good view of the operation of a torque converter at varying speeds.

If the turbine is provided with only one runner, and if the leaving energy cannot be utilized, its efficiency at different speeds of the turbine shaft and with a constant supply of energy will, according to the principles of hydrodynamics, vary in accordance with a parabola. Conditions will be entirely different, however, if the leaving energy from each wheel is fully utilized in the next wheel. In the subsequent calculation, it is shown how the turbine "frictional" efficiency will then vary. Strictly speaking, the calculation is only valid for an axial-flow turbine and an infinite number of stages.

If c is the velocity of discharge from a blade and w designates the inlet velocity, then the useful pressure drop in the blade will be

$$\Delta h_u = \frac{c^2 - w^2}{2g} \quad [1]$$

The pressure drop on account of the friction can be expressed by the following formula

$$\Delta h_f = \frac{f}{2} \cdot \frac{c^2 + w^2}{2g} \quad [2]$$

where f is the friction coefficient, which also includes eddy losess.

Thus the total pressure drop in the blade is

$$\Delta h = \Delta h_u + \Delta h_f = \frac{c^2 - w^2}{2g} + \frac{c^2 + w^2}{2g} \cdot \frac{f}{2} \quad [3]$$

The efficiency of each blade will evidently be obtained from the relation between Δh_u and Δh, or

$$\eta = \frac{\Delta h_u}{\Delta h} \quad [4]$$

The values of Δh_u and Δh are obtained from the foregoing equations.

In the description to be given, the pump will be considered as an energy producer, and the efficiency of the turbine at different speeds will be examined, assuming a constant energy supply, that is, a constant product of pressure drop and quantity to be produced by the pump and absorbed by the turbine. Thus the pressure drop in the turbine, multiplied by the circulating-fluid quantity Q, must be constant, or

$$Q\Delta h = \text{const}$$

Assuming for the moment that Q is constant, then if a triangle for c, w, and u is drawn, and the peripheral speed u is assumed to vary with constant flow, the value of w will be seen to decrease from c, when the turbine is stationary, to a minimum value when the direction of w is perpendicular to u (in the following called the optimum point or the optimum speed), and then to increase to c again at racing speed. From Equations [1], [2], and [3], it will be seen that the value of Δh_u will vary between zero and a maximum value, the value of Δh_f between $f/2 \cdot (c^2/g)$ and a minimum value, and the total pressure drop Δh between $f/2 \cdot (c^2/g)$ and a maximum value. Thus at maximum torque at the stalling point, and zero torque at racing speed, all the available energy is absorbed by friction.

To get a constant product of $Q \times \Delta h$, however, the flow of liquid must be increased at all speeds in relation to the flow at the optimum point. At increased flow, the pressure drop varies with the second power of the flow, and thus the energy consumption must vary with the third power of the velocity of flow. The increased flow at a pressure drop Δh in relation to the flow at the optimum point will thus be obtained from the following relation

$$\sqrt[3]{\frac{\Delta h_{max}}{\Delta h}}$$

where Δh_{max} denotes the pressure drop at the optimum point.

Hence it is clear that the velocity-ratio triangles must be enlarged in the same degree as shown in Fig. 2, where the triangles at starting and racing, as well as at a few intermediate speeds, are given. The triangles are drawn for different "relative speeds," that is, the speed of the turbine in relation to the speed of the turbine at the optimum point.

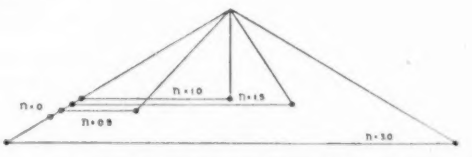

FIG. 2 VELOCITY TRIANGLES WITH $Q\Sigma\Delta h$ CONSTANT
(n = relative speed.)

It may be argued that the number of stages is of no importance for the efficiency of the converter, as the leaving loss always is utilized as inlet energy of the pump but that is not correct, since a certain percentage of the leaving velocity is always lost. Furthermore, it is possible with a multiple-stage converter to get a suitable stalling torque without using too large pump diameter and too much backward slinging of the pump blades which results in efficiency loss over the whole speed range.

Experience with converters, having similar types of blading, indicates that with turbines having one to three stages, the maximum efficiency may be about the same, but that with an increased number of stages, the stalling ratio as well as the over-all performance is improved. The three-stage converter is thus a good combination for most purposes.

When laying out the blading of a converter, the usual pump and turbine equations should be used; thus

$$H_p = \frac{y_p}{g} (U_2 C_{2u} - U_1 C_{1u})$$

$$H_t = \frac{1}{y_t \cdot g} \sum (U_1 C_{1u} - U_2 C_{2u})$$

where

H_p = pump head
H_t = turbine head
y_p = pump efficiency
y_t = turbine efficiency
C_{1u} = peripheral component of absolute inlet velocity
U_1 = peripheral velocity of inlet
C_{2u} = peripheral component of absolute outlet velocity
U_2 = peripheral velocity of outlet

Obviously the head of the pump and turbine must be equal and, further, the exhaust energy of the pump as well as of the last tur-

bine must be equal to the inlet energy of the turbine and pump, respectively, excepting of course carry-over losses.

Naturally due consideration must also be taken of the other losses mentioned in Table 1.

The foregoing equations are preferably solved by a cut-and-try method.

Early Experiments in Sweden

In order to investigate the blade friction at different speeds, some preliminary tests were made with a reaction balance, Fig. 3, by means of which the friction factors at different inlet angles could be studied. The results for two blade-section investigations (Nos. 3 and 2*b*) are given in Fig. 4. Blade section No. 3, Fig. 5, is a reaction blade of ordinary design and section 2*b* is especially suitable for varying inlet angles. However, the last-mentioned type of blade proved to be even better at ideal inlet angles of flow. In Fig. 4, a curve is drawn, calculated from later tests made on the complete hydraulic converter with blades principally of section No. 2*b*.

As will be seen, the results obtained with the converter followed closely the test values with the reaction balance for inlet angles between 50 and 145 deg. At angles smaller than 50 deg, the real values of f are, however, higher than those obtained with the reaction balance, and it is thought that this is due to the fact that the number of blade channels in the reaction balance was too small. However, this test gave sufficiently good results to enable construction of the blade system of the complete gear. It is interesting to note that the blade friction closely corresponds to the friction loss in a smooth tube, as determined by "Blasius" tests.

The blade system in the original Swedish test gear, Fig. 1, consisted of a pump wheel and three rotating blade rings, as well as two fixed guide-blade rings in the stator. Performance tests were made by measuring input torque and stator reaction, as well as primary and secondary speeds.

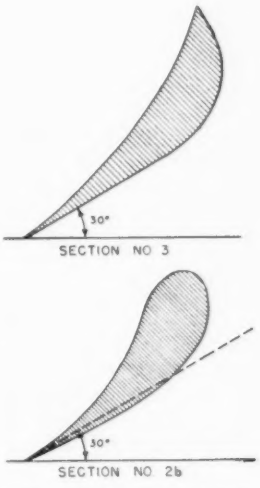

Fig. 5 Blade Sections

Fig. 6 shows the efficiency curve as a function of the turbine speed on the assumption that 50 hp is supplied on the primary side. This efficiency curve is very flat and attains a maximum value of 89 per cent. The corresponding turbine-torque curve is also shown. This curve has a hyberbolic shape which differs considerably from the straight line corresponding to a parabolic efficiency curve.

During the tests, the velocity of the circulating flow of liquid was also measured with a Pitot tube at 800 and 1000 rpm of the primary shaft. From these measurements it appeared that, at a constant primary input, the flow of liquid at stalling speed was 22 per cent, and at racing, 50 per cent higher than at the speed corresponding to the optimum point.

Fig. 7 shows the test results in another form. Here the efficiency curves are drawn for various constant primary speeds from 500 to 1600 rpm as a function of the secondary speed. The maximum efficiency for 500 primary rpm is 83 per cent, and at 1400 rpm the efficiency has increased to nearly 89 per cent.

Converter Input Characteristics. A normal three-stage converter with short third turbine blades absorbs more power at

Fig. 7 Tractive Effort and Efficiency Curves; Original Converter

stalling through racing, and thus the engine speed at stalling decreased to about 70 per cent of racing speed. This is very important for automotive drives as it prevents overspeeding of the engine at stalling and flattens out the efficiency curve.

However, an increased stalling torque of about 15 to 20 per cent can be obtained by using long blades in the last turbine stage, reducing the ratio mentioned to 80 per cent. This is very useful for most industrial applications where engine speeds are generally lower. A further increase in stalling torque of 15 per cent is obtainable by using adjustable pump blades, which also permits control of the input power.

Range of Torque Converter. In order to obtain the correct performance from a torque converter, it must be used with an engine of suitable torque-speed characteristic, in the same way that a ship's propeller must be designed to suit the engine characteristic. Certain variations from the standard characteristic can, however, be made without material alteration of design, or efficiency. The easiest way to alter the torque-speed characteristic is as follows:

1 To reduce the external diameter of the pump wheel, if it is desired to use an engine of lower torque.

2 To increase the effective outlet angle of the pump blades by increasing the number of blades or the blade angle for an engine of higher torque.

3 To use third turbine blades, which increases the input power considerably at high speed ratios.

4 To incorporate a primary step-up or reduction gearing.

Some experiments showing the effect of altering the blade angle are illustrated in Fig. 8. The efficiency curves are shown

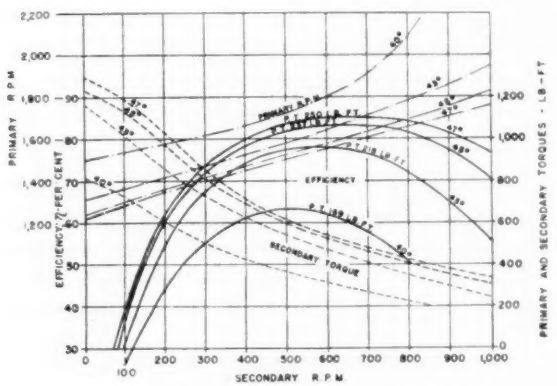

FIG. 8 EFFICIENCY TESTS ON HYDRAULIC TORQUE CONVERTER

for constant primary torques, and the decreased range of the converter and lower efficiency as the angle is decreased will be noted. The available primary-speed range is also shown on the curves for each angle. The curves show the very great importance of having a correct pump-blade angle.

The effect of reducing the pump wheel diameter is shown in the curves in Figs. 9 and 10. It will be noted that, as the diameter is reduced, the efficiency at the lower end of the curve is reduced, and is increased at the higher end. Reducing the diameter displaces the curves along the secondary speed axis owing to the increased input. Fig. 11 shows the alteration of the stalling characteristic produced by reduction of the pump diameter.

From these results a suitable pump wheel diameter to suit any particular engine characteristic or conditions can be determined. The efficiency curves in Fig. 9 are shown for only one constant primary torque and only represent one condition. It will be

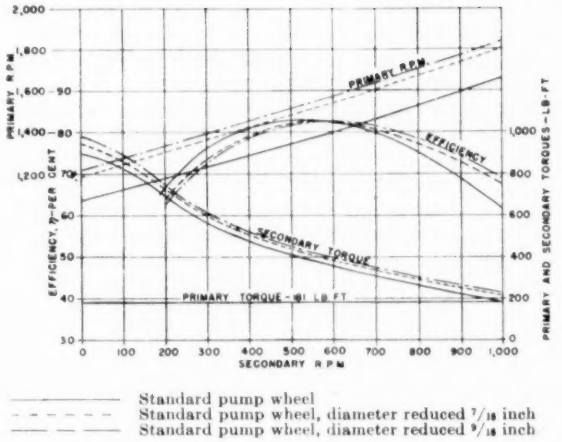

FIG. 9 SPEED-EFFICIENCY CURVES FOR VARIOUS DIAMETERS OF PUMP WHEEL

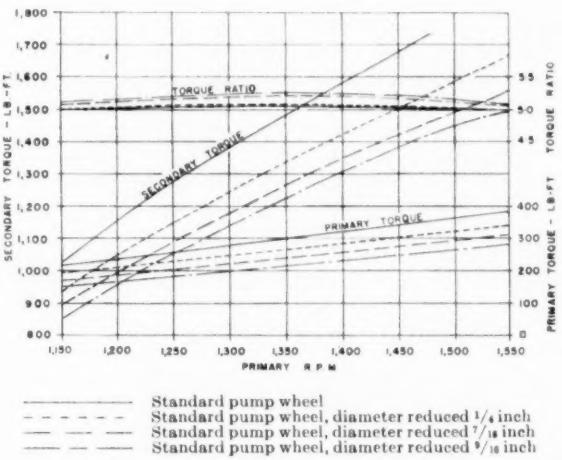

FIG. 10 STALLING TESTS ON PUMP WHEELS OF VARIOUS DIAMETERS

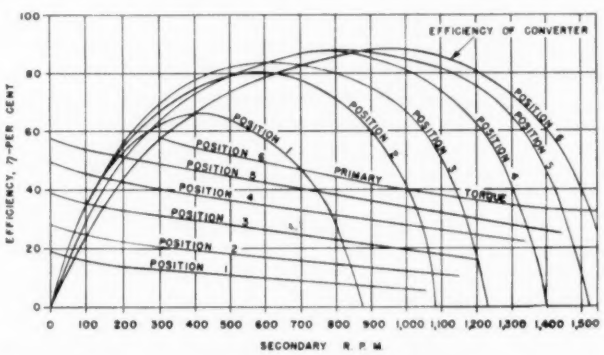

FIG. 11 EFFICIENCY AND PRIMARY TORQUE CURVES FOR HYDRAULIC TORQUE CONVERTER WITH ADJUSTABLE BLADES
(Constant primary speed, 1700 rpm.)

noted in Fig. 10, that the torque ratio at stall increases with decrease of wheel diameter, in about inverse proportion to the diameter.

Torque Converter With Adjustable Pump Blades. In Fig. 11, characteristic curves are given for a torque converter having adjustable pump blades. The numbers of the curves indicate different positions of the adjustable pump blades. It will be noted that the efficiency is less sensitive for different blade posi-

tions than in the case of the pump blades corresponding to Fig. 8. The advantages of the adjustable blades are:

1 Practically no secondary torque with closed blades.
2 Higher stalling torque ratio, up to 6:1.
3 Flatter efficiency curve.
4 Possibility of overloading the engine when desired.
5 Possibility of avoiding critical speeds of the engine crankshaft.

Effect of Turbine Variations. It is a very simple matter to alter a pump wheel on a production converter, as it may only have from 14 to 20 blades, but it is not so easy to make turbine-blade alterations, because of the large number of blades. However, as already mentioned, two different types of third-stage blades are used, a short blade and a long blade. It may be stated generally, however, that the calculations for the turbine are made for a speed which corresponds approximately to a flow perpendicular to the inlet of a blade ring. This "calculation" speed corresponds to the optimum speed previously mentioned. For the tested converters, the speed corresponding to the maximum efficiency is generally higher than the optimum speed owing to the type of blading used.

Maximum Efficiency Speed. The speed at the maximum efficiency point will depend upon (*a*) the number of stages, (*b*) the diameter of the blade rings, (*c*) the head to be utilized, and (*d*) other factors. Obviously, the optimum speed is increased by (*a*) a smaller number of stages, (*b*) a smaller diameter of stages, and (*c*) a larger head. This may also be expressed as a ratio which corresponds to the "Parsons figure" or "quality figure," as used for steam-turbine calculations, namely, $\Sigma u^2/h$, where Σu^2 is the sum of the squares of the turbine-blade velocities, and h is the head utilized in the turbine. For modern steam turbines, this ratio is generally about 2000 (metric units) for impulse turbines having some reaction, and up to 3500 for pure reaction turbines of the Ljungstrom double-rotation type, for instance. To get a direct comparison with these figures it is necessary to multiply the corresponding values for torque converters by the metric mechanical equivalent of heat, 427. The converters now made have a Parsons figure of 3200 to 3500 at "calculation" speed, and up to 50,000 at racing.

It is also possible to use the "specific speed" of the pump and turbine as a basis of comparison. For torque converters, the specific speed n_s will preferably be expressed by the following formula

$$n_s = 3.65 \frac{n\sqrt{Q}}{h^{3/4}}$$

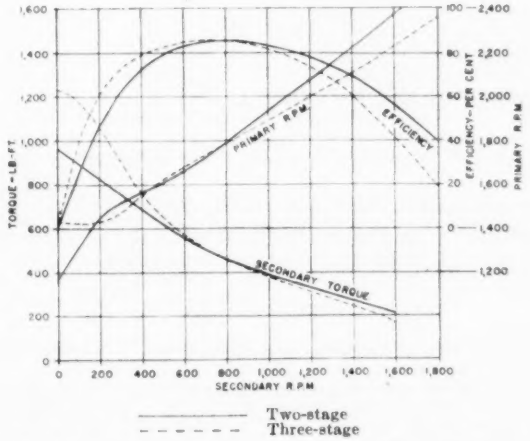

FIG. 12 COMPARISON OF TWO- AND THREE-STAGE TURBINES AT CONSTANT PRIMARY TORQUE OF 245 LB-FT

where n is the revolutions per minute of pump or turbine, Q is the quantity in cubic meters per second, and h is the total head in meters produced by the pump.

The average value of n_s for the pump in the present converters varies between 190 to 210, and for the turbine between 150 to 165 at "calculation" speed.

With a given diameter of converter, the number of stages can be reduced from three to two, but it is not easy to alter the diameter of the stages materially without altering the converter diameter.

Some of the results of changing from a three-stage to a two-stage converter in the same casing are shown in Fig. 12. From Fig. 12, it will be seen that the efficiency curve of the two-stage converter at constant torque is lower for the first 800 rpm of the secondary and, above this speed, is higher. There is also a considerable alteration in the stall ratio, that of the two-stage converter being constant at 4 to 1, and the three-stage varying from 4.5 to 1 to 5 to 1. These figures refer only to the two particular converters compared in the test. Higher stall ratios are available with different blade combinations. The effect of this on the secondary torque curve and engine speed at the commencement of converter operation is very marked. Both converters have the same maximum efficiency of 85 per cent.

DESIGN OF TORQUE CONVERTER

In the design of an efficient and mechanically satisfactory torque converter, the following considerations are important:

1 It is necessary to prevent the short-circuiting of the fluid between the revolving parts and the casing. This is done by a number of labyrinth seals as shown in Fig. 13.

2 Seals must be provided to prevent loss of fluid. These seals are normally of the axial-sealing type generally using a steel ring against a carbon ring for sealing the surfaces having difference in rotational speed. One of these rings has axial movement by means of a copper bellows or a synthetic-rubber diaphragm.

3 Evacuation of gas from the converter must be provided for. New fluid under certain conditions of circulation and temperature is liable to gasify to a slight degree. To insure the removal of this gas, it is drawn through a small pipe from the top of the converter.

4 It is very necessary, in order to prevent cavitation, that the converter be kept full of fluid under pressure. The automatic replacement of fresh fluid is insured by an injector or mechanically driven pump which draws it from a reserve tank as required and feeds it under pressure to the converter.

5 To provide for a temperature rise in the working fluid which may result from prolonged use of the converter, a small cooler is placed in the fluid circulation. This cooler circuit also includes a filter.

Converter Blading. The major component parts of a modern converter are shown in Fig. 13.

Direct-Drive Type. This type was first developed in Sweden by the Ljungstrom Company and in England by Leyland Motors. By using a double-acting clutch, converter drive or direct drive may be obtained at will. In the latter case the pump impeller is cut out by the clutch and the turbine by means of a free wheel and thus all hydraulic losses are eliminated.

A later variety of this type, fitted with an angle drive, is shown in Fig. 14. This unit was built by the Spicer Company for General Motors Truck & Coach Company's buses. The direct-drive type is also very suitable for rail cars and rail-car trains.

The horsepower of the direct-drive converter varies generally between 100 and 300 hp. Many thousands of buses and several hundreds of rail cars equipped with this converter type are in service in Europe, Africa, Australia, and the Americas.

FIG. 13 MAJOR COMPONENT PARTS OF MODERN CONVERTER

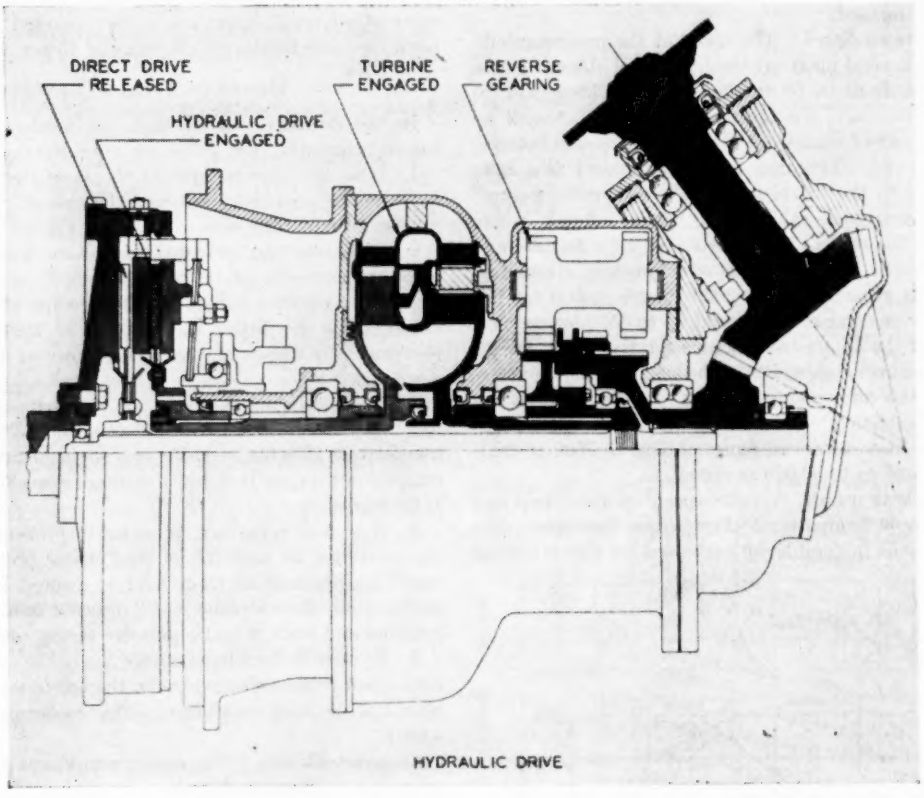

FIG. 14 DIRECT-DRIVE TYPE OF HYDRAULIC TRANSMISSION, FITTED WITH ANGLE GEARING FOR BUS OPERATION

Fixed-Blade Type. This type has been used extensively by the Twin Disc Clutch Company for tractors, for oil-drilling rigs, for logging, for locomotives, and for construction and locomotive cranes. The horsepower generally ranges between 100 and 300 hp.

Adjustable-Blade Type. Fig. 15 shows an installation of a twin-disk adjustable-blade converter for oil-field application.

The largest converter of this type so far has been built for a 1200-hp Diesel-driven locomotive for the Bergen-Oslo Railway in Norway.

New Developments. It is regrettable that, owing to war restrictions, the latest available test data and improvements cannot be included in this paper. It may be said, however, that it seems possible to raise the maximum efficiency as well as widen the range of high efficiency operation considerably.

Discussion

R. EKSERGIAN.[2] The desirable characteristic of any torque converter is a high-efficiency curve through a long speed range. The early Föttinger transformer, when modified to a variable-speed torque converter, had roughly a parabolic efficiency curve, with a decreasing linear output torque against increase of secondary speed. Through his excellent researches, using multistages on the turbine end together with blunt blade sections, the author has greatly improved the efficiency over the entire speed ranges, resulting in a more nearly hyperbolic secondary torque.

It is known in turbine theory that the multistage reaction turbine tends toward increased flow rates at reduced speeds, resulting in increased torque amplification over that of the impulse type with only a single or a few stages. The decreased pressure drop per stage on the turbine end, for a given total head, also results in reduced losses due to the decreased velocities, so that multireaction stages tend toward improved efficiency.

The torque-speed characteristic of a turbine with constant flow rate is approximately linear, decreasing with speed. This implies a parabolic output curve against speed. With improved efficiency, particularly in the speed ranges either above or below the optimum speed at maximum efficiency, the flow rate itself increases, resulting in increased starting torque and an improved efficiency throughout the entire speed range. The effective head is the difference between the impeller head, corresponding to the mechanical input, and the counter head of the turbine, corresponding to the output power. The effective head is balanced by the friction head, corresponding to the shock and friction losses in the circuit. As the secondary speed either decreases below or increases above the rated speed, the turbine-output counter head decreases much more rapidly than the impeller head since the latter operates at more nearly constant speed, and at constant input. At optimum speed, the losses at best are small, and then the impeller head more nearly balances the counter turbine head. At other than optimum speed, particularly at the more extreme over- and under-speeds, if the unbalance effective head is considerable, so that the friction head is small, the flow rate would in-

[2] Chief Consulting Engineer, Edward G. Budd Manufacturing Company, Philadelphia, Pa. Fellow, A.S.M.E.

crease rapidly. Actually, the shock losses increase very rapidly at both lower and overspeeds, thus increasing the friction head and checking the growth of circulation to a much smaller value.

Now the torque on the turbine at any given speed depends upon the change in angular momentum of the fluid per unit time at the several reaction stages and thus directly on the flow rate. Increasing the flow rate therefore increases the torque and output at any given speed. On the other hand, the increase of flow rate results in an increase in torque on the pump impeller, increasing roughly as a quadratic function of the flow rate. But the impeller torque also increases linearly with the speed. For this reason, to maintain constant engine torque and to permit increased flow rate in the starting zone requires a lower pump or engine speed, that is, the primary speed must increase with secondary speed at constant primary torque, as shown in the author's Fig. 8. In some cases it appears that it is not always possible to absorb the full engine output at all turbine-shaft speeds.

In a previous paper, the writer established a compatibility equation $F(Q, \omega_p, \omega_s) = 0$, where Q is the flow rate, ω_p and ω_s are the primary and secondary speeds. This equation was established by expressing the primary torque as a function of the flow rate and primary speed, and the secondary torque as a function of the flow rate and both secondary and primary speeds. On combining with the energy equation of the entire circulating flow and expressing the losses in terms of the flow rate and speeds, the foregoing function was obtained.

Provided the losses can be estimated accurately through proper interpolation of test data, the characteristics of the performance of a torque converter can be arrived at for any given design. For this reason, the author's experimental studies, while interesting for over-all characteristics, would further prove very valuable if the data could be presented in a more detailed form for estimating component losses.

For instance, it would be desirable to express such losses between blade groups in terms of blade angles and relative speeds with different flow rates. It would also be helpful in the present paper to give actual dimensional data of the various proportions of the torque converter in connection with the curves presented.

G. F. Wislicenus.[3] It is a recognized fact that, while there have been various modifications of the original form of the Föttinger transformer, the Lysholm-Smith torque converter represents a significant advance in this field. In view of this situation, the present paper constitutes a valuable contribution to the technical literature on the subject of hydrodynamic transmissions and, as such, might have been presented more fully. It is to be regretted that the paper was not worked out in sufficient detail to offer the reader an adequate introduction into the theory and fundamental characteristics of this type of machinery. There seem to be some omissions in the text which make it difficult to follow the derivations. In order to substantiate this statement, the writer will point out but a few items which he considers to be either incompletely or incorrectly presented.

The difficulties of determining the losses in various parts of hydrodynamic machines are generally recognized. For this reason, it would be most instructive if the method whose results are given in Table 1 could be explained in some detail. It also seems desirable to explain more fully what is meant by "carry-over losses" between the various parts of the machine.

With reference to the following derivations, it is hoped that the author can supplement the paper by a list of notations without which these equations cannot be understood properly. While Equation [1], for instance, is easy to understand with respect to stationary-vane systems, the same equation does not appear to be correct with respect to the moving-vane systems which are in the present case responsible for the greatest part of the head drop through the secondary part of the machine. If, for instance, c and w are interpreted as designating the "relative" velocity, it is seen that what is called the "useful pressure drop" in Equation [1] is actually only the change in "static" pressure in the vane system, always adhering to the author's assumption that this system is considered as one with axial-through-flow direction. The total useful pressure drop in such a vane system, however, differs appreciably from the static pressure drop. In instances under the assumption of a relative entrance angle of 90 deg, measured against the peripheral direction of the system and zero absolute rotation of the fluid at the discharge side, the static head drop without losses is $\frac{u^2}{2g}$ which corresponds to Equation [1], while the total head drop is $\frac{u^2}{g}$, as could be calculated for instance from the equation for H_t, given below Fig. 2 of the paper. It is seen that in this case the total head drop differs from the static head drop by a factor of 2, so that Equation [1] can in general not be used for the total head change in the systems considered. The subsequent derivations, however, seem to indicate that c and w are absolute velocities. Also under the latter assumption, Equation [1] cannot be used for moving-vane systems. For the example just given, the actual head drop through the system would again be twice as great as that given by Equation [1].

Equation [2] for the friction head does not appear justified without further explanations. This equation gives one the impression that the friction losses are calculated as the sum of two friction losses, one being proportional to the velocity head at the entrance and the other to the velocity head at the discharge of the system. If this is true, it is not easy to understand why the same friction factor is applied in both cases. Furthermore, the friction factor must certainly be expected to change over wide limits as the flow conditions vary as a function of the secondary speed, so that the corresponding variations in the total pressure drop cannot even be approximated under the assumption that f is a constant.

From a theoretical point of view, the result that the rate of flow through the transformer reaches a minimum at the point of best efficiency appears to this writer highly improbable, chiefly because of the variations of the primary torque at constant primary speed, as described by the test results given. At constant primary speed, the primary torque appears to fall off as the secondary speed is increased. This fact, in connection with a primary or pump runner of the type used, seems to indicate a reduction in pump capacity. Even if the primary speed is then increased to obtain constant power input (as assumed by the author), the capacity cannot regain its original value, because the primary runner operates at another point of its head-capacity curve than that of best efficiency. In view of this apparent contradiction, it would be highly desirable if the author would give additional information on the method used in determining the rate of flow through the converter by Pitot tube. These test results, if substantiated, would seem to be of far-reaching significance with respect to the theory of this type of machinery.

As indicated in the beginning, the writer believes that most of the foregoing difficulties could be cleared up if the author would have the opportunity to explain his theoretical approach more fully than was apparently possible in this paper. In view of the great interest which exists throughout the industry in this kind of machinery, it is believed that a fuller presentation of the theory would be fully justified.

[Because of wartime conditions, we have been unable to obtain a closure from the author, Mr. Lysholm.—Editor.]

Gas Turbines and Turbosuperchargers

By SANFORD A. MOSS,[1] PH.D., LL.D., WEST LYNN, MASS.

Since his university days, the author has been associated with many of the developments relating to the gas turbine and particularly to the perfection of the airplane-engine turbosupercharger. It is from this intimate and interested viewpoint that he outlines the history of the gas turbine and its potential use as a prime mover. A comprehensive Bibliography of the art of gas-turbine design has been included in the paper to support the author's purpose of outlining the evolution of each component of the modern gas turbine from its earliest inception. United States and foreign gas-turbine research projects are referred to, and then details of advancements in such items as nozzles, compressors, and the like, are discussed. While the gas turbine as a prime mover has not been applied except in isolated cases, such as the Neuchâtel, Switzerland, 4000-kw emergency gas-turbine plant and the Swiss Federal Railway gas-turbine locomotive, partial gas-turbine cycles are in somewhat extensive commercial operation. Examples of these are the Diesel exhaust-gas turbine, the Diesel boiler cycle, the divided-manifold cycle, all of which are mentioned in some detail. The final part of the paper is devoted to consideration of the extremely vital development of the constant-pressure aviation turbosupercharger, which has been brought to its highest state of development by the author's company, in which work the author has taken a leading role, from its inception in the last war down to its present state of extensive application.

PRODUCTION of power by direct action of products of combustion on a turbine wheel has been an engineering dream for a century and a half. A number of approaches to the complete scheme now are in successful commercial operation, and it seems possible that these are paving the way for the long-sought accomplishment of the primary plan of the gas turbine as an efficient prime mover. So it would now seem opportune to give some history and reminiscence (without any thermodynamics), list the partial accomplishments now in commercial use, and speculate on the future. The author can do this from personal association with many of the items ever since he became, in 1895, one of the many who have had dreams in the matter.

This association with gas-turbine developments has occurred during an engineering career which began in San Francisco in 1889, with a machinist apprenticeship, following with work as draftsman, in the shop of Mr. Edward A. Rix (an early master in compressed-air engineering); and continuing as a draftsman in various gas-engine shops. This was before the days of electric transmission and there were several plans of compressed-air power and transmission in successful operation. One was use by Mr. Rix of the early impulse water wheel of Pelton to drive an air compressor, with a transmission pipe line some miles long, and then a reciprocating hoisting engine using the transmitted air after it had been reheated by coal or coke so as to increase its volume (1).[2] So this really was a combustion heat-engine cycle. Its thermodynamics, which is that of the "Brayton constant-pressure cycle," is an early item of the present subject. Mr. Rix and his associates also had a street railway in New York City operating on compressed air stored in steel cylinders. But the author remembers how these and similar schemes soon were replaced by the early electric transmissions.

Gas-Turbine Proposals

Beginning about 1889 both the steam turbine and the internal-combustion reciprocating engine began the competition which finally resulted in the elimination of the reciprocating steam engine as a prime mover, except for the steam locomotive, and some ship installations.

Ever since the beginning of this period it keeps occurring independently to students of thermodynamics that the steam turbine and internal-combustion engine might be combined, and so they "invent" the gas turbine. The usual form of this, shown in Fig. 1, has a chamber into which is forced compressed air and fuel, usually oil, so as to give combustion under pressure. The products pass through a nozzle so as to drive a turbine wheel, part of whose power drives the combustion-chamber compressor, and the remainder (if any) is the net power derived from the fuel burned.

The author was one of the many of these "inventors," while a student in the classes in thermodynamics and hydrodynamics of Prof. Frederick G. Hesse at the University of California in 1895. Since then, the author's engineering career, now drawing to a close, always has been directed toward the gas turbine. He also has tried to keep posted on the numerous advances in other fields which could help the gas turbine, as well as on the many gas-turbine publications, some of which are given in the references.

Like most of the other inventors, the author at first thought he was alone in the gas-turbine field. In 1900 an account was written as a Master's thesis (2) and filed in the University of California Library, which gives early proposals of some details.

Associated with Mr. Rix and the compressed-air street railway in New York City was a Chicago firm, "The Vimotum Company," engaged in promoting operation of railway cars by internal combustion. The author participated during 1898-1899 in the actual operation on the "Big 4" railway tracks between Columbus, Ind., and Indianapolis, Ind., and later on the Pennsylvania Railroad tracks between Chester and Darby, Pa., of full-sized railway passenger cars, self-propelled by gasoline engines, using the "variable-speed transmission" of the Reeves Pulley Company of Columbus, Ind. This probably was the predecessor of all modern internal-combustion locomotives. Plans were formulated in 1898 for replacing the gasoline engine by a gas turbine as was set forth in the Master's thesis (2) cited. This is the earliest proposal that the author knows of for a gas-turbine

[1] Consulting Engineer, Supercharger Engineering Division, General Electric Company. Fellow A.S.M.E.

Contributed by the Aviation Division and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[2] Numbers in parentheses are references contained in the Bibliography at the end of the paper. An attempt is made in the figures herein and the references to give the first published proposal of each item. Of course, this cannot be done with certainty, but at any rate the figures and references give early if not the original proposals. The author would appreciate references to earlier proposals of any items.

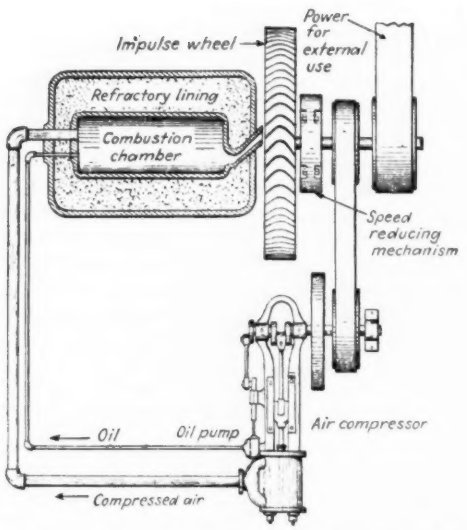

FIG. 1 DIAGRAMMATIC PLAN OF FUNDAMENTAL GAS TURBINE
Reproduced from the Doctor's Thesis, Ref. 9, of 1903. This diagram does not include "Heat Interchanger," of the Theses, Refs. 2, 9.)

locomotive. But the proposition never came to a head, which was just as well, because then it never could have been made operative.

During the planning for this proposed gas-turbine locomotive, patent searches were made, and unexpectedly there was found a British patent of November 30, 1791, to John Barber (3), giving probably for the first time the fundamental gas-turbine plan. There was a combustion chamber into which fuel and air were introduced, with a nozzle from which the products of combustion issued onto a turbine wheel. This supplied power to drive the compressor, as well as external power.

An early diagram of Barber's cycle is given in Fig. 1, from the Thesis (9). Many gas turbines proposed since differ in plan only by the addition of a heat interchanger for transferring the heat of the exhaust gases to the compressed air proceeding to the combustion chamber. An early mention of this is in the Doctor's Thesis (9) and an experimental model of 1905 is shown in Fig. 4. It is not probable that the apparatus shown in Barber's British patent ever was operated.

Davey (8) lists some partial approaches to the gas turbine and gives a list of British patents beginning in 1856. The earliest complete United States gas-turbine patent of which the author has personal knowledge is to Charles G. Curtis, June 24, 1895 (4). Mr. Curtis had extensive connections with regard to steam turbines, with the General Electric Company. The author has some knowledge of these, but none of any actual work on gas turbines by Mr. Curtis.

At this same time was a United States Patent to Læon LePontois (5) filed December 5, 1895, on an explosion combustion chamber for a gas turbine. This was the subject of a Doctor's Thesis at Cornell University by Walter O. Amsler in 1897 (6). Actual tests were made of LePontois' explosion apparatus, as well as a theoretical study, with unfavorable conclusions.

UNITED STATES GAS-TURBINE RESEARCH

The author always has had in mind continuous combustion, and after the gas-turbine-locomotive scheme, proposed in 1898, came to naught, he started gas-turbine research in 1901 in the Sibley College Laboratory, Cornell University. Laboratory time for a year was required to get a continuous-combustion chamber in stable operation. It frequently went out and then the oil on the red-hot firebrick lining filled the neighborhood with dense black smoke, so the Sibley College people well knew of the gas-turbine research.

The first De Laval steam turbine in the United States, Fig. 2, which had been exhibited at the World's Fair in Chicago in 1893, was used for the De Laval nozzle-patent demonstration mentioned

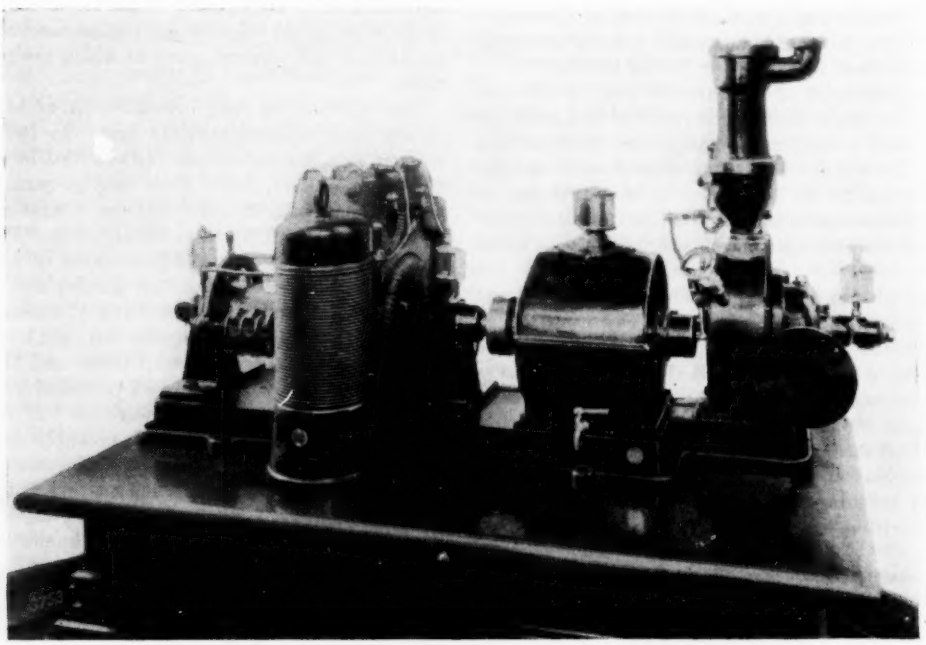

FIG. 2 FIRST DE LAVAL STEAM TURBINE IN THE UNITED STATES, 1893
(Exhibited in the Chicago World's Fair and then sent to Sibley College, Cornell University. The wheel of this turbine was used in 1902 in the gas-turbine research of the Doctor's Thesis, Ref. 9, and was the first turbine operated on products of combustion in the United States and possibly the first anywhere. Reproduced from De Laval pamphlet of Ref. 10.)

FIG. 3 COMBUSTION CHAMBER OF GENERAL ELECTRIC GAS-TURBINE RESEARCH, 1903

(This was made spherical to give minimum radiating surface. This research started in Schenectady in 1903 and was transferred to Factory K, General Electric Company, West Lynn Works, in 1904.)

later (10), and then went to Cornell. So the bucket wheel of this turbine was borrowed and operated with the combustion chamber, about the end of 1902. This probably was the first turbine wheel actually operated by products of combustion in the United States, and possibly was the first such turbine wheel ever operated. The entire power was absorbed by a prony brake, and the air for compression was furnished by a steam compressor, with computation of the power required.

But, as with many other experimental gas turbines, the power for compression was more than the turbine power. So except for the historical fact that the combustion chamber actually operated the turbine wheel, the experiment was a flat failure. A Doctor's Thesis (9) was prepared and presented to Charles P. Steinmetz and Ernest J. Berg of the General Electric Company. The author previously had been a draftsman on steam-turbine work with General Electric. In June, 1903, the connection was resumed and has continued ever since, with work on various items more or less connected with gas turbines.

A number of General Electric models of gas turbines successively were gotten into operation, first at Schenectady, and beginning in 1904 at Lynn, with consultation with Prof. Elihu Thomson and Richard H. Rice. There were combustion chamber, heat interchanger, nozzle, and single-stage impulse turbine wheel; but with power for compression from an independent air compressor and allowed for by computations. Some U. S. patents were obtained during this research (9½). Figs. 3, 4, and 5, respectively, show the combustion chamber, heat interchanger, and nozzle jet of 1903 and 1905. The results of this research will be given later in the paper. The patent drawings (9½) show fairly well the actual apparatus that was used.

FOREIGN GAS-TURBINE RESEARCH

A gas-turbine patent was applied for by Charles Lemale (8) about 1901 and he began association with Réné Armengaud in 1903 in actual operation in France of a continuous-combustion gas turbine (8, 21). This probably was the earliest elaborate gas-turbine experimental work. From then on, there have been many proposals and tests of various sorts of gas turbines.

Numerous publications have been made, a few of which are given herewith, i.e., references, (4, 5, 6, 7, 8, 12, 13, 21, 22, 23, 24, 25, 26, 27). Others are in the Engineering Index Annual and in references (7, 8). Some of these operate with a hydraulic column; operate below atmospheric pressure; have cooling by water injection; have hollow turbine buckets with cooling; have cooling by air excess; use pulverized coal; use reheating combustion; or have cooled compressors. But most of these have not led to any conclusive results. The cycle now receiving the most attention is that of Fig. 1 with the addition of the heat interchanger of the previously mentioned theses (2, 9).

NOZZLES FOR STEAM AND GAS TURBINES

Beginning about 1885 there were many arguments concerning the power that could be obtained by expansion in a nozzle of a jet

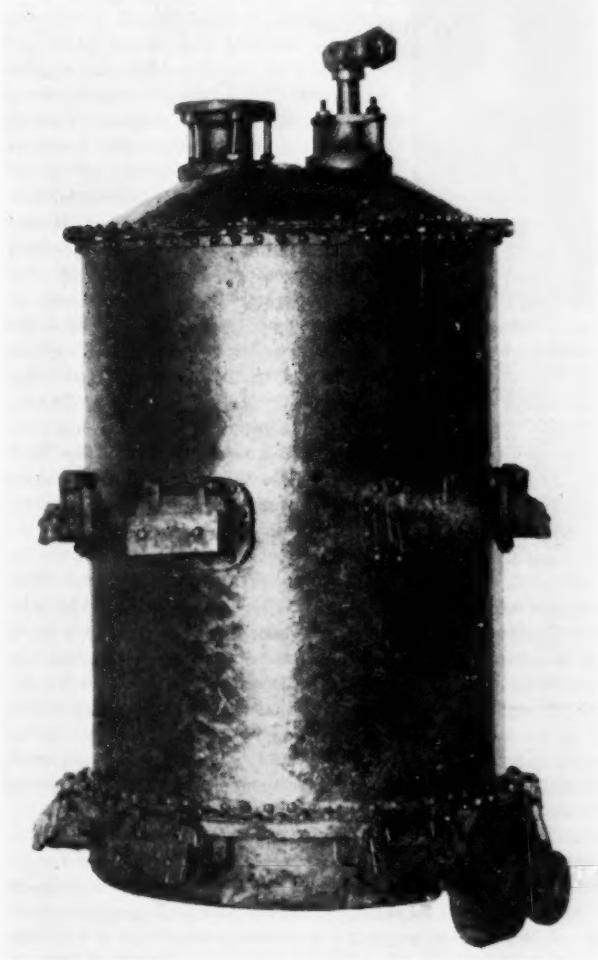

FIG. 4 HEAT INTERCHANGER OF GENERAL ELECTRIC GAS-TURBINE RESEARCH, 1905

(The air from the compressor passed through some tubular coils on its way to the combustion chamber. The turbine exhaust gases circulated outside of these coils.)

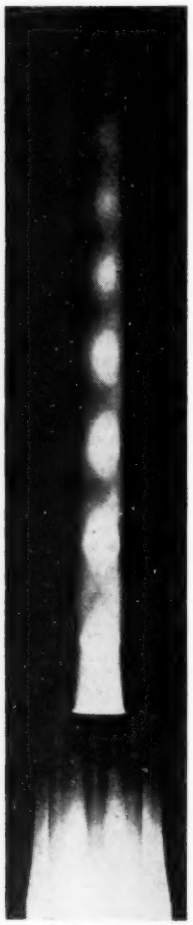

FIG. 5 NOZZLE JET OF GENERAL ELECTRIC GAS-TURBINE RESEARCH, 1905

(Curious white-hot nodes appeared in this jet of products of combustion, being of one type when the mouth of the convergent-divergent nozzle was too small for the pressure ratio; of another type when it was too large, and vanishing between when it was about the right size. Similar nodes later have been observed with steam nozzles.)

directed on a turbine wheel. Napier had shown experimentally that when steam was discharged from an opening in a vessel into a region of lower pressure, the flow increased as the pressure in the outer region decreased, until the outer pressure became about one half of the pressure in the vessel. For lower values of the outer pressure there was no increase in flow. Therefore, it was argued that full theoretical velocity of a steam-nozzle jet could not be obtained when the pressure ratio was less than 0.5. It seemed reasonable to assume that the theoretical power from a steam-turbine wheel was the same as from a reciprocating steam engine, for pressure ratios between 1.0 and 0.5. But Napier's law meant that for pressure ratios less than 0.5, a steam turbine would not theoretically give the same power as a steam engine.

Carl Gustaf Patrick De Laval was building single-stage steam turbines in Sweden with steam pressures of 115 psia or so, exhausting into atmospheric pressure of about 15 psi. He said he was avoiding the disability of Napier's law by using a nozzle first convergent and then divergent, popularly called an "expanding nozzle" because of the final divergent portion. De Laval tried to get a United States patent on this shape, and the official file shows that Napier's law was cited against him, with the support of scientific experts, including Gustave Zeuner, the famous German engineer. Finally, De Laval with his 1893 Chicago World's Fair turbine of Fig. 2 gave an actual demonstration that he was right (10).

The theoretical reasons for a nozzle first convergent and then divergent already had been given by Osborne Reynolds (11), with the first diagram of such a nozzle, reproduced as Fig. 6. But this was buried in a philosophical magazine and does not seem to have been appreciated by engineers. At a much later date it began to be understood that the theoretical available energy for a steam turbine with proper nozzles is the same as for the corresponding reciprocating engine. But there was a period within the memory of the author when engineering ignorance in this matter held back steam-turbine development.

Next it was argued (12, 13) that, while proper power could be developed by use of a steam nozzle, it was because of proximity of the fluid to condensation. But, so it was said, circumstances differed with gases far removed from condensation, such as products of combustion, so that a gas-turbine nozzle never could be efficient. Experimental measurements were published (12) of temperatures measured along a nozzle producing a jet of a nearly perfect gas, showing that the temperature did not fall with lowering of pressure as was predicted by the formulas for isentropic expansion. It was pointed out that with an expanding gas, mechanical energy only could be developed by conversion of internal energy, as manifested by temperature drop. Thus it was argued that proper conversion of pressure drop into velocity could not be accomplished by a gas-turbine nozzle.

To give further support to this contention, a test was published (13) in which a De Laval single-stage turbine was operated at full speed with compressed air. To avoid complication, no power was abstracted from the turbine shaft. There was measurement of temperature in the pipe preceding the nozzle, and in the exhaust pipe. The pressures in the inlet pipe varied in different tests from about 12 to 123 psi, with atmospheric pressure in the exhaust pipe. But in spite of these pressure drops, which corresponded to appreciable drops of isentropic temperature, the temperatures in the exhaust pipe always were nearly the same as in the inlet pipe. Since compressed air within the pressure limits used is nearly a perfect gas, the equality of temperature showed that in spite of passage through the nozzle no internal energy had been abstracted corresponding to an isentropic drop of temperature. Thus a nearly perfect gas such as air or products of combustion would not liberate its energy by isentropic drop in a turbine nozzle, and so a gas-turbine could not be efficient.

This experiment was published in all seriousness as a demonstration of the point made. But if a student of engineering has not by now detected the fallacy, he has fallen into a trap which often before has been set by the author for the unwary thermodynamist. As was mentioned with planned casualness, no energy was abstracted from the turbine shaft, so that all of the kinetic energy of the jet, which no doubt was nearly the theoretical isentropic value, was converted into heat by turbine-bucket and rotation-loss friction. With the nearly perfect gas used, this restored the original temperature, as could be expected.

The temperature-measurement experiment (12) was equally fallacious. The jet flowing along the nozzle no doubt had the full isentropic velocity and low temperature at each point corresponding to the pressure drop. But the temperature-measureing apparatus destroyed this velocity, converting it into heat, and so, with a perfect gas, restoring the initial temperature.

The theory of this, possibly for the first time, was published in

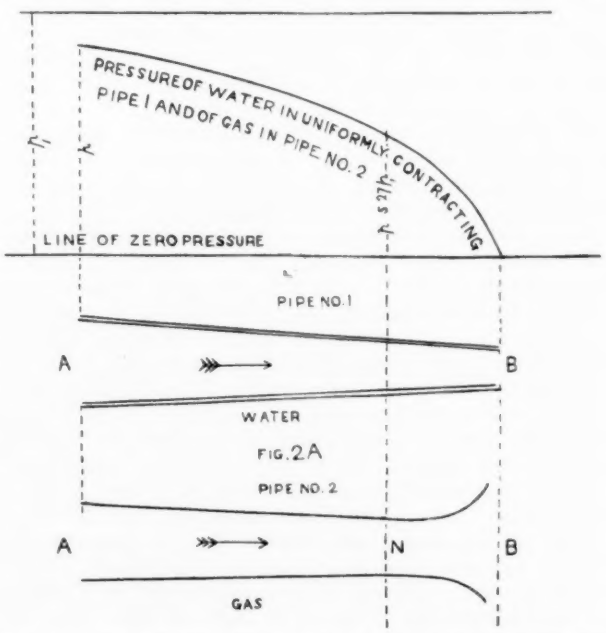

FIG. 6 FIRST PROPOSAL FOR A NOZZLE FOR ELASTIC FLUID TURBINES, WHICH WAS FIRST CONVERGENT AND THEN DIVERGENT (Reproduction of Fig. 2A of the 1885 paper of Osborne Reynolds, Ref. 11.)

1916 (14). This paper describes an experiment made by the author about 1905. Steam, initially slightly wet, and at an appreciable pressure, was discharged into the atmosphere through a properly shaped nozzle. As is well known, the initially wet steam became wetter as it expanded to atmospheric pressure, and so the jet leaving the nozzle had the "static" temperature of wet steam at atmospheric pressure, which is 212 F. But a thermometer inserted in the nozzle jet showed a much higher temperature, the result of conversion of some of the jet velocity into heat. Complete conversion would give a temperature called "impact temperature" in the 1916 reference (14), but now beginning to be called "total temperature." The situation nowadays is fairly well understood (14½), and it seems to be remembered that it was explained in the 1916 publication (14) of the 1905 experiment.

But although the fallacies of the two publications mentioned (12, 13) are very evident now, and cannot be cited against the ultimate success of the gas turbine, and were partially refuted at the time (12, 13), they were disturbing factors during the General Electric gas-turbine research and had to be argued against.

Compressors for Gas Turbines

A part of a gas-turbine plant is an air compressor to force air into the combustion chamber, which must be driven by part of the power from the turbine wheel. In the fall of 1903, the General Electric gas-turbine research began to include development of a "centrifugal compressor," with rotative speed suitable for direct connection to the gas-turbine wheel. High-speed wheels previously had been proposed for air compression (15, 16), with some sort of "reversed nozzle," since called a "diffuser," for converting into pressure the absolute velocity of air leaving the wheel periphery. Such diffusers had begun to be used for incompressible fluids. They probably first had been used in 1895 in a centrifugal pump of the famous English scientist Osborne Reynolds (17), which is shown in Fig. 7.

But De Laval's plan of a turbine nozzle, first convergent and then divergent, for a compressible fluid, now was firmly fixed. With this was the idea that a "reversed nozzle" for converting velocity into pressure with a compressible fluid such as air always should be the reverse of the De Laval expanding nozzle. Therefore the foregoing compressor references (15, 16) show such passages beyond the high-speed wheels, with the minimum section or throat of De Laval, and speak of "throat conversions of velocity into pressure." The famous French engineer August Rateau was working on high-speed centrifugal air compressors about this time (18), but the author never has been able to find out if he then used diffusers, and if so what his early ideas were about their shape. Rateau supplied centrifugal compressors for the Armengaud-Lamale gas-turbine work (7, 8, 18, 21).

In a patent applied for in 1904 (19), it was set forth correctly, probably for the first time, that with velocities below the velocity of sound, in the case of a diffuser for a compressible fluid, the velocity changes are the major items, so that passage areas change inversely as velocities, just as with an incompressible fluid. But with velocities greater than the velocity of sound, the change of volume with a compressible fluid, due to change of pressure, is the major item, so that increase of velocity in a nozzle requires increase of area, and decrease of velocity in a diffuser requires decrease of area. So with a centrifugal air compressor with impeller exit velocity less than the velocity of sound, the diffuser must be divergent, just as with a centrifugal pump. But for velocities greater than the velocity of sound, the theoretical diffuser first is convergent, has a throat, and then is divergent. All of this now is elementary knowledge, but in 1904 it was not evident.

The velocities of the General Electric centrifugal compressor for the proposed gas turbine always were such as to require theoretically a divergent diffuser, and development work on this basis was begun in 1904 under the supervision of Richard H. Rice, with the collaboration of the author and other General Electric engineers. When the primary gas-turbine research ceased in 1907, the centrifugal compressor had developed so that it became a commercial product of itself. One early result was the use of centrifugal compressors for blast furnaces for production of pig iron (20). This met early opposition from advocates of reciprocating "blowing tubs," and it was alleged that a centrifugal compressor, operated by a flow-metering device to deliver a constant weight flow of air, nevertheless was subject to a process called "churning" whereby the impellers would rotate without delivering any air, in spite of the indication of the flow meters. This was shown to be a fallacy. Also it was shown (20) that even though internal-combustion engines operated by blast-furnace gas might have somewhat better thermal efficiency, the small fixed and maintenance charges of the centrifugal compressor gave lower total cost of blast-furnace operation.

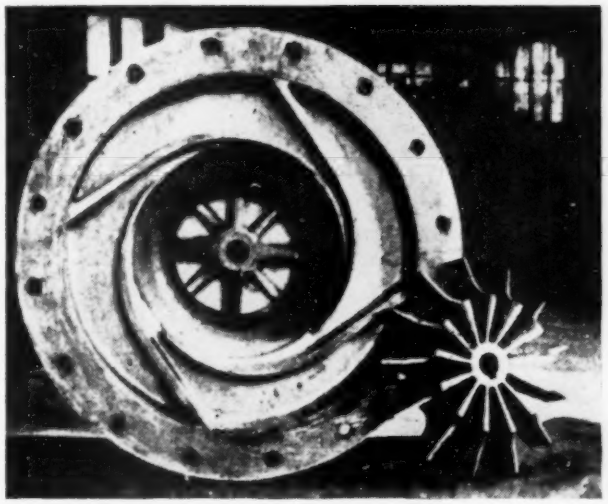

Fig. 7 First (or Very Early) Fluid Pump With Impeller Having Axial-Flow Inlet and Radial Vanes at Exit, and Diffuser for Converting Into Pressure the Impeller Exit Absolute Velocity

(Mather-Reynolds pump of 1895 from Ref. 17, p. 112.)

Rateau did some early centrifugal-compressor work already mentioned, a great deal of it for gas turbines (7, 8, 18, 21). Some work probably also was done elsewhere in Europe. The Ingersoll-Rand Company has continued the development in the United States. As one result, centrifugal compressors, started in the United States as a gas-turbine by-product, now are almost exclusively used throughout the world for blast-furnace blowing, as well as for many other purposes.

As another part of the General Electric development, geared centrifugal superchargers for United States aviation engines began about 1925 and now are in enormous production (28), using impellers based on the original Osborne Reynolds design (17), Fig. 7. But in spite of the fact that some of this centrifugal-compressor development was inspired by the gas turbine, there is present evidence that the centrifugal compressor may be exceeded in efficiency by a comparatively recent competitor, the "axial-flow blower." If so, this blower will be the one used in the ultimate gas turbine. These blowers are used in the Neuchatel gas-turbine power plant (34) and Swiss gas-turbine locomotive (35). But on the other hand they have a shorter operating range and many more stages than the centrifugal compressor, and progress is being made in improvement in effi-

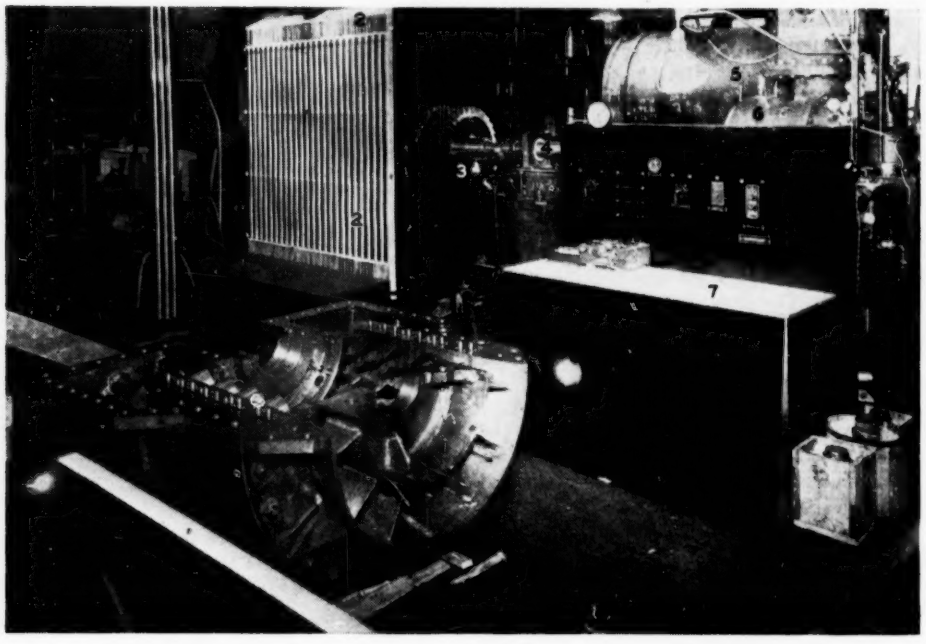

FIG. 8 GAS-TURBINE LABORATORY NOW IN OPERATION IN THE UNITED STATES

ciency of the latter. However, this is a matter for the future and cannot be settled here. At any rate, the gas turbine had its part in introducing centrifugal compressors for blast furnaces, many industrial purposes, and present geared and turbosuperchargers.

UNITED STATES GAS-TURBINE RESEARCH CONTINUED

The General Electric gas-turbine work, previously mentioned as beginning in June, 1903, continued until about 1907. At first the power for compression consumed all of the turbine power. Some approximate figures will show why. Suppose a gas-turbine wheel theoretically delivered 100 hp, and suppose the compressor theoretically required 49 hp. Then there would be theoretically 51 net hp. But the turbine wheel might have an efficiency of 70 per cent so that it actually would deliver 70 hp; and the compressor might have an efficiency of 70 per cent, so the net horsepower would come out $100 \times 0.70 - 49/0.70$. Before the reader is cruel enough to laugh at this result, let him put himself in the place of lots of us gas-turbine inventors who have sweated blood through years of research only to come out this way or worse. The reason is that with the 51 theoretical hp net, we have apparatus of 149 theoretical hp, with consequent losses, instead of the losses directly corresponding to 51 hp. A reciprocating internal-combustion engine deducts the power for compression from the gross power, before any power is delivered, and so the losses are based upon the net power output rather than upon the sum of powers of compression and expansion.

This paper purports to give items other than the vast number of gas-turbine thermodynamic computations which have been published by many persons, the author among them. But a simple approximate computation can be made which will show the other side of the foregoing picture of a gas turbine with a zero net power. This is on the basis that the products of combustion act as a perfect gas and have mass and properties of the same nature as those of the original air for combustion. Suppose the initial pressure for the compressor and the exhaust pressure of the turbine is 14.7 psia and suppose the final pressure of the compressor and the nozzle inlet pressure of the turbine is 49 psig or 63.7 psia. With such equality of initial and final pressures for turbine and compressor, the ratio of the theoretical power from the turbine to the theoretical power required for the compressor is equal to the ratio of the absolute temperature at nozzle inlet to the theoretical absolute temperature at the end of isentropic air compression.

A test of the Neuchatel gas turbine is cited later (34), and its figures should be before every gas-turbine student. The ratio of the theoretical powers in test No. 2 is 1.83 and the ratio of the absolute temperatures is 1.82 which shows the character of the approximation here being made. With 70 F inlet temperature the compressor isentropic final temperature is 802 F abs. Suppose the temperature at the turbine nozzle inlet is 1946 F. This is a high temperature, but within the bounds of possibility. The absolute temperature at the nozzle inlet then is 2406 F. The ratio of absolute temperatures, which is approximately the ratio of the theoretical powers, then is 3, that is, the theoretical power for the compressor is 33 per cent of the theoretical turbine power.

Using the efficiencies of the Neuchatel gas-turbine test (34), the compressor efficiency is about 85 per cent, so the actual power for the compressor is 0.33/0.85 or 39 per cent of the theoretical turbine power. With 88 per cent efficiency of the turbine, the actual power from the turbine is 88 per cent of the turbine theoretical power. That is to say, the net power is (0.88—0.39)/0.88 or 55 per cent of the turbine actual power. This figure is far beyond the 1907 possibility and is on the basis of all of the progress since that date, and then some. The Neuchatel gas-turbine test has a turbine temperature of about 1000 F, much lower than the 1946 F previously assumed, so that the net power only is about 27 per cent of the actual turbine power. But while in 1907 we hoped for everything that since has been shown by the Neuchatel test, the turbosupercharger, and all the other progress, the actual reality was far different.

So the General Electric gas-turbine research continued until a fuel consumption was in sight, of 4 lb of kerosene per net hphr. At that time good oil engines were using 1 lb of oil per net hphr. Even though it seemed certain that the clouds cast upon the operation of a gas-turbine nozzle (12, 13) had no basis in fact, it was thought desirable to measure actual spouting velocity of products of combustion. So the combustion chamber was flexibly mounted and nozzle reaction measured.

The work was difficult to conduct with accuracy, but enough was done to indicate that the only corrections needed were to take account of departures from the perfect gas laws of the products of combustion. Similar nozzle-reaction experiments later were conducted by Mr. Glenn B. Warren (30) with similar results. Recently, Dr. Chester W. Smith and other General Electric engineers have worked on tables of available energy of products of combustion for turbosuperchargers, with exact values of specific heat. But probably more work needs to be done to get exact available energies for gas turbines.

All early General Electric gas-turbine work was conducted with temperatures possible with materials then known, and no vision was had of the possibilities which the turbosupercharger work to be described later has developed. So the temperatures were kept low by air excess or water injection, both resulting in inefficiencies. No way then seemed open to do better, and so the gas-turbine part of the research was postponed, but with vigorous commercial work on centrifugal compressors, as already mentioned.

Among the many persons who long have had gas-turbine ideas are two with whom the author has had the pleasure of personal acquaintance, and who have made some publication, Dr. Harvey N. Davis (29), president of Stevens Institute of Technology, and Mr. Glenn B. Warren (30), designing engineer of the Steam Turbine Division of the General Electric Company.

Explosive and Continuous Combustion

The gas turbine had been expected to replace the reciprocating internal-combustion engine, and so there was an early idea that it was essential gas-turbine combustion should be similar. This led to a number of proposals for explosion gas turbines, as in the case of LePontois (5, 6) already cited. A German engineer, Hans Holzwarth, has made extensive publications on such apparatus through many years. But there seems doubt as to whether he ever reported performance of a complete machine which compressed its own air (27).

Opposed to these explosion gas turbines are those based on continuous combustion under pressure. The possibility of efficient operation once was doubted. Since then many continuous combustion chambers have been operated with complete success, so demonstration on this point no longer is needed.

An original, or at least an early continuous-combustion chamber, was that of the Doctor's Thesis (9). Such combustion in a chamber at a pressure of any amount above atmospheric proceeds exactly as it does in the open combustion chamber of a steam boiler, where the absolute pressure is about 14.7 psi; and the same heat of combustion is liberated. Because of constancy of conditions, the nozzle-spouting velocity is constant, which is a necessary condition for efficient operation of a turbine. On the other hand an explosion combustion chamber delivers a jet with variable velocity, which only can be proper for the turbine speed during a fraction of the time and so results in inefficiency. At any rate modern gas turbines are wholly on the continuous-combustion basis, and explosion outfits are not now attracting any attention.

Gas-Turbine Prime Movers

Thus the gas-turbine idea has been kept alive through many years, with some partial approaches, as will be discussed later, but always with the hope among enthusiasts that someday it will compete with such high-efficiency prime movers as the modern steam central station or the internal-combustion reciprocating engine. Prof. Lionel S. Marks, now professor emeritus of the Graduate School of Engineering of Harvard University, long has been a gas-turbine student (31), and on December 14, 1939, he gave a lecture (32) which presented a realistic view of immediate gas-turbine prime-mover probabilities. He pointed out that the successful use of the temperatures necessary to give high efficiency might be far off, but that there were many immediate prospects with lower temperatures. Among these were locomotives to compete with the modern steam locomotives of moderate efficiencies, plants where water is scarce, and stand-by plants where low first costs would give total charges competing with more efficient but expensive units. Similar ideas were expressed by Dr. Adolphe Meyer of Brown, Boveri & Company (33), in a paper which mentioned the starting in the Brown-Boveri shops of the Neuchatel 4000-kw gas turbine (34) and the Swiss Federal Railway gas-turbine locomotive (35), whose completion is described next.

The town of Neuchâtel, Switzerland, arranged for an emergency power plant, in a bombproof place, as a war protection, and a 4000-kw gas-turbine plant was constructed. An efficiency test of this in actual operation was published by the famous Swiss turbine authority, then in his old age, Dr. A. Stodola, and seems to be a worth-while operation of a gas-turbine prime mover (34).

Recently actual test results have been published of the gas-turbine locomotive mentioned by Dr. Meyer as being constructed by Brown-Boveri for the Swiss Federal Railway (35), which seems ready for actual use. This is another operation of the sort of gas-turbine prime mover which has been sought through many years. Both of these gas-turbine prime movers are of the sort that Professor Marks and Dr. Meyer mention, where useful purposes are served by temperatures of about 1000 F. But like the other cycles here mentioned, they pave the way for such higher temperatures as will make high gas-turbine efficiency a primary object. Admiral Mills recently has mentioned development by the United States Navy of gas turbines for ship propulsion (35½). Fig. 8 shows part of the laboratory in which gas-turbine research now is being conducted in the United States.

Partial Gas-Turbine Cycles

There are some gas turbines in extensive commercial operation, but not as complete prime movers. An early one is the gas turbine in extensive use by Brown, Boveri & Company and others, to supply compressed air to the supercharged combustion chambers of the steam boilers for the Brown Boveri Velox System (36) and other similar systems.

Many partial gas-turbine cycles have been in successful operation for years, for oil refineries, built by the Allis-Chalmers Company (37), which has some connection with Brown-Boveri. Outfits of a similar sort have been constructed or planned by the General Electric Company (38) and others. Fig. 9 shows an example.

All of the foregoing outfits are planned for the comparatively moderate temperature of about 1000 F. They use gases produced in the course of chemical and combustion operations, and drive air compressors. They do not have the obligation imposed on a gas-turbine prime mover, which has to produce net power as well as to compress the air which produces by combustion or otherwise the fluid which drives the turbine. But they are definite steps in gas-turbine progress.

In the meantime, temperatures used in steam turbines have been rising, and many are operating at temperatures around 900 to 1000 F and show present general use of such temperatures (39). But to a "red-hot" enthusiast who lathers himself into a white heat in trying to get white-hot gas turbines, a mere 900 F is almost a refrigerator temperature. But it is a step on the way.

Reciprocating Engines Exhausting Into Gas Turbines

A gas-turbine enthusiast dreams of complete prime movers such as the Neuchatel power plant (34) and the gas-turbine

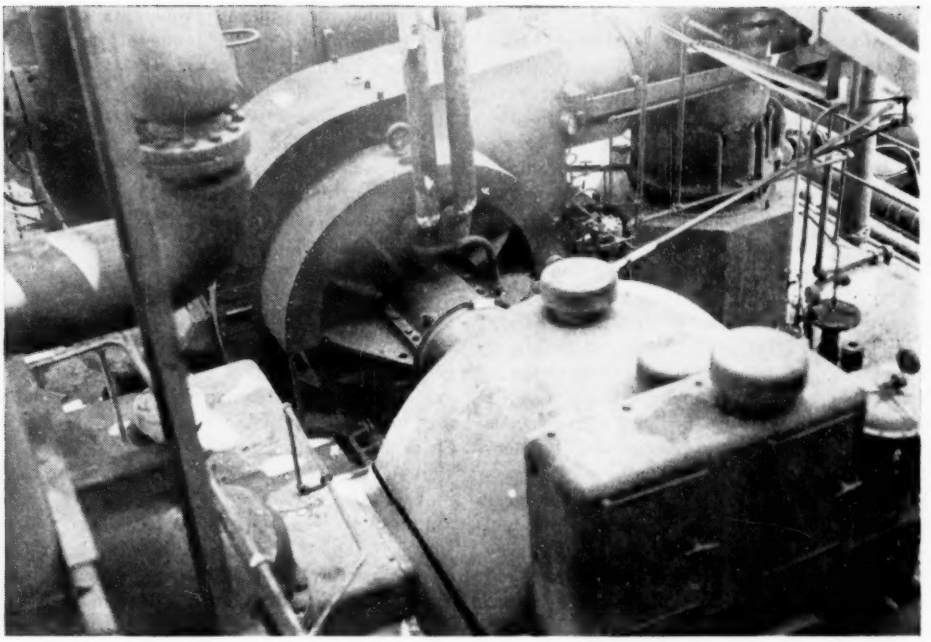

FIG. 9 GAS TURBINE OPERATING ON PRODUCTS OF COMBUSTION AT ABOUT 1000 F, AT UNION OIL COMPANY, OLEUM, CALIF. (Manufactured by General Electric Company.)

locomotive (35), but with such temperatures as will give efficiencies competitive with any other cycles. However, there are those who argue that for moderate powers, the upper part of the high-temperature range which is necessary for high prime-mover efficiencies, can best be handled in a reciprocating engine, with the gas turbine to take the gases at a reduced temperature and carry the expansion to the limit. But whether or not this is going to be the ultimate is a question. There are three sorts of such cycles in present use where reciprocating internal-combustion engines exhaust into gas turbines. These may be called (*a*) Diesel-boiler or Götaverken-Sulzer cycle, (*b*) Büchi divided-manifold cycle, and (*c*) constant-pressure-turbosupercharger cycle; and will be discussed in this order.

(*a*) *Diesel-Boiler Cycle.* An early system was proposed by the engineer Johannsen (40) of Götaverken, a prominent shipbuilding concern of Gothenburg, Sweden, of which Mr. Hugo Heyman has been managing-director. A two-cycle Diesel engine exhausts at the high back pressure of about 4 atm and drives only its scavenging reciprocating air compressor, which is mounted on its crankshaft. The exhaust, cooled by a large amount of scavenging air, proceeds to the turbine, all of whose power is net. Sulzer Brothers, Ltd., of Winterthur, Switzerland, has been working on various modifications of the same general plan (41), as shown in Fig. 10. Free pistons also have been used.

(*b*) *Divided-Manifold Cycle.* Dr. Alfred Büchi of Winterthur, Switzerland, long has worked on turbosuperchargers and, as discussed next (43), made a very early proposal for the modern type with constant pressure, since used by others. Büchi and his associates, Brown, Boveri & Company, also have used what may be called a divided manifold (42). This has a Diesel engine with the usual sort of turbosupercharger, next discussed, except that nozzle-box sections and exhaust-manifold passages are divided so that a given exhaust passage into which exhaust is proceeding from one cylinder is never connected to another cylinder which is at the end of exhaust and beginning of intake. Büchi says there never can be "blowback" of exhaust gas into the intake manifold during the overlap period when both exhaust and intake valves of a cylinder are open at the same time. This cycle also has been used by Rateau.

In most cases, the cycle is used with Diesel engines having low exhaust temperatures and low speeds, as compared with aviation engines. The divided-manifold sections are of such reduced area as to avoid sudden drop of exhaust pressure. Furthermore, each cylinder exhausts by itself until its exhaust pressure dies out.

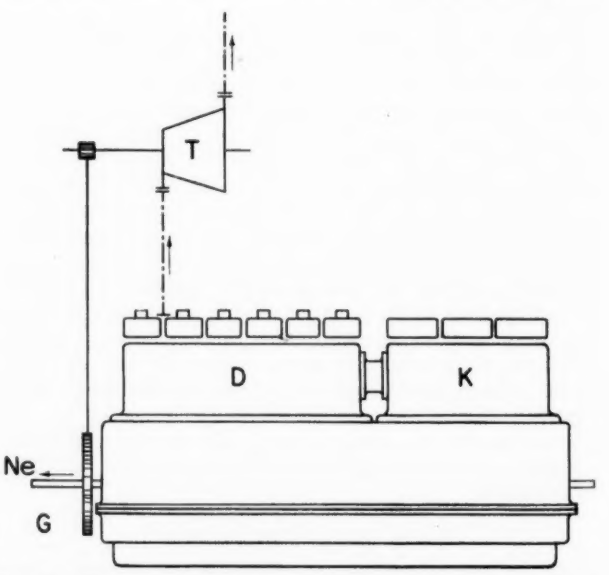

FIG. 10 HIGHLY SUPERCHARGED TWO-STROKE DIESEL ENGINE, WITH DIRECT-COUPLED RECIPROCATING COMPRESSOR AND MECHANICAL TRANSMISSION BETWEEN EXHAUST-GAS TURBINE AND DIESEL ENGINE

(The exhaust-gas turbine is coupled by gearing, represented diagrammatically as chain gear, to the crankshaft of the two-stroke engine; Ref. 41.)

D Two-stroke Diesel engine
K Compressor
T Exhaust-gas turbine
G Gear between Diesel engine and exhaust-gas turbine
Ne Effective output at the shaft

So there is a variable nozzle-spouting velocity, which does not match the turbine-wheel speed during the entire time and thus causes a loss. The system of interlocking sections of the exhaust manifold connected to the different cylinders causes appreciable complexity.

With a turbosupercharger system of such efficiency that the intake-manifold pressure is nearly equal to or less than the exhaust-manifold pressure, the divided-manifold-system advocates say that it avoids "blowback" and gives scavenging instead, and so maintains full engine power. But with the aviation turbosuperchargers next discussed, the efficiency is such that the intake-manifold pressure is higher than the exhaust-manifold pressure, and so there is proper scavenging with the constant-pressure-turbosupercharger cycle.

History of Aviation Turbosuperchargers

The constant-pressure-turbosupercharger cycle first began practical use with high-altitude aviation. The constant pressure started as that of sea-level atmosphere, 30 in. of mercury abs, and the expansion and compression are to and from the low pressure of altitude atmosphere. The part of this aviation turbosupercharger in the gas-turbine picture will be begun with its history, by taking a flashback to World War I. Military aviation was in its infancy, but already there was difficulty in the loss of engine power even at the moderate altitudes then possible. Hence efforts were made to attach, by gearing, air compressors of various sorts, to give airplane-engine supercharging, but none was successful. General Electric later supplied geared superchargers having the design of the centrifugal compressor developed during the gas-turbine research, but these did not come into use until 1925.

During World War I Dr. William F. Durand was chairman of the National Advisory Committee for Aeronautics, and in the course of one of his duties of examination of schemes for aviation improvement, there came to him in the fall of 1917 a plan of the French engineer, Rateau, for using a turbine wheel driven by the products of combustion of the engine exhaust, at constant pressure, to drive a centrifugal compressor to do the supercharging. Dr. Durand had been a professor at Sibley College, Cornell University, in 1901, and he remembered the black smoke from the gas-turbine research and knew of the extensive business that the General Electric Company then had in steam turbines and centrifugal compressors. So he asked General Electric (42½) to undertake turbosupercharger development in the United States. General Electric engineers had their own ideas about design details from their experience with gas turbines, steam turbines, and centrifugal compressors, and so started a development entirely independent of Rateau, which has continued to this day, with production successively increasing on account of the present war.

The first General Electric turbosupercharger was constructed with wartime speed and was assembled on one of the Liberty motors then being used, by the U. S. Army Air Corps, McCook Field, Dayton, Ohio, in May, 1918, as shown in Fig. 11. It was operated there so far as possible at sea level and then tested at the 14,000-ft summit of Pike's Peak, Col.

The airplane turbosupercharger is so arranged that as the plane ascends to the successively lower atmospheric pressures at altitude, there continues to be maintained in the exhaust manifold and turbine nozzle box the normal sea-level pressure. The difference between this and the low pressure of altitude gives the nozzle jet that drives the turbine wheel. This drives a centrifugal-compressor impeller on the same shaft, which compresses the low-pressure air of altitude and supplies it at sea-level pressure to the engine intake manifold. So, regardless of altitude, the engine exhausts at sea-level pressure and receives its charge at sea-level pressure. So it continues to deliver sea-level power at all altitudes, up to the critical one where the turbine wheel reaches its maximum safe speed. Due to the low resistance of the low-density air at altitude, sea-level engine power gives increased airplane speed.

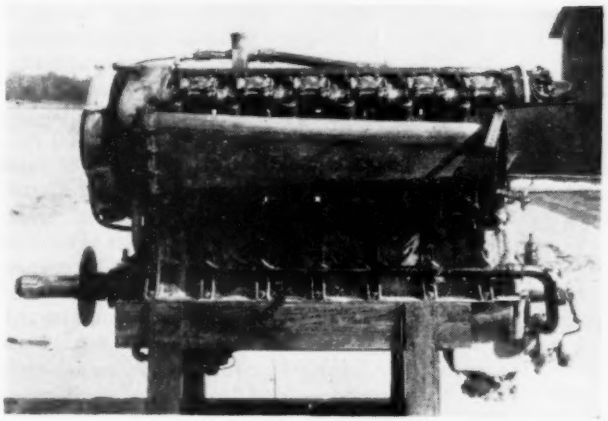

Fig. 11 First American Turbosupercharger on a Liberty Motor at McCook Field, Dayton, Ohio, May, 1918

The constant pressure of the engine-intake manifolds of the early airplane turbosupercharger was 30 in. of mercury. This is greatly exceeded nowadays. Values around 50 in. are usual for take off or short periods, and continuous operation is common with "boost" of intake-manifold pressure as discussed later.

Rateau's turbosupercharger development in France continued for a while after World War I and developments were started in England and Germany. But the resources devoted to the project abroad do not seem to have been sufficient to bring it to a state that warranted continuation. At any rate there is no evidence of any turbosuperchargers other than those of General Electric being used in the present conflict. Other differing American designs recently have begun to be developed.

It once was thought that the 1917 work in France was first mention of the modern turbosupercharger plan, but later searches show what seems to be an earlier publication by Büchi (43). Nevertheless, Rateau made important contributions (44).

In the United States, the development encountered the usual experience of the "glassy eye." But there were enough enthusiasts among the officers and engineers of the United States Army Air Forces, and enough help from them (44½), from engine and airplane manufacturers, and from metallurgists, and sufficient resources available to General Electric, to bring the project to its present originally undreamed of state (45).

The principal interest that the turbosupercharger has in connection with the gas-turbine problem is its development of a turbine to operate at high temperatures of products of combustion. It is true that the aviation turbosupercharger has only short-time operation at extreme conditions and does not have to meet the conditions of continuous operation in a power plant. Nevertheless, many problems have been solved, due to the impetus of World War II, which advance the prospects of a gas turbine as a prime mover. Thus the turbosupercharger, originally a gas-turbine by-product, has not only proved very useful of itself, but has accelerated gas-turbine development.

The turbosupercharger in the United States started in 1918 with a turbine wheel suited only for steam temperature, provided in a rush by the De Laval Steam Turbine Company. Since then there has been continuous progress in materials, fabrication, heat-treating, design, and cooling, of all of the parts, whether exposed to exhaust-gas temperatures or not.

Originally the nozzle area covered only a portion of the wheel

periphery, with cooling between, and this may be an item in the ultimate gas turbine. But for many years the turbosupercharger has had a 360-deg nozzle arc. For years, the rated temperature at the nozzle-box entrance was 1200 F. This meant that the entire nozzle box and the outer portion of the turbine buckets were visibly red-hot, at rotative speeds of about 22,000 rpm. Successive improvements have permitted much greater rated temperatures. Since about 1930 a part of the General Electric turbosupercharger research has been a "hot-gas test" where turbines were operated in the laboratory on products of combustion, with all conditions as when flying at altitude. By opening a peekhole in the altitude chamber in which the turbine wheel was running, there was seen for the first time operation with red-hot turbine buckets, and colored photographs were taken. Since the author always has considered the turbosupercharger as merely a step on the way to the gas turbine, he has often exhibited as gas-turbine propaganda this really inspiring sight of a turbine wheel operating at about 1200 fps with buckets red hot.

Fig. 12 is an accurate reproduction of a water color taken from life, showing a recent turbosupercharger undergoing a standard factory endurance test with products of combustion. In this test, and in actual service, the exhaust-gas conduit from engine to turbine is incipient white, and the nozzle box varies from white to red. A few inches away is the air inlet of the compressor, with a temperature at high altitude of about 50 F below zero, the reproduction of which in the test covers the pipe with frost. Similar conditions exist in the many turbosuperchargers which are reported as successfully flying at high altitude in the war in Europe, Asia, Africa, and the South Pacific, with the *Flying Fortress* B-17 made by Boeing, the *Lightning* P-38 made by Lockheed, the *Liberator* B-24 made by Consolidated, and the *Thunderbolt* P-47 made by Republic. Some of this is shown in the Army illustration, Fig. 13. This is not the place to give details of turbosuperchargers, as this has been done by Reginald G. Standerwick and W. J. King, engineers of the General Electric supercharger Division, in a paper read at the Semi-Annual Meeting of the A.S.M.E., in Los Angeles, Calif., June, 1943, and published in the Transactions of the A.S.M.E. for January, 1944.

(*c*) *Constant-Pressure-Turbosupercharger Cycle.* Turbosuperchargers on American airplanes are examples of the third of the cycles previously mentioned, where reciprocating engines exhaust into gas turbines. They are designed for pressure ratios which give absolute pressures above sea-level value, when flying at altitude. This means that absolute pressures in the engine-intake manifold appreciably above sea-level value are easily possible at moderate altitudes. Such pressures are used for take-off or for regular operation under special circumstances, which is called "boost." Pilots flying airplanes with turbosuperchargers have instruments showing airplane altitude, intake-manifold pressure, turbosupercharger speed, various temperatures, and so on. They have rules and technical orders which give values for the readings of the various instruments which give values for the boost of engine-intake-manifold pressures safe for the engine and turbosupercharger. The greater the boost, the greater the engine horsepower and the greater the airplane speed.

Thus when a pilot with a turbosupercharger is in battle, he has means of greatly increasing his plane speeds at most altitudes, by increased boost. So, when an enemy plane is on his tail, does the pilot take out his technical orders, look at his instruments, and figure out what he ought to do? He does *not*, but subjects the turbosupercharger to pressures far beyond its test rating.

Extension of such operation, which easily is possible independent of aviation, would give a four-stroke Otto- or Diesel-cycle engine with a constant-pressure turbosupercharger, which is this third one of the cycles where a reciprocating internal-combustion engine exhausts into a gas turbine. It has been called a "compound internal-combustion cycle."

As already mentioned, reports of operation of turbosuperchargers in war show that they are subjected to conditions far exceeding their test rating. Therefore the average of the conditions in war has some relation to conditions of long-time operation at sea level to which a gas-turbine prime mover would be subjected.

High-Temperature Progress

One major item in operation of turbine wheels at high temperature is "creep," which is continuous nonelastic elongation, finally resulting in rupture. Hence stresses for a gas turbine to be operated in a power plant for years are lower than for a turbosupercharger in war. Information about creep is rapidly accumulating in connection with turbosupercharger as well as with other turbine work (46).

Reference already has been made (42) to Büchi, Brown-Boveri, and Rateau work on turbosuperchargers with divided manifolds, probably always with low-exhaust-temperature, low-speed Diesel engines. Accounts also have been published (47) of Swiss, French, and German use of turbosuperchargers on aviation engines, with Diesel or Otto cycles and with divided or constant-pressure manifolds. None of the apparatus thus referred to is in use in World War II, the only known turbosuperchargers being those of the United States Army Air Forces, which as already mentioned are in very extensive use.

Nevertheless, some progress is being made abroad with turbine wheels operated by products of combustion. One example is a publication by Brown-Boveri (48), which includes a night picture of a turbosupercharger for an aviation engine (probably with a constant-pressure exhaust manifold) in a factory test at about 1800 F and 30,000 rpm. Glowing exhaust-gas conduit and nozzle box are shown with the remark, "The set presents an exceptional and fascinating appearance. It is surrounded by the glowing gas pipe and carries the mind back to some medieval machine."

Thus the thousands of turbosupercharger turbines, in operation by the United States Air Forces, and being investigated abroad, are adding to the other gas-turbine items already mentioned, in paving the way for temperatures much higher than those which have been used, and with a minimum of loss from cooling. No thermodynamic studies can be given here, but it is well understood that such higher temperatures mean higher gas-turbine efficiencies. So the long sought gas-turbine prime mover, with temperatures much beyond the 1000 F now in use, and consequent higher efficiency, seems to be getting nearer. Of course, this same progress is paving the way for higher temperatures and higher efficiencies with the regular steam cycle and with two fluid cycles. So we only can speculate as to whether the gas turbine with its compressor, combustion chamber, and heat interchanger is going to compete with the other cycles which instead have economizers, feedwater heaters, feed and air pumps, boilers, and condensers.

Acknowledgment

The author is greatly indebted to many individuals and companies who have been kind enough to furnish data, references, and illustrations which are used in this paper.

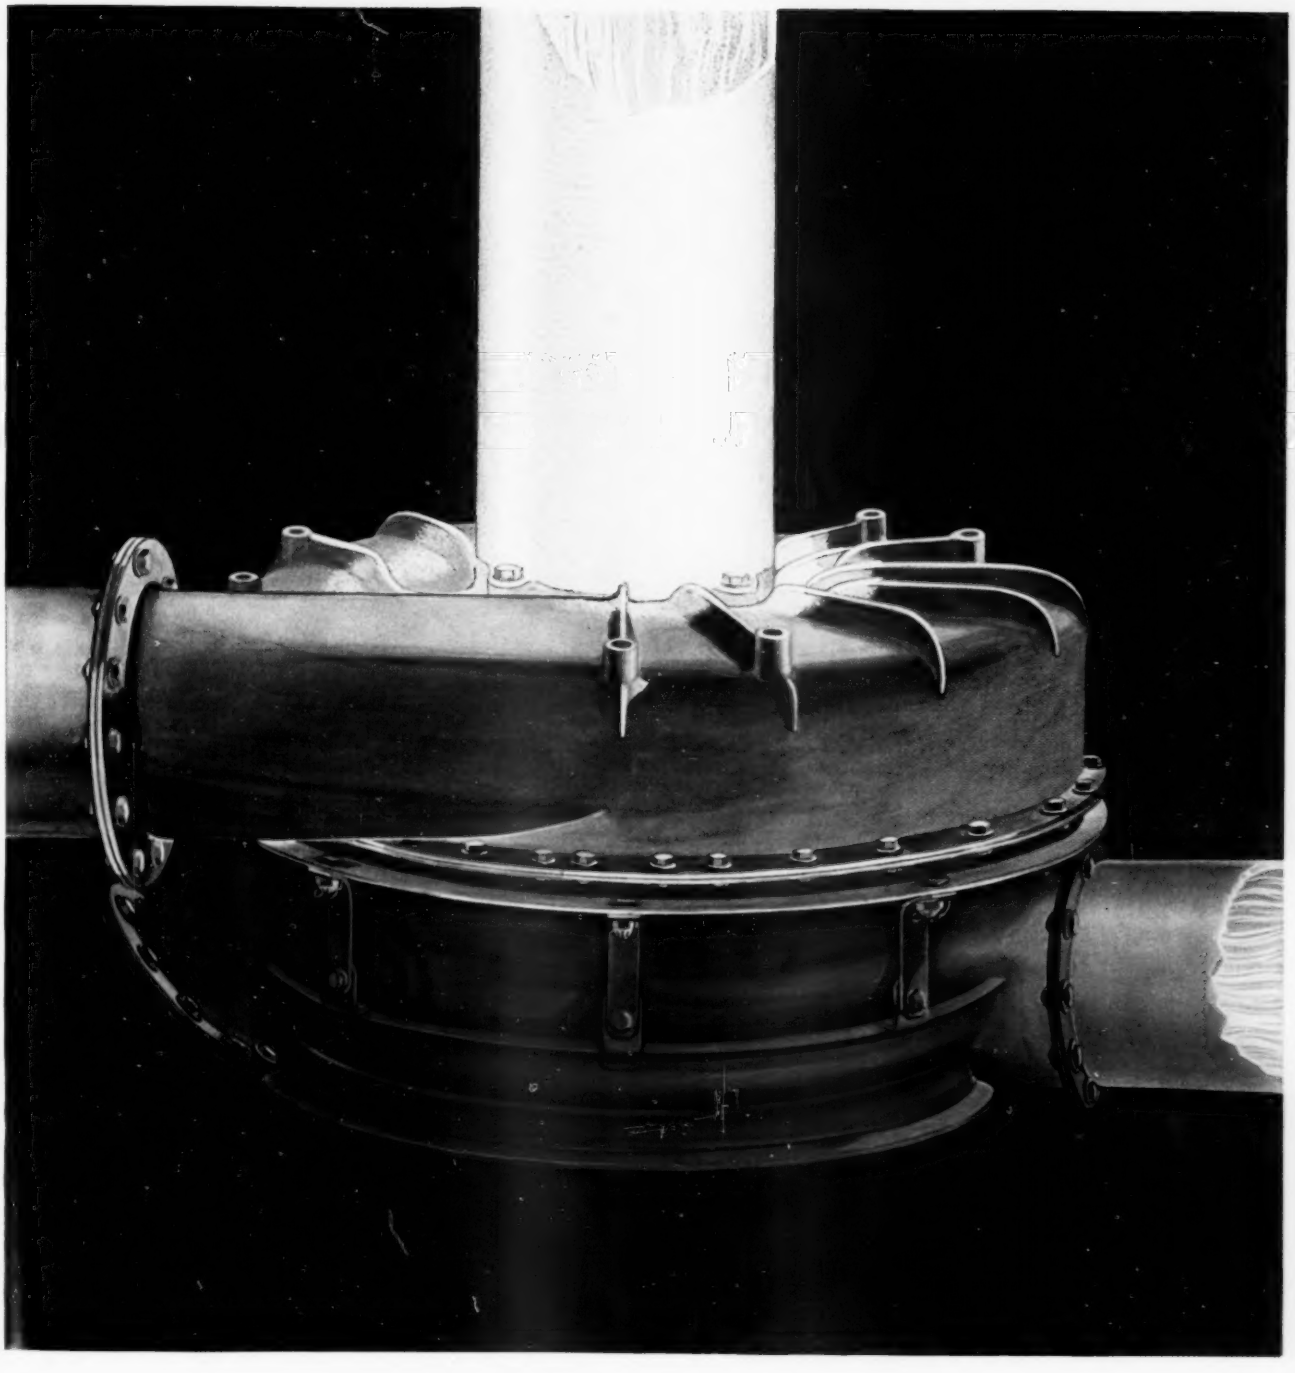

FIG. 12 GENERAL ELECTRIC TURBOSUPERCHARGER OPERATING UNDER STRATOSPHERE CONDITIONS
(Painting from laboratory test.)

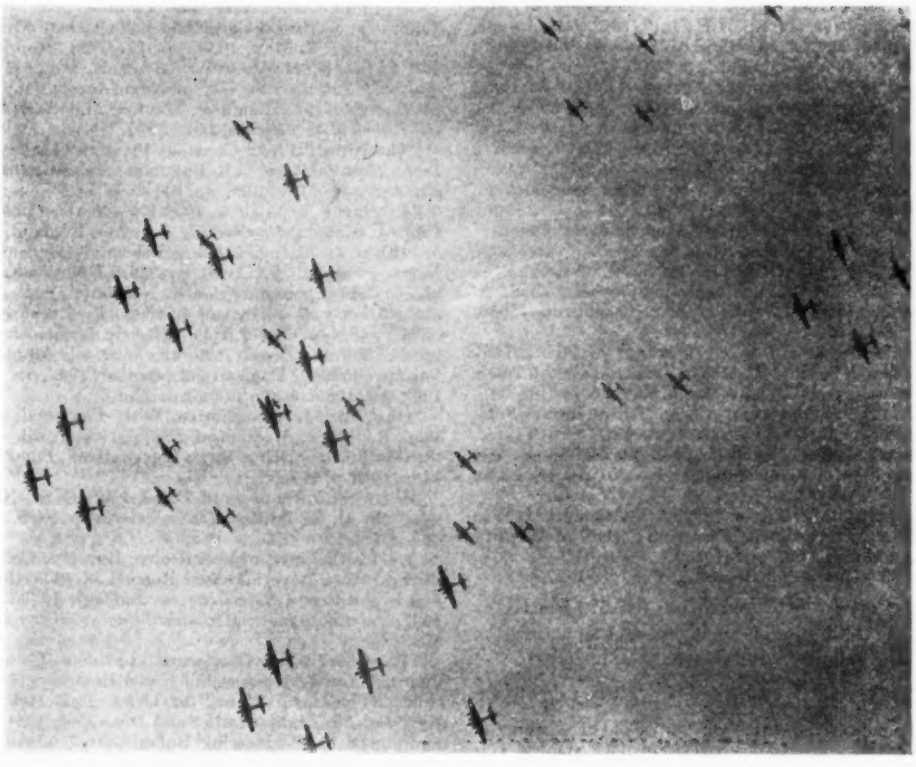

FIG. 13 SQUADRON OF BOEING FLYING FORTRESSES, EACH WITH FOUR TURBOSUPERCHARGERS
(Every one, in battle everywhere, as well as every Consolidated *Liberator*, Lockheed *Lightning*, and Republic *Thunderbolt*, has four, two, or one gas turbines receiving products of combustion from aviation engines.)

2 "Thermodynamics of the Gas Turbine," thesis for degree of Master of Science, by Sanford A. Moss, December, 1900, Library of University of California. The author's draft of this thesis includes thermodynamics of a regenerator or heat interchanger, but this first was published in the Doctor's Thesis (9).

3 "British Patent Reports," vol. XXIII, 1791–1792. Nov. 30, 1791, patent number 1833 to John Barber; shows a complete gas turbine. The illustration of this patent was reproduced in (9, 8, 7, 33, 37).

4 U. S. Patent 635919 to Charles G. Curtis. Filed June 24, 1895; issued Oct. 31, 1899.

5 U. S. Patent No. 617753 to Leon LePontois. Filed Dec. 5, 1895; issued Jan. 17, 1899. Shows an explosion combustion chamber for a gas turbine.

6 "An Investigation of the Gas Turbine," by Walter O. Amsler, thesis for degree of Doctor of Science, 1897; Cornell University Library. Published in Sibley *Journal of Engineering*, May, 1900. A theoretical and experimental study of LePontois explosion combustion chamber of (5); mentions (3).

7 "The Gas Turbine," by H. H. Supplee, published by Lippincott, Philadelphia, Pa., 1910.

8 "The Gas Turbine," by Norman Davey, published by Constable & Co., London, England, 1914.

9 "The Gas Turbine," thesis for degree of Doctor of Philosophy, by Sanford A. Moss, M.S., published in Ithaca, N. Y., May, 1903; Cornell University Library. This has gas-turbine mathematics and a brief account of a turbine wheel actually operated by products of combustion but with very poor performance. There was included the gas-turbine-cycle diagram reproduced in Fig. 1, which was an early representation of Barber's cycle in diagrammatic form. There also was included the "regenerator" or heat interchanger for transferring the heat of the turbine exhaust gases to the air proceeding from compressor to combustion chamber, which may be the first publication of this item. The drawing of Barber's British Patent (3) is reproduced probably for the first time since 1791. This was afterward reproduced in (8, 7, 33, 37). This thesis is referred to in (7), pp. 6 and 26.

9½ General Electric Gas-Turbine Patents (issued to the author, S. A. Moss), as follows:

	Filed	Issued
1064665 Gas Turbine	Dec. 31, 1904	June 10, 1913
891715 Combustion Chamber	April 4, 1906	June 23, 1908
969760 Gas Turbine	April 4, 1906	Sept. 6, 1910
1000968 Governor Mechanism for Gas Turbines	April 4, 1906	Aug. 15, 1911
1000969 Regenerator	April 4, 1906	Aug. 15, 1911

10 U. S. Patent 522066 to Carl Gustaf Patrick De Laval; filed May 1, 1889; issued June 24, 1894. British Patent 7143; filed April 29, 1889; issued March 1, 1890.

"A Pioneer in High Pressure Steam," by George H. Gibson, *Power*, Nov. 6, 1928; republished, with Fig. 2 herein, by De Laval Steam Turbine Company, pamphlet E1141A, 1936.

11 "On the Flow of Gases," by Osborne Reynolds, paper read before Manchester Literary and Philosophical Society, Nov. 17, 1885. Published in London, Edinborough, and Dublin *Philosophical Magazine*, fifth series, vol. 21, no. 130, March, 1886, p. 185, and "Scientific Papers of Osborne Reynolds," vol. 2, p. 311; source of Fig. 6 herein.

12 "Pressures and Temperatures in Free Expansion," by A. Borsody and R. C. Cairncross, presented by Prof. C. E. Lucke, Trans. A.S.M.E., vol. 26, 1905, pp. 114–158.

"Practical Investigations in the Gas Turbine Problem," by C. E. Lucke, *Engineering Magazine*, April, 1905, pp. 96–101.

Discussion by Charles E. Lucke of "Some Possibilities of the Gasoline Turbine," by Prof. Frank C. Wagner; *Journal A.S.M.E.*, vol. 31, no. 2, Febuary, 1909, pp. 241–242.

Partially refuted by Professor Wagner in the closure to his paper, Ibid., p. 244.

Also partially refuted by "The Question of the Gas Turbine," by Prof. Sidney A. Reeve, *Engineering Magazine*, vol. 29, 1905, p. 407.

13 "The Gas Turbine, Some Tests of Practical Efficiency," by Charles E. Lucke, *Engineering Magazine*, vol. 31, August, 1906, pp. 641–656.

Completely refuted by Prof. Frank C. Wagner in closure to his paper given in (12), and by Prof. Sidney A. Reeve in his paper (12).

14 "The Impact Tube," by Sanford A. Moss, Trans. A.S.M.E., vol. 38, 1916, pp. 766–769, section on "Impact Temperature." This since has been called "Total Temperature," to correspond to "Total Pressure."

14½ "Measurement of High Temperatures in High-Velocity Gas Streams," by W. J. King. Trans. A.S.M.F., July, 1943, pp. 421–428.

15 U. S. Patent 1086755, "Elastic-Fluid Compressor," to Charles G. Curtis; filed Aug. 4, 1896; issued Feb. 10, 1914.

42½ Copy of letter of 1917:

National Advisory Committee for Aeronautics
Washington, D. C., November 19, 1917

Mr. E. W. Rice
General Electric Company

Dear Sir:

At the present time in connection with the development of the airplane and the Liberty engine for driving same, there is not a problem which is perhaps more seriously before the Government officials than that of maintaining at high altitudes the power of the engine. In this connection we are especially desirous of developing the possibilities of a precompression of the air before going to the engine carburetor, thus maintaining as nearly as may be constant conditions regarding pressure at all altitudes.

In this connection we believe that your Dr. Sanford A. Moss could be of very great service in advising with us regarding the possibilities

of turbo-compression as applied to this problem, and I have written informally to Dr. Moss inviting his attention to the problem as outlined.

I desire, therefore, to ask your approval of this request, and that, if possible, you will authorize Dr. Moss to give to us the results of his experience in the study of such matters.

Thanking you in advance for your anticipated cooperation in this matter, I remain,

Very truly yours,
/s/ W. F. Durand
Vice-Chairman

43 "Über Vebrennungskraftmaschinen," by Dr. Alfred Büchi, *Zeitschrift fur das gesamte Turbeninwesen*, 1909, pp. 313–316, 322–332, 347–351. Clearly shows a turbine wheel driven by engine exhaust gases on a shaft separate from the engine shaft, and driving a "turbokompressor" which supplies air through a "kuhler" to the cylinders of a reciprocating internal engine of either what is now called the "Otto" or "Diesel" types. Mentions the use of the process on "aircraft, automobiles, motorboats, railway motors, stationary engines," etc. Refers to German patent 204, 630, filed Nov. 16, 1905, issued Nov. 28, 1908; but this shows turbine and compressor on the engine shaft.

"Supercharging in Internal Combustion Engines," by Alfred Büchi, *The Engineer*, London, England, Aug. 14, 1925, p. 171.

Discussion

A. G. CHRISTIE.[3] The author has presented an interesting history of the development of the gas turbine and turbosupercharger. He discusses his early experimental work at Cornell University using the DeLaval steam-turbine wheel of the unit that was shown at the Chicago World's Fair and which was said to be the first De Laval unit in this country.

The writer went to Cornell in October, 1904, as an instructor. When the late Prof. R. C. Carpenter, then in charge of the mechanical laboratories, learned that the writer had built steam turbines, he asked whether or not the old De Laval turbine could be fixed up and run. Professor Carpenter said that a former student had tried to use this rotor as a gas turbine and, as a result of overheating, the shaft had broken.

Balancing was not a refined art in those days. The De Laval designers provided a flexible shaft to care for wheel unbalance. This shaft was reduced to a small diameter (about $^3/_8$ in. as nearly as can be recalled) on either side of the disk. The fracture occurred in one of these small sections. The shaft was either repaired by a sleeve or replaced, for the turbine was in service the following winter for laboratory purposes.

The blading of the wheel showed no ill effects of its operation as a gas turbine. In view of our more extended knowledge of fatigue failures, it is quite certain that the shaft fracture was due to fatigue rather than to Dr. Moss's use of it as a gas turbine. The shaft was well away from the wheel, and the wheel itself showed no ill effects from the application of gas. The writer recalls that Professor Carpenter said the wheel had been "very hot," so his curiosity was aroused to see what had been the effect on the blades and disk. Apparently, the effect was not serious for the unit ran for some time afterward in regular laboratory service.

Later, about 1912, when the writer was at the University of Wisconsin, the late Prof. Carl C. Thomas had him fit up a small gasoline engine with a quick-opening valve on the indicator-cock connection. This valve was opened somewhat before the end of the power stroke and the gas was discharged through a nozzle onto a small turbine wheel. This ran satisfactorily and developed a small amount of power but the hot gases quickly de-

[3] Professor of Mechanical Engineering, The Johns Hopkins University, Baltimore, Md. Fellow, A.S.M.E.

stroyed the valve. The writer believes that Professor Thomas later filed an application for a patent on this device as a power-generating unit but no further construction or experimental work was done.

W. F. Durand.[4] In this paper, the author has presented a vast amount of historical information on the development of the gas turbine which will be of the greatest interest and value to all who are concerned with this new form of combustion engine. My own small part in this history goes little beyond the letter which I wrote in the fall of 1917, to Mr. Rice, president of the General Electric Company, asking him to detail Dr. Moss on the problem of the exhaust turbosupercharger, as an aid to the airplane in reaching higher atmospheric levels.

In 1917, the members of the National Advisory Committee for Aeronautics were becoming acutely impressed with the need of some means for the maintenance of sea-level power at high altitudes. We knew something of what Rateau in France had been doing in this line, and the salvaging of some of the power wasted in the exhaust seemed a promising means for achieving this end. As Dr. Moss has noted in his paper, I had been in contact with his work at Cornell in 1901 and knew of his connection with the General Electric Company in 1917; and hence it seemed to be a most natural approach to address the letter to Mr. Rice as he has noted. The response was prompt and generous and the work was started.

The growth, since that beginning in 1917, has far outrun anything that either Mr. Rice, Dr. Moss, or I could have possibly foreseen or even imagined at that time. The turbosupercharger is firmly established as an absolutely essential feature of aircraft motive equipment where navigation at high altitudes is contemplated, and the rate of production in recent months has reached figures which, 26 years ago, would have seemed nothing short of a fantastic dream.

The splendid record of achievement in this particular domain of power drive may well be an indication of continually improving adaptation of the gas turbine as a prime mover, to the requirements of engineering and industry broadly.

J. S. Haverstick.[5] The author has presented an interesting and instructive account of his work, and the work of others, in attempting to develop a commercial gas-turbine power plant. It is to be hoped that recent wartime developments, both in this country and abroad, may soon be published for the benefit of those who design this type of equipment.

This year is the fiftieth anniversary of the first De Laval steam turbine in the United States. We were interested to note that its bucket wheel was probably the first to operate on exhaust gas; and, further, that 25 years later De Laval was the source of supply for high-speed wheels.

Since mention has been made of the bucket wheel supplied to the author in 1918, we feel that we should add a few notes on the other development program which paralleled that of the author, and with which De Laval was connected more intimately.

Fig. 14 of this discussion is a copy made from the drawing by Rateau and is probably the starting point for turbosuperchargers in this country.

During 1918, tests were conducted at De Laval for the Fergus Motors of America, Inc., using the turbosupercharger developed the previous year by E. H. Sherbondy. Several changes in design were made as the tests progressed, for it was soon found that

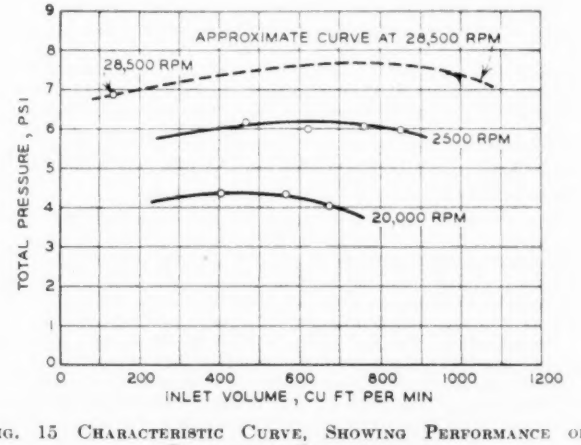

Fig. 15 Characteristic Curve, Showing Performance of Centrifugal Compressor

the unit could not be brought to its full speed of 30,000 rpm because of congestion in the flow passages. Fig. 15 is a characteristic curve of the compressor taken before completion of the tests.

Unfortunately, this program was discontinued after the last war. For a description of the machine one should refer to Stodola's text (25),[6] where it is shown in cross section alongside the General Electric turbosupercharger of that period.

Richard Herold.[7] This paper presents a valuable chronological history of the gas turbine with a quite natural emphasis on the work done in this country. Due no doubt to the imposition of wartime secrecy, the paper does not add anything to the facts already known; it does not submit any figures about present results, and it does not offer suggestions about the probable aspect of further gas-turbine development.

The writer feels therefore that while the paper is of great

[6] Numbers in parentheses in this discussion refer to the author's Bibliography.

[7] Sulzer Bros., Ltd., New York, N. Y. Jun. A.S.M.E.

value for all those interested in gas turbines, it does not offer material for discussion. It is regretted that the author has not mentioned the studies which he has surely made, with a view to using gas turbines for jet-propulsion high-altitude aircraft. This again, is unquestionably due to wartime secrecy.

W. J. KING.[8] One of the most remarkable aspects of this subject of gas turbines is the rapidity with which interest has developed within the very recent past, as manifested in the published literature and in the transactions of several of our engineering societies. Along with this, there seems to be a similar growth of interest in various combinations of the gas turbine with other types of heat engines, such as the Velox boiler and the "Diesel boiler" or Götaverken cycle which the author mentions.

After reading the article on the Diesel boiler, to which the author refers, the writer became interested in comparing the theoretical efficiency of the particular cycle described with that of the simple gas-turbine cycle. Of course the actual performance of either cycle will depend to a major degree upon the efficiencies of the component machines, but it was felt that the results of a basic thermodynamic analysis using idealized compression and expansion, with adiabatic or 100 per cent efficiency, would be of some interest.

The cycles assumed in this study are indicated in Fig. 16 of this

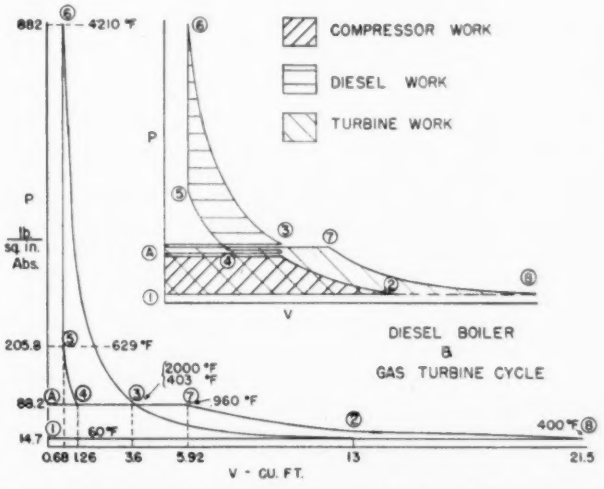

FIG. 16 THEORETICAL INDICATOR DIAGRAM FOR GAS TURBINE AND "DIESEL BOILER" OR GÖTAVERKEN CYCLES
(Lower diagram is to scale, upper diagram is schematic, to show sequence of operation.)

discussion, in which the "Diesel boiler" cycle is superposed upon the ordinary gas-turbine diagram. In either case, atmospheric air is initially compressed through a 6:1 ratio in a separate compressor, which discharges it at 88.2 psia and 403 F, at point 3. In the simple gas turbine, this air is heated in the combustion chamber to a temperature of 960 F, at constant pressure. It is then expanded down to atmospheric pressure in the turbine. The efficiency, defined as the difference between the turbine work and the compressor work divided by the heat input, is 40 per cent.

In the Götaverken cycle, all of the air discharged from the compressor is taken into the Diesel cylinder, point 3, but on the compression stroke the exhaust valve is not closed until 65 per cent of the charge has been expelled into the exhaust-receiver feeding the turbine. The remaining 35 per cent is compressed along line 4–5 to a pressure of 205.8 lb, where it is mixed with fuel, ignited, and heated to 4210 F at 882 lb, point 6. It is then expanded isentropically to point 3, where it is discharged into the receiver at 2000 F. The mixing of this hot gas with the 403-deg air, previously expelled into the receiver, results in the same temperature, pressure, and weight of gas at point 7 as before. The work done in the turbine is, therefore, exactly the same as in the previous case, but the cycle has been so chosen that the net output of the Diesel supplies the work done in the compressor. The efficiency is, therefore, equal to the total turbine output divided by the heat input between points 5 and 6, which turns out to be 49.2 per cent. This particular cycle is thus 23 per cent more efficient, on this idealized basis, than the simple gas turbine.

The advantage of the Diesel boiler cycle in this instance cannot be attributed to the fact that the maximum temperature of the cycle is much higher than in the simple gas turbine. With isentropic compression and expansion, as assumed herein, it is interesting to note that the over-all efficiency of the gas turbine is independent of the temperature of the gas entering the turbine. The superiority of the Diesel cycle lies in the fact that it supplies the compressor work more efficiently by virtue of the greater expansion ratio in the Diesel cylinder, 5.30, as compared with 3.63 in the gas turbine.

On the basis of actual compressor and turbine efficiencies, substituting the rather optimistic figure of 85 per cent for both units, the over-all gas-turbine efficiency drops from 40 to 16.4 per cent. If the Diesel output is likewise 85 per cent of the theoretical value, the actual efficiency of the Götaverken cycle would be reduced to about 30 per cent. With lower efficiencies of the components, it may be seen that the gas-turbine cycle rapidly collapses to zero output, at the specified inlet temperature of 960 F, unless the Diesel or some other engine is provided to drive the compressor. These considerations indicate that the addition of a relatively small piston engine in this manner may make it possible to utilize a gas turbine as the final drive under conditions where it would otherwise be impracticable.

R. C. MUIR.[9] The author's closing statement shows great restraint, when one considers the faith that he has in the ultimate successful development of the gas turbine, a faith supported by study, experiment, and research on the gas turbine throughout his entire engineering career of nearly 50 years; and those who know the author know that these were years of great activity.

It must be with great satisfaction that he has seen the gas turbine become such an important part of the gas-and-oil-engine cycle, more specifically in the form of the turbosupercharger which has given us superior airplanes.

However, he does speak encouragingly when he says the gas-turbine prime mover seems to be getting nearer, notwithstanding the equities and probable improvements in other heat cycles.

The gas-turbine prime mover has been slow in coming because its principal elements, the compressor and the turbine, had to be highly perfected before the gas turbine had any output. Other forms of prime movers gave some output even though each element was very inefficient. With efficiencies of turbines and compressors in the 80 to 90 per cent bracket, and with materials capable of high stress and low creep at temperatures of more than 1000 F, we have arrived at a point where the gas-turbine prime mover is a fact.

There are some applications where light weight, low space factor, and scarcity of water are necessary, and these are the applications for which the gas turbine should be studied today,

[8] Supercharger Engineering Division, General Electric Company, West Lynn, Mass. Mem. A.S.M.E.

[9] Vice-President in Charge of Engineering, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

even though its thermal efficiency is less than that of some other heat cycles.

However, it is probable that higher efficiencies of turbine and compressor will be obtained, and that materials capable of higher temperatures under stress conditions in the turbine will come through metallurgical research, and with these the gas-turbine prime mover will become a legitimate competitor of other forms of prime movers in more extended fields of application.

FREDERICK NETTEL.[10] The story of the good old days of the gas turbine, when everybody was happy if it turned at all, as related by the Nestor of American gas-turbine engineers, is truly fascinating and will forever form a valuable contribution to the history of this oldest and, at the same time, newest, power machine.

The historic references may be rounded out by mentioning a few pioneer thinkers, whose contributions to the art, even though in the form of patent specifications only, seem important enough, or may become so, considering the more recent trend of developments in gas or air turbines. These are as follows:

1 U. S. Patent 18,435 to Philander Shaw of Boston, dated May 2, 1854: Reissue No. 1014, dated July 17, 1860, which discloses the principle of passing the air exhausted from a hot-air engine through the fire (in the furnace) for purposes of economizing heat. This is important in connection with efforts to realize coal-burning air-turbine plants.

2 British Patent 18,435, convention date Norway, Aug. 26, 1903, to J. W. A. Elling of Christiania (Oslo) showing an early example of gas-turbine plant with multiple-stage centrifugal compressor embodying precooling and intercooling of the air in two stages, in combination with one turbine and recuperator.

3 German Patent 216,191 of Sept. 12, 1906, to S. Z. de Ferranti of Sheffield, England, illustrating probably for the first time useful power turbine and compressor driving turbine on separate shafts. The turbines are arranged in series as regards the flow of the combustion gases, with the low-pressure turbine driving the compressor. Included is the first discussion of regulating problems in multishaft gas-turbine plants.

4 U. S. Patent 853,124 to E. L. Schaun of Baltimore, May 7, 1907, describes for the first time starting of a gas turbine by compressed air.

5 U. S. Patent 1,316,234 of Sept. 16, 1919, to J. O. Heinze of Springfield, Ohio, mentions most likely for the first time gas turbines with oppositely rotating runners used for neutralizing gyroscopic action on vehicles with particular reference to airplanes. (This was in the meantime reinvented several times!)

While the author quite logically omits detailed thermodynamic computations in his predominantly historical paper, he draws certain conclusions from a simple approximate calculation which at this date tempts the "red-hot" gas-turbine enthusiast to a few remarks:

Much has happened since the days when it was thought possible to dispose of the gas-turbine problems "comprehensively" or even "definitively" by thermodynamical calculations of probable efficiencies along textbook lines.

Without wishing to go into details in this discussion, it appears timely to take cognizance of the fact that during the last few years much fundamental work has been done all over the world on the thermodynamics of the gas and air turbine. This brought to the fore, among other things, the long underestimated value of intercooling and reheating of the working fluid. Due to the war, and other considerations, much of this work will have to remain unpublished for some time. However, it seems opportune here to emphasize in the interest of the healthy development of the gas turbine, that its future as a serious competitor of the steam turbine, and under certain circumstances even of the Diesel engine, is today no more predicated upon the employment of extraordinarily high temperatures.

[10] Manhasset, L. I., N. Y.

In short, a modern gas-turbine plant of about 4000 hp, or preferably more, working at a maximum gas temperature of 1050 F, consisting of two stage compressors with interposed intercooler, two turbines with interposed reheater, and a recuperator of acceptable size, can be designed and built to give a rated-load thermal over-all efficiency of 30 per cent, referred to the coupling of the useful power turbine. The efficiencies assumed in that plant for both turbines and compressors, as well as the parasitic losses (pressure drops, etc.) are well within the range of figures measured in actual plants (Neuchâtel, etc.)

Steam-turbine designers know only too well why they prefer not to go much above 1000 F at present, in spite of the fact that the steam turbine would also profit from a rise in superheat, particularly in high-pressure plants. If they thus avoid what they consider grave risks, evaluated from vast experience, there is little basis for crediting gas-tu bine designers, with much less to build upon, with greater ingenuity or wizardry in dealing with 1200 F, or even 1500 F.

Since, as mentioned, the gas turbine must be considered a potential thermal and—on account of savings in weight, space, and cooling water—economic rival of high-pressure steam plants, even when employing gas temperatures in the range of what has been accepted for some years for steam turbines, higher temperatures should be resorted to only with the greatest caution and gradually.

Setbacks due to gambling with higher temperatures are liable to be unjustly blamed on the gas turbine and are bound to retard rather than to assist its healthy development.

J. T. RETTALIATA.[11] The author, in devoting his efforts since the beginning of the century to the advancement of the gas turbine, deserves much credit for the recognition it is receiving at the present time. In his interesting paper, he rightly points out the antiquity associated with the gas-turbine art, thus correcting any erroneous beliefs, which may have arisen due to the recent attention being accorded it, that the gas turbine is a modern invention.

The author may well be proud of his contributions in the many years of development of the turbosupercharger, a device playing such a vital part in the present conflict. The modern turbosupercharger is exhibiting admirable performance in the type of installation now being employed. The efficiencies of its respective compressor and turbine elements are adequate in the present application where no additional power is required from the turbine beyond that needed to effect compression.

Since the aim of the aviation industry is ever to decrease the weight per horsepower of the power plant, the next logical modification of the turbosupercharger would be to achieve compressor and turbine efficiencies of the highest order so as to produce an excess of power. This additional power could be fed back into the engine or propeller shafts or utilized in the form of a jet-propulsion effect from the turbine exhaust gases.

The large-scale prime-mover type of combustion-gas turbine has benefited and will, undoubtedly benefit from turbosupercharger experience but it should be remembered that they are basically different types of units. The supercharger approaches a limit design in that minimum-weight requirements necessitate relatively high speeds and stresses resulting in a limited service life. Some of the high-temperature metallurgical problems of the supercharger therefore differ from those of the more conservatively designed, longer-life, prime-mover type of gas turbine. For the supercharger, materials having good stress-rupture properties are desirable, whereas, for longer-life units creep char-

[11] Chief Research Engineer, Steam Turbine Department, Allis-Chalmers Manufacturing Company, Milwaukee, Wis. Jun. A.S.M.E.

acteristics may be more important. Further, high-temperature alloy castings and forgings in sizes suitable for superchargers are easier to produce than those required for large-size gas-turbine units.

As a prime mover, the combustion-gas turbine is quite versatile owing to the many different kinds of cycles that can be employed; giving a wide range of thermal efficiencies. The basic cycle, embodying a single turbine, compressor, and combustion chamber, will represent the lowest part of the range. Fortunately, it can be modified so, when operated with temperatures permissible with materials now available, good thermal efficiencies are possible.

One such cycle modification, comprising intercooling in the compressor, reheating between the power and compressor turbines, and preheating of the compressor discharge air with the turbine-exhaust gas, is shown in Fig. 17 of this discussion. This cycle is capable of yielding a coupling thermal efficiency of 30 per cent when operated with turbine, inlet temperatures of 1200 F, a pressure ratio of 5, and 1500 and 5000 sq ft of surface in the intercooler and heat exchanger, respectively.

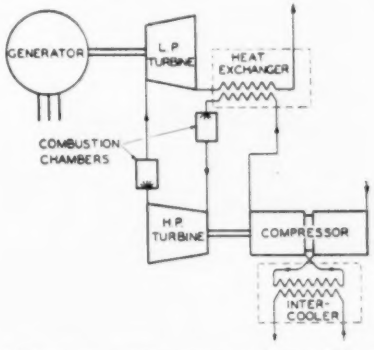

Fig. 17 Gas-Turbine Regenerative Cycle With Reheating and Intercooling

As has been pointed out previously on many occasions the gas turbine has progressed mainly through the development of better materials and more efficient compressors. As a further step, assuming thermal efficiencies of 30 per cent for the present, it will probably be necessary to adapt pulverized fuel to justify economically the general use of the gas turbine in central-station practice. Such a procedure appears to have merit considering the appreciable difference in cost between coal and oil and the possible future scarcity of the latter.

The major commercial application in this country of the combustion-gas turbine in prime-mover sizes has been in oil refineries employing the Houdry catalytic cracking process in the manufacture of high-octane gasoline. Figs. 21 and 22 of Mr. Sidler's discussion show the first of these machines supplied by Brown Boveri. Many other units of the same type have since been built by Allis-Chalmers under Brown Boveri license. To date Allis-Chalmers has supplied 27 such gas turbines to the oil industry and much valuable operating experience has been obtained with these units.

The well-recognized limitations of the gas turbine preclude the possibility of its being considered as the answer to all future power problems. It is believed, however, that its inherent characteristics make it an ideal aspirant for certain applications in land, heavy traction, aeronautical, and marine fields.

P. R. Sidler.[12] In the course of the last 3 or 4 years several papers on gas turbines have appeared in the technical literature; some also have been presented before meetings of this Society. It is perhaps more than a coincidence that quite a few of them, notably those covering the subject in greater detail, devote very considerable space to a historical survey. Possibly Dr. Meyer's paper (33)[13] before The Institution of Mechanical Engineers and before this Society in 1939 started this trend. At any rate, several of the early gas-turbine "inventors" mentioned there have since reappeared in a number of papers, only to be summarily dealt with, as having contributed rather little that could be of use today.

It is interesting to speculate on the purpose of such extensive backward glances, especially if it is admitted that most of the gas-turbine proposals advanced during the first decade of this century were impractical or not workable at all. One good reason may be the desire to establish priority of ideas; another to make a case for continuity of research and study undeterred by early failures or lack of appreciation; still another could be to show why there is as yet in many quarters only a modest beginning on the road toward real gas-turbine power machinery.

Whatever the reasons, such historical surveys do help to focus attention on the many difficulties that stood in the way of a practical gas turbine which actually delivers useful power. They also emphasize that modern technical accomplishments are not the invention of any individual but the result of a co-operative effort of many minds, a structure slowly built up on primitive and often rather unsafe foundations. Again, the gas-turbine development shows that even large numbers of patents, issued through the years to many corporations and individuals in various countries, do not necessarily insure success. What really counts is the slow but consistent accumulation through tests and research of data and experiences, the building-up of shop techniques, and of "know-how."

The present paper is a very interesting account of the author's struggle with gas-turbine problems for over 40 years and of his successes in the field of turbosuperchargers for airplanes. The very detailed Bibliography should also be of definite value to the student of gas-turbine matters.

The fundamental work done in this field by Prof. A. Stodola (25) would seem to merit greater emphasis. A large part of his life work as research scientist, teacher, and consultant had been devoted to the development of the gas turbine, and he had the satisfaction of seeing his dreams come true (34), before he died on Christmas Day, 1942.

In the author's discussion on compressors for gas turbines there are a few points where the picture might be rounded out on the basis of available records.

It is stated that Rateau supplied centrifugal compressors for the Armengaud-Lemale gas-turbine work carried out in France. It is known that Professor Rateau had some preliminary models of single-stage centrifugal compressors built for this experimental gas-turbine work, but when the definite gas-turbine design was evolved in 1906, and the need for a larger centrifugal compressor developed, Mr. Armengaud turned to Brown Boveri. Fig. 18 of this discussion shows this machine on the test floor of the Brown Boveri factory in Switzerland. This is a three-cylinder unit with 25 impellers, built for about 2150 cfm at 55 psig, 4000 rpm, and required about 328 hp. It showed an efficiency between 65 and 70 per cent, depending upon the load.

This was incidentally the first commercial centrifugal compressor in the world and it was so successful that Brown, Boveri & Company immediately launched a manufacturing program for this new machine. Between 1906 and the end of 1910, a total of nineteen centrifugal compressors or blowers for blast-furnace operation were installed, among them six in England, three each in France and Chile, two each in Belgium and in Canada, and single units in a few other countries. Their air

[12] Resident Engineer, Brown, Boveri & Co., Ltd., of Baden, Switzerland, 19 Rector St., New York, N. Y. Mem. A.S.M.E.

[13] Numbers in parenthesis in this and subsequent discussions refer to the author's Bibliography.

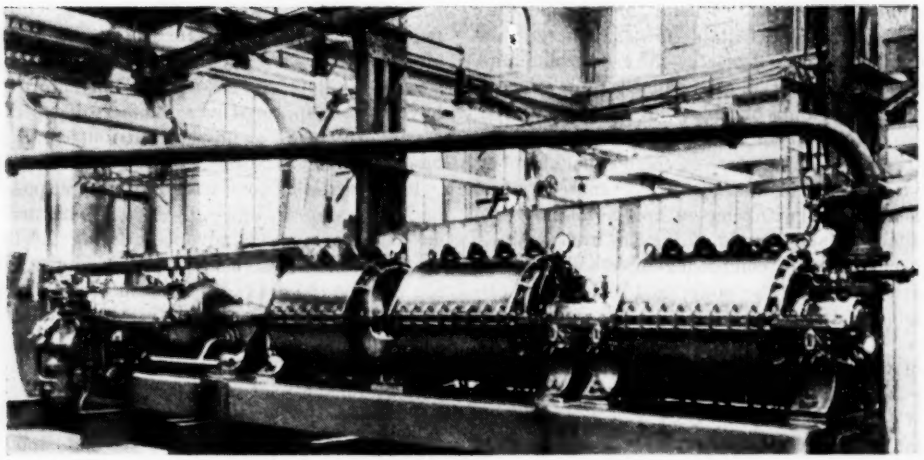

FIG. 18 THREE-CYLINDER TURBOCOMPRESSOR BUILT IN 1906 FOR ARMENGAUD-LEMALE GAS TURBINE

volume varied between 5000 and 32,500 cfm. During the same period Brown Boveri also completed eight turbocompressors for pressures between 62 and 103 psig and for installations in France, England, and other countries, besides about a dozen centrifugal blowers in various applications. It is interesting to note that this development finds a close parallel in the decisions of the General Electric Company, which installed the first two blast-furnace turbocompressors in this country in 1910.

With this background in centrifugal-compressor work and fully realizing its limitations, Brown Boveri worked on the development of a more efficient rotating machine and found the solution around 1931, in an improved axial-flow compressor, the principle of which had already been known for over 20 years. In fact Parsons had built several machines of this type in the period, 1905–1908, but had abandoned the design as it did not then show any advantage over the centrifugal compressor. It was only by applying newly developed data from the field of aerodynamics that a more efficient axial-flow compressor could be built. Since 1932, there have been put into commercial operation over seventy-five multistage axial-flow compressors in Velox plants, some forty units in gas-turbine applications, and about a dozen large machines up to 128,000 cfm in other fields, such as wind tunnels for airplane research, refrigerating plants, etc. Operating results on some of these plants have been published repeatedly and prove that the axial-flow compressor is indeed much more efficient than a centrifugal machine. Adiabatic efficiencies between 82 and 86 per cent have been consistently obtained (34).

Fig. 19 of this discussion shows the cylinder of an axial compressor built about 1933, for a Velox plant. The machine has 10 blade rows and produces a pressure of 36 psig. Fig. 20 shows the rotor for the same machine. To be sure, the pressure ratio of the axial-flow blower is at present somewhat lower than that of centrifugal compressors, but this is not considered a serious handicap for successful gas-turbine operation. Their greater number of stages on the other hand is no cause for apprehension either. There are many thousand steam turbines of the reaction type in service in the world today which have even more blade rows and work under more severe conditions of pressure and temperature.

This higher efficiency of the axial-flow compressor is one of the basic reasons for the existence of a practical gas turbine today, that is, a prime mover which actually delivers useful power and does not use up all its output for driving the air compressor.

Incidentally, the axial-flow compressor is a perfect illustration

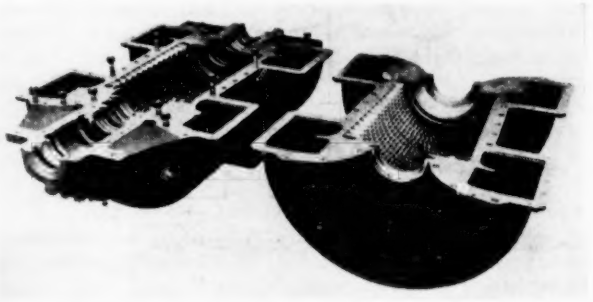

FIG. 19 UPPER AND LOWER HALVES OF AXIAL-COMPRESSOR CYLINDER FOR VELOX BOILER

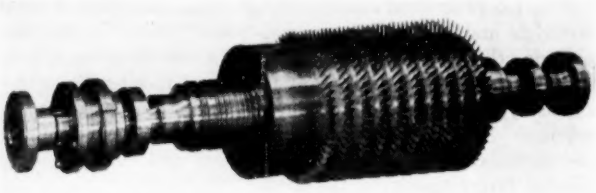

FIG. 20 ROTOR OF AXIAL COMPRESSOR AS PER FIG. 19, WITH ROLLER BEARINGS AND COUPLING FLANGES

for the statement that patents by themselves do not necessarily result in practical machinery. "It is rather the careful attention to details in manufacturing, rigid inspection, and thorough testing, in short, "know-how," which insures success. Even seemingly minor deviations from these rules may spell the difference between a machine that goes into service immediately after erection and another that requires perhaps several months of adjustment and partial rebuilding.

It is true that the application of such machines in the Houdry catalytic cracking process does not constitute a self-contained prime mover. Their main purpose in this process is the delivery of substantial air volumes. Nevertheless, all these units (nearly thirty machines are now in operation in the United States, the first eight being imported from Switzerland between 1936 and 1939) show a net surplus of power and are thus properly classified as gas turbines. In most cases this surplus is fed back into the electrical system, except where local conditions or contractual arrangements make it desirable to take it out in the form of heat.

Fig. 21 shows the rotating element of the first gas-turbine unit for the Houdry process, built in 1936, and in continuous operation since January, 1937, except for a few days of inspection and maintenance work on the whole plant, every 6 months. To the right is the five-stage gas turbine, to the left the 21-stage axial compressor, which is designed for 40,000 cfm at a delivery pressure of 45 psig and a speed of about 5100 rpm. The gear and the electric generator for the surplus power are not shown here, but may be seen in Fig. 22; at the extreme right is the starting motor for bringing the whole set up to speed, which can be uncoupled after the gas turbine takes over.

Beside the 4000-kw Neuchatel gas turbine and the 2200-hp unit powering the Swiss locomotive our company completed, during 1939 and 1940, four other self-contained gas turbines

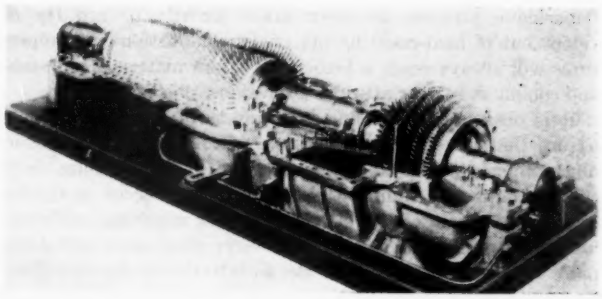

FIG. 21 GAS-TURBINE-DRIVEN COMPRESSOR SET FOR HOUDRY PROCESS WITH TOP CASING REMOVED

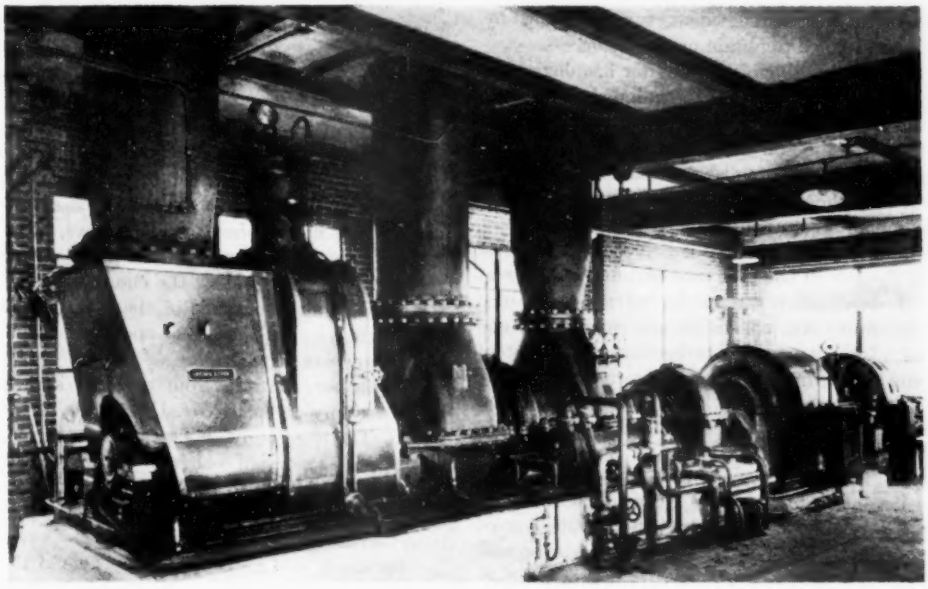

FIG. 22 FIRST GAS-TURBINE-DRIVEN COMPRESSOR SET FOR HOUDRY PROCESS, INSTALLED IN EASTERN REFINERY

which went into operation after extensive tests. Two of them are working in blast-furnace plants, delivering the blast air and burning furnace gas. Unfortunately, it has not been possible to publish any performance data on these units due to wartime restrictions, but there is room for the hope that such information will be available before long.

In the field of superchargers, the author indicates that the first gear-driven machines for United States aviation engines were built in 1925. It might be noted in passing that several hundred gear-driven centrifugal superchargers, following Rateau or Brown Boveri design, were in use in Europe during the first world war.

As to exhaust-turbine-driven superchargers, the writer has noted the statement that no turbosuperchargers other than those of General Electric are in use in the present conflict. He does know, however, of rather extensive developmental programs started several years prior to the outbreak of this war with well-known airplane-engine builders in England and France, following the Brown Boveri - Büchi system. It would seem likely that these efforts have produced some results, although no supporting evidence is available due to censorship restrictions.

Under the heading "High-Temperature Progress," the author mentions some tests made in the Brown Boveri shops with an airplane supercharger running at 30,000 rpm and about 1800 F. It should be added that the diameter of the turbine wheel is in the range of 10–12 in. This is considerably smaller than that of turbosuperchargers used in this country and running at substantially lower speeds and temperatures.

After discussing some controversial points, the writer is very glad to conclude with a note of entire accord, namely, in regard to the important contributions of the author's work on turbosuperchargers, especially in the line of high-temperature operation, for the advancement of the combustion-gas turbine. This experience will be particularly interesting for checks and comparison with the results of research work that has been going on in other quarters, all directed toward the development of alloys which will stand up in gas turbines for continuous service with gas temperatures of 1500 to 1700 F.

By using these results in conjunction with the other known and developed elements of the gas-turbine cycle, particularly the efficient axial-flow compressor, we shall surely construct in the coming peace years gas-turbine power plants of high thermal efficiency which will find ready acceptance in many fields that are now being regarded as the exclusive domain of the steam turbine or the Diesel engine.

W. E. TRUMPLER.[14] In this presentation, attention has been called to the importance of heat-resisting materials, high compressor and turbine efficiencies. It is felt that not enough emphasis has been placed on the problem of blade cooling. While

[14] Development Engineer, Carrier Corporation, Syracuse, N. Y Mem. A.S.M.E.

remarkable progress has been made recently toward the development of heat-resisting materials, combustion-gas temperatures will always reach a higher level than materials can stand, and cooling may offer attractive solutions.

It is obvious that cooling in a gas turbine is of a different nature that in combustion engines. Cooling by air circulation must supersede the cooling-water jacket. Air cooling to be effective must use similarly high velocities as occur in the turbine-blade channel. To do this without involving additional losses, the cooling circulation must serve some other useful purpose, such as compression of the air into the combustion chamber. The losses then are only slightly higher than with compression performed independently. Lorenzen (26) is to the writer's knowledge the first to have used passages in the turbine wheel and through hollow blades to produce centrifugal compression and cooling combined. His arrangement suffered from hydraulic imperfection and failed to obtain practical success.

Following the same basic principle, the writer has devised an arrangement wherein the turbine wheel is equipped with specially shaped blades suitable for both compression and expansion and partially admitted to the flow of each function. The blade in question is bound to be a compromise design and the blade efficiency will suffer, also the change from one operation to the other twice during one revolution involves additional losses. Very complex hydraulic problems must be solved to keep these losses to a tolerable figure. It has been proved, however, even at this early stage of development, that the advantage gained by cooling the blades more than offsets the additional hydraulic and thermal losses. It is impossible to predict the extent of future improvements in this direction, but it is certain that blade cooling will have an economic justification in the gas turbine of the future.

G. B. Warren.[15] The development of the gas turbine has been the grand passion of the author's life. His not inconsiderable participation in the development of the centrifugal compressor, then of the steam turbine, and finally of the airplane turbo and geared centrifugal supercharger, has, if the writer judges him correctly, been but a stepping stone in his quest for the ultimate development of the gas turbine itself. It is altogether fitting and proper that as a result to an appreciable extent of these efforts, combined, to be sure, with the achievements now of many other men, the author can begin to see the real possibilities of the development of several successful gas turbines on the part of numerous groups. This new but old form of prime mover is destined to play a very important role in our industrial life.

Another important achievement, for which it is believed the author is more responsible than any other one man and regarding which he says nothing in his paper, but which came as a by-product of his other work, was the development of the gear-driven centrifugal supercharger for airplane engines. This machine is now used on practically every military airplane engine in the world whether or not a turbosupercharger is used. A very large number of these have been produced from the designs of the division of the General Electric Company that the author organized.

It is, of course, unfortunate that the requirements of the national war effort limit the matters which the author could have discussed in this paper. Such will not always be so, and the sequel to this paper written by the author or others will make interesting reading when that time comes.

The very complete Bibliography will undoubtedly prove to be a particularly helpful tool to the many others now working in this field.

Author's Closure

The author feels highly complimented by the discussions which have been contributed and wishes to express his thanks and appreciation. A number of the discussions are by eminent authorities who have had actual experience with the subject so that they add a great deal to the author's presentation. The author also is thankful for a number of new references which may increase the bibliographical value of the paper. Some of these are given in the discussions, and a few have been communicated to the author and are added to the list of references.

As several of the discussers have mentioned, some of the items presented in the paper already are known to some extent. However, correspondence which the author has received indicates that even though some items may be known to some of the older generation, it is desirable to include them all for the sake of completeness and for the benefit of the younger generation. They are the ones who are to have the task of bringing the gas turbine to the successful fruition which is foretold by the present situation.

In spite of some belief to the contrary, the author feels that the ultimate gas turbine will successfully and conservatively operate at very high temperatures. Fig. 12 of the paper, and colored photographs that have been taken, of nearly white-hot nozzle boxes and red-hot turbine wheels, are visual evidence of the purpose of the portion of the paper devoted to turbosuperchargers, which is to show the enormous contributions that the thousands upon thousands of these turbosuperchargers now in use are making to the art of operating turbines safely at very high temperatures.

The author can add from personal knowledge, to the discussion kindly given by Mr. Haverstick of the De Laval Company. The Sherbondy apparatus that Mr. Haverstick mentions started out as a design sent from France by Rateau to his American agents, the Rateau-Battu-Smoot Company, and no doubt shown in Mr. Haverstick's Fig. 14. But there was great change from this design of Rateau in the course of the development work by Sherbondy and Fergus Motors. One of the changed models is given in the 1927 New York edition of Stodola (25),[16] as Mr. Haverstick states. But the accompanying diagram (Fig. 1086) is not, as stated by Stodola, the General Electric apparatus, but is a general diagram of the cycle, probably first presented by Rateau. The General Electric details always differed materially from Rateau or Sherbondy. Major George E. A. Hallet had charge during this period of the Powerplant Division of the United States Army Air Corps, McCook Field, Dayton. He wrote at the time ($44^1/_2$,) which gives further details of this period, " . . . . . no way was seen to overcome the faults of the Sherbondy machine. Therefore, the latter was dropped and General Electric was given a contract to rebuild the old supercharger designed by Dr. Moss." Major Hallett recently gave similar details, which have been quoted by Frederick Neely.[17] The Rateau machine did operate in France and was given a test in England. But as the author and other General Electric engineers have learned the hard way, it is one thing to have apparatus that operates on paper or on test, and another to obtain actual service on many airplanes at high altitude. The "know-how" that Mr. Sidler of Brown Boveri appropriately mentions only is obtained through such experience.

There has been included the oft-repeated gas-turbine thermodynamics only by citation of references. But one thermodynamic item that probably is novel has been called to the author's attention by Mr. F. K. Fischer of the Westinghouse

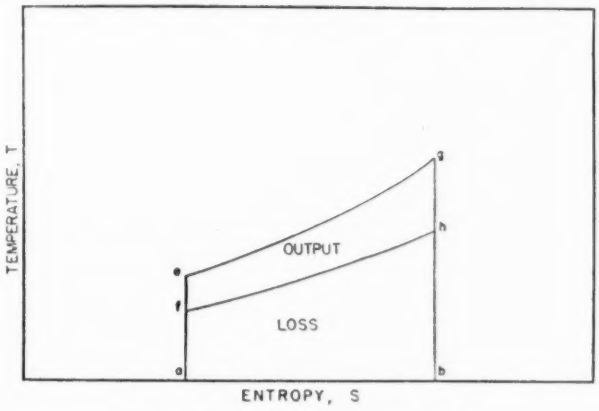

FIG. 23 SIMPLE GAS-TURBINE CYCLE

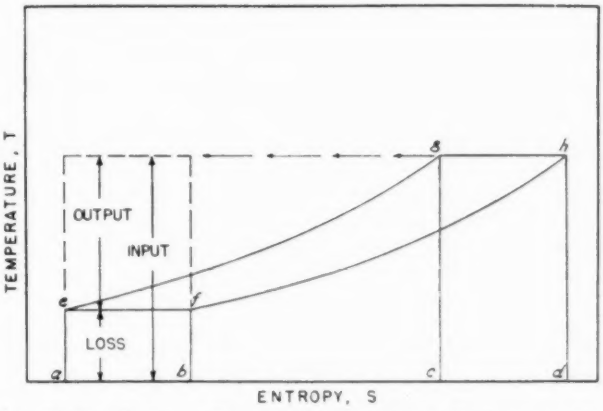

FIG. 24 GAS-TURBINE CYCLE WITH COMPLETE REHEATING, REGENERATION, AND INTERCOOLING

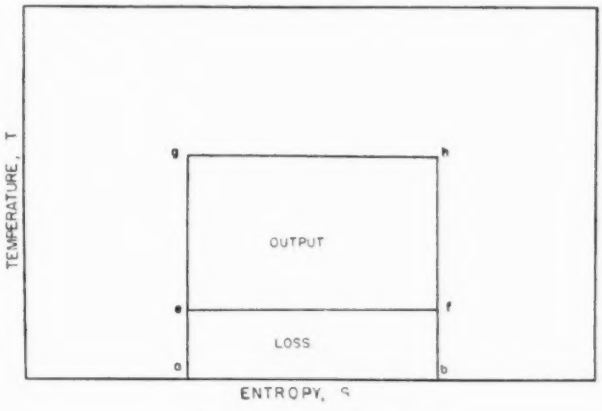

FIG. 25 CARNOT CYCLE

Company, Philadelphia, and Mr. Lee J. Fischer of the General Electric Supercharger Division, Lynn, Mass., and seems worthy of inclusion as follows:

Although the simple gas-turbine cycle, Fig. 23, has a lower efficiency than the Carnot cycle for given temperature limits, a plan with complete reheat, regeneration, and intercooling will give a theoretical cycle, Fig. 24, which has the full Carnot efficiency, which is the maximum of efficiency obtainable with given temperature limits Fig. 25. Dr. Rettaliata's Fig. 17 shows a well-known partial approach to this scheme.

The simple gas-turbine cycle, Fig. 23, consists ideally of an isentropic compression (*f* to *e*), a constant pressure heating (*e* to *g*), an isentropic expansion (*g* to *h*), and a rejection of the exhaust gases at constant pressure (*h* to *f*).

The improved cycle Fig. 24, has compression (*f* to *e*) in a compressor with sufficient intercooling to maintain practically constant temperature. The constant pressure heating (*e* to *g*) is completely accomplished through regeneration by a theoretically infinite heat exchanger, utilizing the heat of the exhaust gases (*h* to *f*, area *b-f-h-d* being essentially equal to area *a-e-g-c*). The gases are expanded (*g* to *h*), in a turbine having sufficient reheat to maintain constant temperature.

The only external heat added to the improved cycle is, therefore, that put in during the reheating process (area *c-g-h-d*). The heat rejected is that rejected to the compressor cooling medium (area *a-e-f-b*). The work done (area *e-g-h-f*), Fig. 24, practically is equivalent to a rectangular area of the same base and height. This assumes that expansion and compression through the same pressure ratio gives the same entropy increment, (which is the case with a perfect gas). Consequently, for the same temperatures, the efficiency of this improved cycle is the equal of the Carnot cycle, Fig. 25, in which the compression (*e* to *g*) practically is isentropic, the heating process (*g* to *h*) practically is isothermal, the expansion (*h* to *f*) is isentropic and the rejection of heat (*f* to *e*) also practically is isothermal.

In actual practice, therefore, if sufficient heat-exchanger surface and properly high efficiency of the various elements could be obtained, the gas-turbine cycle would be able to approach Carnot efficiency as a limit.

Of course, this only is a theoretical dream and there are a lot of limitations and practical difficulties to be overcome betore its realization even can be approached. But it is inspiring to realize that there is such a theoretical possibility even though it may take a long time to approach it.

The author has had many years of pleasant association with Mr. Glenn B. Warren and must admit the statement made in his discussion, that the development of the gas turbine has been the "grand passion" of the author's engineering career. This career no doubt now is drawing to a close; but nevertheless the author expects to see many power-plant-gas turbines commercially developed by the younger generation.

Bursting Tests of Steam-Turbine Disk Wheels

By ERNEST L. ROBINSON,[1] SCHENECTADY, N. Y.

Bursting tests on model disks of steam-turbine-rotor material both with and without a central hole show that the average hoop stress at bursting speed for a good alloy steel is likely to exceed the tensile strength of the material as determined in an ordinary tensile test whether or not the hole is present. With a good turbine-wheel material, the maximum stress at bursting speed in a flat disk, calculated on the basis of elastic theory, greatly exceeds the tensile strength of the material; and if there is a central hole, it is more than double the tensile strength. Thus a comparison of tensile strength with average hoop stress in a wheel gives a fairly reasonable estimate of the factor of safety against actual bursting. Test results are also given on low-carbon and on high-alloy materials.

DURING the past 10 years and especially since steam temperatures have increased to the level where materials suffer a gradual deformation called creep, it has become quite common to construct turbine rotors out of solid forgings instead of assembling a succession of wheels on a shaft and expecting them to stay tight by virtue of their elastic grip on the shaft. Such rotors are often quite large, and it has been thought good practice to bore an inspection hole through the geometrical center in order to be sure of the soundness of the material. Under such conditions a calculation of the elastic-stress distribution in the immediate vicinity of the central hole shows the tangential stress to rise at the edge of the hole to double the value in the center of the rotor without any hole.

There is no question as to the existence of this elastic-stress concentration, but only a limited amount of material which depends on the size of the hole is subjected to the extra stress. Thus with a ductile material it seems likely that no ill effects will be experienced in having such a local stress exceed ordinary rules of design. Thus it may be reasonable to be guided by the bore stress in a shrunk-on wheel, but it does not seem equally reasonable to count the local stress at the boundary of an inspection hole. Of course, this stress can be avoided by not boring such a hole. However, such a decision would tend to place too much reliance on the attainment of a perfect calculation and would blindly assume perfection of the material. It has therefore been deemed good practice to bore the hole and not count the local stress concentration.

The several series of tests described herewith were originally undertaken to make sure that this judgment was well founded, and this turned out to be the case.

Heat-Treated Nickel-Chrome-Molybdenum Steel, S.A.E. 4340

Chemical Composition: (Per cent) C—0.39, Ni—1.81, Cr—0.74, Mo—0.38, V—0.09, Mn—0.57, Si—0.18

Heat-Treatment: 950 C (1742 F) 8 hr furnace cool, 100 C (180 F) per hr, 650 C (1202 F) 4 hr furnace cool

The first series of wheels consisted of four flat disks 11 in. diam and $^{9}/_{16}$ in. thick, two without any center hole and two with a center hole 1.5 in. in diam. Fig. 1 shows the elastic-stress distribution in these wheels. It may be noted on the right-hand scale that the maximum stress at the center (without any hole), as given by the ordinary elastic theory, is 10,000 psi at 10,000 rpm, while the average bursting stress is 80 per cent of the maximum, or 8000 psi. The diagram also gives at the left the stresses at 40,000 rpm, the stress being greater in proportion to the square of the speed.

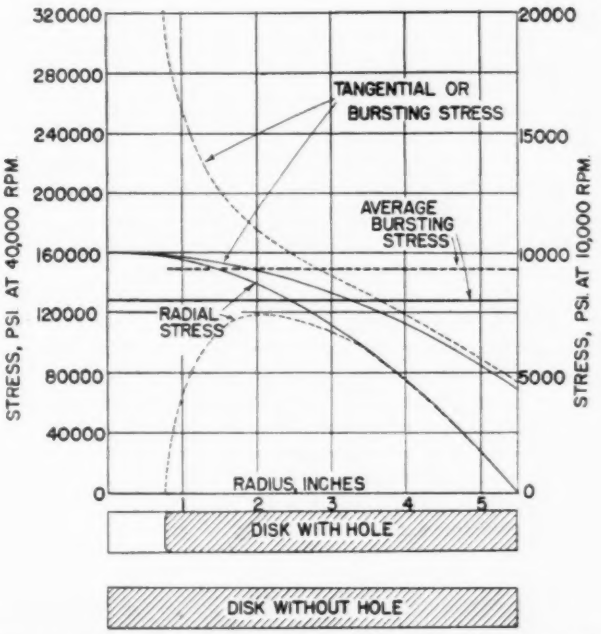

FIG. 1 ELASTIC STRESS DISTRIBUTION IN ROTATING DISKS WITH AND WITHOUT A CENTRAL HOLE

(The solid lines represent the stress distribution in the solid disk and the dotted lines the disk with hole.)

Table 1 gives the physical properties and the results of the bursting tests. Regardless of whether or not the central hole was present, these wheels burst with average stresses ranging from 121,600 psi to 131,000 psi, or 98.9 to 106.5 per cent of the tensile strength. The presence of the central hole thus reduced the actual bursting strength just about in proportion to the amount of material cut out.

The maximum center or bore stresses which would have existed at bursting speed if the wheels had remained elastic amounted to 130.1 and 131.3 per cent of tensile strength for the solid wheels and 229.3 and 213.0 per cent of tensile strength for the wheels with holes. Thus with this typical steam-turbine-rotor material the average bursting stress is an excellent measure of ultimate strength.

The measured deformation also given in Table 1 may or may not be significant. WB4 with center hole enlarged almost 4

per cent on the diameter; whereas, the solid wheel WB1 had enlarged less than 1 per cent on the last run before bursting. This wheel went into very small fragments, the largest "piece of pie" being just about 1/8 of the whole. Three of these fragments had radii smaller than the original wheel as if bursting had released a star- or spider-shaped void in the center and allowed the rim to go scallop-shaped. Undoubtedly it is necessary to take note of such behavior in order to understand the results and assign proper significance to them.

original 11 in. may be seen plainly on the foot rule. The thinning toward the center is also perceptible below the straight edge of the rule. The white paper sticking out of the center hole shows how much it has enlarged over the original 1.5 in.

LOW-CARBON STEEL, S.A.E. 1020

Chemical Composition: (Per cent) C—0.15 to 0.25, Mn—0.30 to 0.60

Heat-Treatment: 850 C (1562 F) oil quench, 650 C (1202 F) air cool

The second series of wheels consisted of four flat disks just like those of the first series. In addition, there were two more disks made with the bottle-shaped cross section necessary to give a uniform distribution of stress over the entire interior of the wheel as shown in Fig. 3. These two wheels were designed to get the maximum peripheral speed out of a given material. They are directly comparable with the flat wheels of 11-in. diam, since the elastic stress at 10,000 rpm is also 10,000 psi. This stress, as with the flat wheels, would rise to 160,000 psi at 40,000 rpm. However, whereas the stresses in the flat wheel fall off from the maximum at the center to much lower values toward the outside, both the radial and tangential stresses remain equal and of constant magnitude from the center to the inside of the small rim. In the rim there is a slight falling off of the hoop stress, and within the small increase of dimension the radial stress drops rapidly from its maximum value to zero at the outside.

Thus these six wheels of the same material all have strictly

FIG. 2 NICKEL-CHROME-MOLYBDENUM STEEL DISK, WB4, 11 IN. DIAM AFTER RUN AT 36,000 RPM
(Enlargement at rim, 2.2 per cent; at hole, 21.2 per cent; thinning at rim, 1 per cent; at hole, 9.7 per cent.)

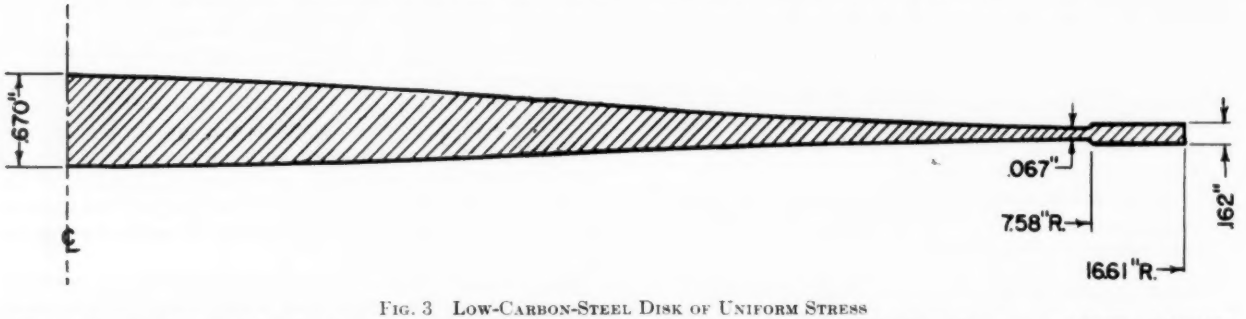

FIG. 3 LOW-CARBON-STEEL DISK OF UNIFORM STRESS
(The small rectangular rim takes the place of a bucket loading and is the only portion of the wheel in which the uniform stress of 10,000 psi at 10,000 rpm is not maintained. The thickness in inches, t, of this wheel at any radius r in inches is given by the formula $t = 0.670\ e^{-0.04r^2}$ where 0.670 in. is the center thickness.)

The solid wheel WB3 thinned 16.3 per cent at the center, an amount in excess of the elongation in the tensile test. The other wheels thinned about 2/3 as much. The center holes enlarged approximately one third from 1.5 in. diam to about 2 in. diam.

Fig. 2 shows one of these disks, WB4, with the central hole, after it had been run to 36,000 rpm, very close below the bursting speed of 36,120 rpm. The enlargement of diameter over the

comparable elastic-stress distributions at the same speed. In the two solid wheels the maximum elastic stresses are the same, but localized around the center of the flat wheel and of wide extent in the bottle-shaped wheel. In the flat wheel with the central hole the elastic-stress distribution in the outer half radius or 3/4 of the volume is very close to that in the flat wheel without any hole. However, in the inner half radius, comprising less than 1/4 of the volume of the wheel, the elastic stress rises

[a] Based on diameter after last run before bursting.

to a maximum value at the bore which is twice what it is in the other wheels. (Precisely speaking, this ratio is nearer 201 per cent than 200 per cent.)

This material was chosen as representative of very ductile materials, and it was heat-treated for maximum ductility. In examining the results, it is necessary to keep these facts in mind. The tensile test shows a real "yield point" where the material refuses to hold until it has stretched a considerable amount. After this stretching has occurred, it holds again, but this kind of ductility has its disadvantages.

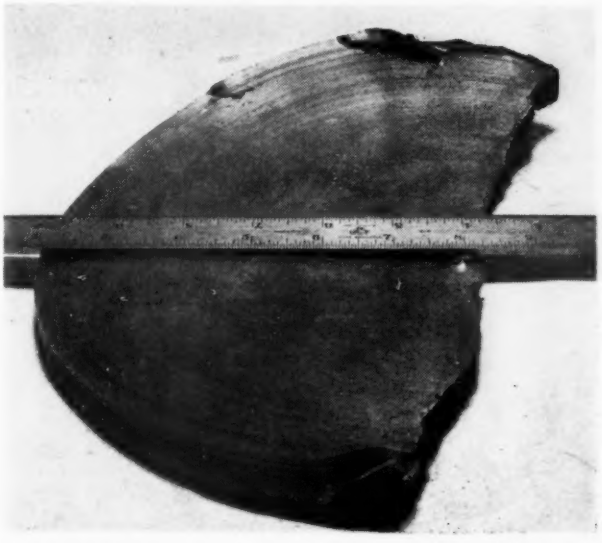

FIG. 5 LOW-CARBON-STEEL DISK WB5, 11 IN. DIAM AFTER BURSTING AT 29,000 RPM

(Enlargement at rim 9.1 per cent; thinning at rim, 5 per cent; at center, 38.4 per cent. Note that this is just about a full half wheel. The rupture is close to perpendicular to the plane of the disk.)

much as it got longer which is like a tensile bar. The wheel as a whole got thinner at the center, 38.4 per cent in each case, as compared to 37.5 per cent elongation in the tensile test. In each case this is the deformation in the direction of the axis of deformation, although the nature of the deformation is completely opposite. In the tensile test, the bar is pulled along its axis and goes in from all sides. The bursting disk is pulled out in all directions and goes in along its axis.

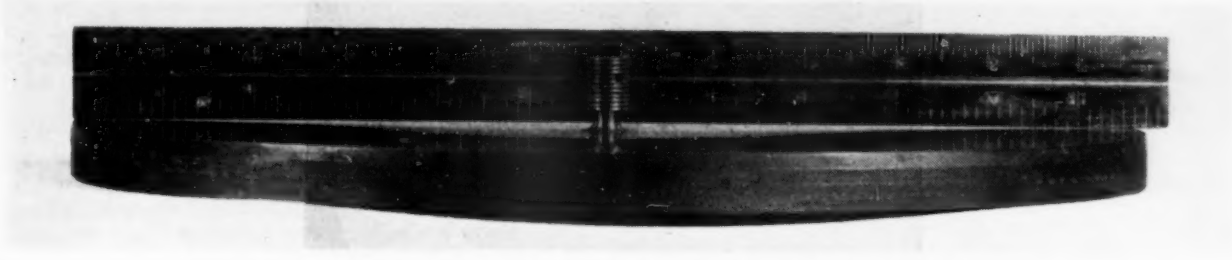

FIG. 4 LOW-CARBON-STEEL DISK WB7, 11 IN. DIAM AFTER RUN AT 28,320 RPM

(Enlargement at rim, 5.5 per cent; thinning at rim, 2.7 per cent; at center, 9.7 per cent.)

Table 2 gives the physical properties and the results of the bursting tests. The two solid wheels, WB5 and WB7, burst with average stresses based on the original dimensions of 98.8 per cent and 101.6 per cent of the tensile strength. However, the wheels enlarged 9.09 per cent and 7.37 per cent, respectively, with corresponding increases in the actual centrifugal bursting forces. Thus, going by the enlarged diameters, these wheels actually had average stresses at bursting of approximately 108 per cent of tensile strength. A pretty good case could be made out for basing the actual stress on the square of the enlarged diameter; but, since the centrifugal force itself goes only with the first power of the radius, such a procedure would correspond with the occasional practice of computing tensile strength on the basis of the reduced section instead of on the original dimensions. Analysis in terms of the original dimensions has the advantage that such dimensions are known in advance.

Note that the circumference got thinner about one half as

The two wheels with holes burst at too low speeds to develop average stresses equal to the tensile strength even if credit is allowed for the enlargement at the rim. (This has not been done in the table where all calculations are based on original dimensions.)

The rims got thinner almost as much as they got larger, but the center holes enlarged more than 40 per cent and only thinned less than 20 per cent.

The enlargement of these wheels was less than one half as much as the solid wheels. Apparently this material has a kind of ductility that does not allow all portions of these wheels to participate in the job of resisting the centrifugal force. The burst takes place at a time when the rim is not able to do its share in carrying the load or at least has not yet picked up its full share.

Fig. 4 illustrates WB7 after having been run at 28,320 rpm which is a little more than 1000 rpm below its bursting speed of 29,400 rpm. The foot rule in this picture shows plainly the

(Enlargement at rim, 9.5 per cent.)

enlargement of the diameter of the disk and its thinning toward the center.

Fig. 5 shows the fracture in the case of disk WB5. This appears to be a rather characteristic fracture. It seems necessary to conclude that, however instantaneous the burst, the fracture started at the center and finished up at the outside. There appears to be a tendency for these wheels in the final stages of enlargement to try to neck down on two perpendicular diameters, thus ever so slightly trying to make a square out of a circle.

Strain Lines. Fig. 6 shows the appearance of strain lines on the surface of disk WB8 after having been run to 20,100 rpm. The markings originate at the bore which is the first part of the wheel to attain a stress in excess of the yield point of the material. Fig. 7 shows the appearance of the same disk after having been run to 21,300 rpm. The markings have now reached the periphery of the disk while the region around the central hole has cleared up. Fig. 8 shows the appearance of the other identical disk WB6 after having been run to 22,380 rpm. The entire inner quarter of the surface out to the half radius of the disk has now cleared up.

Uniformly Stressed Wheels. The two wheels of uniform stress developed slightly less than full tensile strength on the basis of their original dimensions. However, it should be noted that WB9, shown in Fig. 9, enlarged from $16^{5}/_{8}$ to $18^{3}/_{16}$ in. diam or almost 10 per cent without bursting. Based on the actual centrifugal force with these enlarged dimensions, this wheel developed at least 105 per cent of tensile strength when it burst. While the flat wheels appear to have all burst from the center, these wheels of uniform stress both lost their rims, and neither gave way anywhere throughout the whole central web.

Peripheral Speeds. It is noteworthy that WB3 which was just a flat wheel with a tensile strength of 123,000 psi attained a peripheral speed of 1975 fps at bursting, and that WB9 with the theoretical shape and a tensile strength of only 68,650 psi attained a peripheral speed of 2025 fps at bursting. (In each case credit is here taken for the enlargement of diameter.) These figures give some indication as to the real value of design shape. Thus in this comparison the special contour of the wheel of uniform stress enabled a material 56 per cent as strong to attain fully as high a speed, or even a trifle higher.

Cyclops 17W

Chemical Composition: (Per cent). C—0.49, Mn—0.68, Si—0.60, Cr—13.30, S—0.012, P—0.020, Ni—19.31, Mo—0.68, W—2.30 (Allegheny Heat 34413).

Heat-Treatment: Preheat 5 hr at 1500 F; transfer to 2100 F and hold for 1 hr; forge to within 10 per cent of finished forging thickness; cold work at 1200 F to finished size; anneal 2 hr at 1200 F.

The third series of tests consisted of four 10-in-diam wheels of Cyclops 17W material $^{7}/_{16}$ in. thick, two without center holes and two with center holes 1.364 in. diam. This size of center hole bears the same relation to the over-all diameter as the 1.5-in-diam hole in the 11-in-diam disk. Thus all stresses are comparative with the first two series at a speed ratio of 11/10. In other words, the stresses in the 10-in. disks when running at 10 per cent higher speed are the same as in the 11-in. disks.

The results of the bursting tests are given in Table 3. The two solid wheels burst with average stresses of 77.4 and 81.3 per cent of the tensile strength. If perfectly elastic at bursting, the maximum stresses would have been 95.7 per cent and 100.6 per cent of tensile strength.

The two wheels with holes in them burst with average stresses 79.7 per cent and 81.2 per cent of the tensile strength. If they had remained elastic, the maximum stresses would have been 171.3 and 174.8 per cent of the tensile strength.

It is a noteworthy happenstance that the two wheels without holes in them burst when the maximum elastic stress reached 100 per cent of the tensile strength. This is not a reliable criterion for bursting, however, because the maximum elastic stress in the wheels with holes reached almost 75 per cent over the tensile strength.

For these wheels the best rule for bursting would be to say that they would develop an average stress equal to 80 per cent of the tensile strength, and this would be approximately true whether or not there is a center hole.

FIG. 10 GAMMA COLUMBIUM DISK G4, 10 IN. DIAM, WITH 1.364-IN-DIAM HOLE AFTER BURSTING AT 37,200 RPM

(Note that the wheel has quartered itself. The rupture in the foreground approximates 45 deg to plane of disk, except near the center hole.)

two solid wheels burst with average stresses 82.8 per cent and 83.2 per cent of the tensile strength. Had they remained elastic, the maximum stresses at bursting would have been 102.0 per cent and 103.0 per cent.

The two wheels with holes in them burst with average stresses 79.2 per cent and 81.8 per cent of tensile strength. If they had remained elastic, they would have burst with maximum stresses of 169.8 per cent and 175.8 per cent of tensile strength.

The behavior of these wheels was remarkably similar to the behavior of those in the third series, and the same remarks might be made about them.

Fig. 10 shows typical fragments, illustrating the manner in which the wheels of the three high-alloy series burst. The sequence of the several types of rupture is not so clear as for the single type illustrated in Fig. 5. Certain interesting speculations might be indulged in as to what type of stress or strain reached a limiting value and constituted itself the trigger to release the burst. It seems certain that a variety of limitations can be observed among the various types of break so that the most useful conclusion is that no one theory of failure can be relied on to represent all conditions of stress or strain.

TIMKEN "25-16-6"

Chemical Composition: (Per cent) C—0.15, Mn—1.14, P—0.010, S—0.022, Si—0.84, Cr—16.75, Ni—25.26, Mo—6.29, N_2—0.175 (Heat No. 0213)

Heat-Treatment: Same as for Cyclops 17W

The fifth series of tests consisted of four wheels of Timken 25-16-6 material, $^7/_{16}$ in. thick, all 10 in. diam, except T1 which was 8.517 in. diam. As in the third and fourth series, two wheels were solid and two had center holes 1.364 in. diam.

The results of the bursting test are given in Table 5. The two solid wheels burst with average stresses 71.6 per cent and 61.5 per cent of tensile strength. If they had remained elastic, the stresses at bursting speed would have been 88.6 per cent and 76.2 per cent of tensile strength.

The two wheels with holes in them burst with average stresses 75.2 per cent and 72.5 per cent of tensile strength. If they had remained elastic, the stresses at bursting would have been 156.9 per cent and 156.4 per cent of tensile strength.

The behavior of these wheels differed somewhat from that of all the other series. The average stresses at bursting speed were lower relative to the tensile strength than for any of the other materials, being 71.6 and 75.2 per cent, respectively, except for T4 which developed only 61.5 per cent.

It is noteworthy that the wheels with center holes actually ran to practically the same bursting speeds as the solid wheels. The average stress at bursting was actually a higher percentage of the tensile strength in the wheels with holes than in the solid wheels.

[a] Wheel T1 was actually only 8.517 in. diam and burst at 42,000 rpm; 36,200 rpm would give the same average stress with a 10-in-diam wheel. The elastic stress is based on the actual original dimensions.

THE HIGH-ALLOY MATERIALS

As a lot, the materials of the third, fourth, and fifth series differ in certain characteristics of performance from those of the first two series. They are like the first two series in that all the bursts on flat wheels appear to originate at the center where both the elastic stress and the measured strain are maximum. However, the three high alloys show a change of center thickness or bore diameter around one third of the percentage elongation in the tensile test while the carbon-steel and nickel-chrome-molybdenum wheels show corresponding deformations equal to or greater than those attained in the tensile test.

If there is a quality that might be called "biaxial ductility," the wheels of the first two series might be said to possess it while those of the last three series are not so ductile under biaxial stress regardless of the tensile-test results.

However, in spite of this condition, these high-alloy materials develop average bursting stresses of about the same level relative to their tensile strengths as the very ductile carbon steel. But none of them equals the nickel-chrome-molybdenum material in developing an average bursting stress equal to or greater than the tensile strength.

The nickel-chrome-molybdenum steel has both biaxial ductility and a continuously increasing strength with deformation. It has no region of weakness such as the carbon steel displays when "the beam drops" in the tensile test.

TABLE 6 PERCENTAGE ELONGATION IN TENSILE TEST AND SPEED REDUCTION DUE TO CENTER HOLE OF VARIOUS MATERIALS

	Elongation in tensile test, per cent	Speed reduction due to center hole, per cent
Low-carbon steel	37.5	16 to 17
Ni-Cr-Mo steel	15.0	6 to 10
Gamma Columbium	15 to 18	6 to 8
Cyclops 17W	15 to 18	3 to 5
Timken 25-16-6	11 to 17	0 to 5

The lower ductility of the high alloys would suggest that these materials might be more sensitive to the elastic-stress concentration near the center hole shown in Fig. 1. However, the results, collected in Table 6, appear to show these materials to be even less sensitive than the more ductile materials.

The actual bursting speeds of the various wheels were influenced by some variation in tensile strength for which it would be proper to make some correction. However, it is impossible to escape the conclusion that the most ductile material at the top of the list, the carbon steel, loses most due to the hole, while the least ductile material at the bottom of the list is very little affected by the center hole.

It is to be noted that the two carbon-steel wheels with center holes did not enlarge so much in over-all diameter as did the solid wheels with no center hole, although the center holes in the low-carbon steel had the greatest percentage enlargements measured in any of the wheels. It may be that the rims had not yet stretched enough to be carrying their fair share of load while the holes were working at the limit of what the material was good for.

At the bottom of Table 6, the high-alloy materials may have had the elastic-stress concentrations to some degree neutralized by the cold work during heat-treatment. Thus these disks may initially have been in a state of internal compression with the rim in tension like the tire on a wagon wheel. This would give the outer portions of the disk a head start toward carrying a fair share of the bursting load in contrast to the handicap in the case of the rims of the low-carbon steel disks.

These tests do not include any comparisons with small and highly localized concentrations such as would be caused by keyways, bolt holes, pinholes, or balance holes. It is, however, evident that the manufacture of a high-speed wheel is a complex art which involves much more than any mathematical analysis of stress distribution. Furthermore, these tests do not reflect any evaluation of the high-temperature qualities of the various materials. That would be quite another story.

Factors of Safety and Criterions of Failure: It would seem that a series of tests to complete destruction should offer some useful data relative to factors of safety and criterions of failure. In considering these questions, it is necessary to decide on a point of view as to what constitutes a failure.

It is no doubt legitimate to call a bad case of malfunctioning due to unbalance, with consequent vibration, a failure. Similarly, a gradual loss of clearances with resulting rubbing, injury to packings, and consequent deterioration of efficiency might be called failure. But failure is a rather strong word; and if easily repairable malfunctioning is to be called failure, what word is left for destructive rupture?

Many articles are written in which the incidence of any plastic distortion with consequent permanent set, however small, is called failure. It would be more accurate to say that elastic theory has failed to apply than that any real failure has occurred in the machine.

However, it is certainly true that there are few useful structures either among machines or buildings that do not exceed the elastic limit in many regions of local overstress. Certainly this does not constitute failure. Indeed, its occurrence is usually very difficult to detect.

On the other hand, there is usually no doubt about the complete destruction accompanying actual rupture. Largely for this reason, but also because it seems a fundamentally sound viewpoint, the wheel bursts here reported have been discussed in terms of bursting speed rather than in terms of the speed or local maximum stress at which some measurable permanent set was first detected.

Certainly elastic stresses should be computed and design proportions should take account of them, but when the question of a true ultimate factor of safety is concerned, it would seem better judgment to compare operating conditions with actual rupture rather than with some half-way point of less critical significance.

Conclusions

The fact that the average bursting stress frequently equals or exceeds the tensile strength throughout the first series of tests shows that in some locations there must be maximum stresses considerably in excess of the tensile strength, since it is hard to believe that the leveling effect of the plastic yielding can have completely reduced all stresses to the average value. Thus it is necessary to conclude at least for the nickel-chrome-molybdenum steel, that the biaxial-stress distribution has some strengthening value which would tend to justify the maximum-strain theory of ultimate failure. In other words, looking at the center of the solid wheels, the presence of two equal stresses at right angles to each other enables each to attain a higher value than it could if deformation were not in part restrained by the presence of the other stress.

It might be possible to study the redistribution of stress during the plastic enlargement of the disk by noting the change of thickness along the radius. However, the fact that carefully duplicated bars show widely varying plastic behavior under stress suggests that such a detailed analysis would not be fruitful of any useful information.

The most important item of information given by these tests is that with ductile materials such as here tested the real factor of safety against bursting may be more closely estimated by comparing the average bursting stress with the ordinary tensile strength than by trying to go by the maximum elastic stress. Thus, the weakening effect of an inspection hole is nowhere near the 50 per cent that elastic theory suggests. In fact, with the type of material most likely to be used, the weakening effect is no more than in proportion to the material removed.

Acknowledgments

The author wishes to acknowledge the generous co-operation of K. D. McMahan of the General Electric Research Laboratory in Schenectady, E. E. Stoeckly of the Supercharger Engineering Division, and W. L. Badger, Thomson Laboratory, both of River Works of the General Electric Company, West Lynn, Mass. together with their respective associates.

Appendix

The formulas for elastic stress distribution in flat disks with and without central hole are collected herewith for convenient reference. Note that the centrifugal force per cubic inch of steel is

$$8N^2r$$

where r is the radius in inches and N the speed of rotation in thousands of revolutions per minute. (The even figure 8 happens to be correct for the density of steel. For other metals, this figure should be multiplied by the density relative to steel.)

Elastic-Stress Distribution in a Flat Steel Disk

The elastic distribution of the stresses in a flat disk due to centrifugal force is described by the following formulas:

Hoop stress at any radius r in a solid flat disk of diameter $2R$ is

$$N^2[(3 + n)R^2 - (3n + 1)r^2]$$

where n is Poisson's ratio.

The radial stress is

$$N^2[(3 + n)(R^2 - r^2)]$$

The maximum value of each occurs at the center and is

$$N^2[(3 + n)R^2]$$

Hoop stress at any radius r in a flat disk of diameter $2R_2$ with a central hole of diameter $2R_1$ is

$$N^2\left[(3+n)\left(R_2^2+R_1^2+\frac{R_2^2R_1^2}{r^2}\right)-(3n+1)r^2\right]$$

The maximum value occurs at $r=R_1$

$$2N^2[(3+n)R_2^2+(1-n)R_1^2]$$

The radial stress is

$$N^2\left[(3+n)\left(R_2^2+R_1^2-\frac{R_2^2R_1^2}{r^2}-r^2\right)\right]$$

Average Bursting Stress in a Flat Steel Disk

Regardless of the stress distribution throughout the volume of the disk, the average bursting stress may be computed by dividing the total centrifugal bursting force by the total area of cross section.

The average bursting stress in a flat disk of diameter $2R_2$ with a central hole of diameter $2R_1$ is

$$\frac{8}{3}N^2\frac{R_2^3-R_1^3}{R_2-R_1}$$

If there is no central hole the average bursting stress in a flat disk of diameter R is

$$\frac{8}{3}N^2R^2$$

The ratio of the average bursting stress in the solid flat disk to the maximum stress at the center under elastic conditions is

$$\frac{8}{3}N^2R^2/N^2[(3+n)R^2]=\frac{8}{3(3+n)}$$

For various values of n this ratio is as follows:

n	$\frac{8}{3(3+n)}$
0.25	0.820
0.30	0.808
0.33	0.800
0.40	0.784
0.50	0.762

Computation of Centrifugal Bursting Stress for Special Steel Shapes

In any particular wheel, the average centrifugal bursting stress may be computed as follows where t is the thickness in inches:

$$\frac{8N^2\int tr^2dr+\frac{N^2}{2\pi}\times\text{total radial bucket load at 1000 rpm}}{\text{Cross-sectional area of disk profile from center out}}$$

For a section of uniform thickness

$$8N^2\int_{R_1}^{R_2}tr^2dr=8N^2t\frac{R_2^3-R_1^3}{3}$$

For a section of conical profile whose thickness is t_1 at R_1 and t_2 at R_2

$$8N^2\int_{R_1}^{R_2}tr^2dr=8N^2\left[(t_2+AR_2)\frac{R_2^3-R_1^3}{3}-A\frac{R_2^4-R_1^4}{4}\right]$$

where $A=(t_1-t_2)/(R_2-R_1)$

For a section of hyperbolic profile defined by the relationship

$$\frac{t}{t_2}=\left(\frac{R_2}{r}\right)^k$$

$$8N^2\int_{R_1}^{R_2}tr^2dr=8N^2\frac{t_2R_2^k}{3-k}(R_2^{3-k}-R_1^{3-k})$$

In the last case the corresponding area of cross section between R_1 and R_2 is

$$\int_{R_1}^{R_2}tdr=\frac{t_2R_2^k}{1-k}(R_2^{1-k}-R_1^{1-k})$$

The area for the first two profiles is easily computed without formulation.

Discussion

Hans Dahlstrand.[2] A short time ago the writer's company made similar tests to those of the paper on disks machined from a large forging which was scrapped because of flaws in one end of the forging. These flaws consisted of inclusions and pin-point cavities which occasionally occur in forgings. Normally, flaws of this type will cause the forging to be scrapped if they are located at a critical point or if the flaws cover a large area. There are at present no reliable means by which the extent of such flaws below the finished surface may be examined; consequently, the decision of whether or not the forging is suitable for use rests largely upon the judgment of the engineer. It is clear that any cracks or seams cannot be tolerated, as during operations flaws of that nature are likely to increase until bursting occurs.

The purpose of the tests was to determine the extent to which the inclusions and round cavities would affect the ductility and the strength of the steel. Several disks from this forging, both from the area showing the flaws and from areas showing sound metal, were machined for the tests. While the report of tests has not been fully completed, it is sufficient to mention that flaws of the nature described do not materially affect the strength or the ductility of the steel. It is therefore concluded that forgings having such flaws may be used with safety without any particular danger. Care nevertheless must be exercised in the examination of the flaws before approving the use of such forgings, as it is reasonable to assume that these flaws may be of such nature and cover such large areas at vital points that the forgings could not be safely used.

R. V. Kleinschmidt.[3] Perhaps the most interesting data presented in this paper, and material which would warrant very careful study, are the behavior of the disks at speeds lower than the rupturing speed. The study of distortion gives considerable insight into the actual phenomena occurring. It would be interesting to have more consideration of the phenomena of distortion, and some comments as to the practical possibilities of prestressing wheels by overspeeding to stabilize the deformations before final finishing and assembly.

The findings on the importance of ductility in relation to stress concentration around a central hole are somewhat surprising until we realize that all of the materials tested were sufficiently ductile to permit the necessary relief of stresses without

[2] Consulting Engineer, Steam Turbine Department, Allis-Chalmers Manufacturing Company, Milwaukee, Wis. Mem. A.S.M.E.

[3] Commander, U.S.N.R., Bureau of Ships, Navy Department, Washington, D. C. Mem. A.S.M.E.

rupture. An extension of the tests to materials having 2 to 5 per cent elongation would probably present another story. Also, it must be remembered that these remarks apply to a central hole with uniform stress conditions around it. It is doubtful if similar conclusions can be drawn with respect to holes eccentrically placed. Possibly the author could comment upon experience with such holes in disks.

Another item which has not been mentioned and which must be considered is that of temperature effects. There are three interesting conditions which come to mind: (1) Uniform high temperature or low temperature, will change the strength and ductility relationships of the materials. Atmospheric tests alone may be misleading at other temperatures. (2) Stresses due to nonuniform temperature distribution. In this connection one possible type of nonuniform temperature distribution would appear, from the data given, to be very serious, namely, a cooled disk with a hot rim. (3) Temperatures varying rapidly with time as in heating up and cooling down. One of the major problems in gas-turbine development may be the possibility of changes of several hundred degrees in the temperature of the working fluid in a fraction of a second.

R. P. Kroon.[4] It is a commonly accepted idea that when a ductile material is under steady load, a local stress concentration is not too serious. It is assumed that there will be some plastic flow, after which the stresses will be distributed more evenly. This presupposes that the amount of local deformation will not be sufficient to cause rupture.

On this basis the notion that average stress instead of local peak stresses should be a criterion for disk failure seems sound enough.

We are confronted, however, with the results shown in Table 6, indicating that "the most ductile material loses most due to a hole."

It would certainly be interesting to establish whether this behavior is due to some internal-stress condition of the disks or whether the type of stress-strain curve of the material might play a role. A mathematical analysis might prove helpful in the latter case.

The high-temperature alloy disks with holes, examined by the author, have elongations of at least 15 per cent and fail at stresses in the order of 120,000 psi at room temperature.

In high-temperature service these materials would be loaded with stresses of perhaps 30,000 psi, and their elongation, with a reasonable service life, would be only a few per cent.

It would be extremely interesting to know whether under high temperature, with creep as the dominant factor, the comparison of disks with and without holes would be similar to that established at room temperature. Can the author throw any light on this phase of the disk problem?

J. A. Maul.[5] This paper has positively answered a question which has been an open point for discussion in the dynamometer engineering section of our company for several years, i.e., the possibility of taking advantage of the fact that a solid wheel theoretically has only one half the maximum stress of a corresponding wheel with a small central hole. Cracks at the center of a forging or minute openings between the grains may be the equivalent of a central hole.

It is important to know that we can run a solid wheel to higher speed than the corresponding shrunk-on shaft construction. However, the writer would be interested in knowing how much faster the solid wheel could be run. Evidently the limiting feature in the case of the solid wheel would be the ductile expansion of the outer surface of the wheel. In the case of a shrunk-on wheel, the limiting feature would be the expansion of the bore to the point where the wheel loosened on the shaft.

D. J. McAdam, Jr.[6] The writer cannot agree that the evidence presented by the author gives a basis for conclusions as to criteria for "failure."

The combination of principal stresses affects all three strength indexes; yield stress, ultimate stress, and breaking stress.[7,8,9] In considering criteria for fracture, one should compare "true" breaking stresses under different stress systems, and allowance should be made (if possible) for differences in total plastic deformation under the two conditions. The author, however, compares the breaking stress, either average or "elastic," with the tensile strength of a specimen under unidirectional loading. The "true" breaking stress under unidirectional loading would be somewhat greater than the ultimate stress, and probably would be greater than the breaking stress under biaxial loading. The higher value under uniaxial loading, however, would be due to the greater total plastic deformation. The relative values of the two technical cohesion limits would be the resultant of two factors, total plastic deformation (ductility) and the stress system. As the ductility (measured by decrease in sectional area) was much less for biaxial than for uniaxial loading, the influence of the stress system cannot be determined from the experiments.

For a brittle metal, the technical cohesion limit probably would be greater under biaxial than under uniaxial loading. Such a relationship, however, would not necessarily mean that the criterion for fracture is the greatest principal strain. As illustrated in Fig. 17 of a paper by the writer,[7] the criterion for fracture possibly is a function of both the volume stress and the greatest principal stress; if not, the criterion must be expressed in terms of the three principal stresses.

Arthur McCutchan.[10] This paper is a straightforward account of tests made to verify engineering judgment regarding the significance of certain types of stress concentration. Such tests insure that results of stress analysis will be considered in their proper perspective.

The improvement in performance of the wheels made with a special contour giving a uniform stress throughout the wheel is noteworthy. An examination of the cross section of this special design, as shown in Fig. 3 of the paper, however, suggests that straight lines giving a trapezoidal shape would be simpler to produce than the double-curve bottle shape and should give practically identical results.

The means of fastening the solid disks onto the rotating device is evident from Fig. 4 of the paper, but how this was accomplished for the disks with center holes is not shown. It would seem that any clamping or expanding device applied at or around the hole might appreciably affect the results. It would be of interest to learn how the wheels with holes were attached in making these tests.

While, as stated by the author, the evaluation of high-temperature qualities of the various materials is another story, it occurs to the writer that if spinning tests of this kind could be made at high temperatures they might furnish quite different information than conventional creep and rupture tests. For one thing, it is possible that the ductility of the high-alloy materials under biaxial stress might be more nearly like that of the carbon and low-alloy steels than found from tests at room temperature.

K. D. McMahan[11] and E. E. Stoeckley.[12] This paper confirms the intuitive beliefs of most designers of high-speed rotors who lacked actual tests to prove them. The work signals the approach of a new method of specifying materials for high-speed rotors. Fortunately, most "good rotor materials" give a higher factor of safety than classical calculations indicate. However, rotors from certain aluminum alloys, usually having low elongation in tensile tests, are known to burst at speeds equal to or below that at which the bore stress, as calculated by classical methods, equals the tensile strength. Similarly other alloys having not too different tensile characteristics behave like the turbine-rotor materials and burst at speeds corresponding very nearly to average stresses. Thus the difference in bursting speeds of similar specimens may vary almost by a factor of 2:1 for materials having the same apparent tensile strengths as determined by the usual tensile tests.

A discussion of this paper seems incomplete without mentioning the rather unique apparatus that makes these bursting tests possible. As early as 1939, the G. E. Research Laboratory, noting the work of Beams[13] and others, undertook to develop apparatus for whirling aluminum-alloy rotors weighing from 10 to 25 lb up to 50,000 rpm. Subsequently, in March, 1940, a steel rotor weighing 25 lb was burst at just under 40,000 rpm. Since the early work in the laboratory, the art has progressed beyond all early expectations, and there now seems to be no limitation to the size of rotors that may be tested by this method.

An adequate description of this test apparatus is a subject for a paper in itself. Plans have been made for such a paper when the time permits. It must suffice at present to state that the specimens are driven by a small air turbine while suspended on a small vertical piano-wire shaft in an evacuated explosion chamber.[14] The turbine mounts atop the chamber with a special seal to prevent leakage around the wire shaft.

A. Nadai.[15] The distribution of the internal stresses in a rotating steam- or gas-turbine disk which has been stressed beyond the plastic limit of the material is an attractive mechanical problem which, however, is not new. Several investigation reports have been published dealing with the analysis of this case and some related cases of biaxial stresses with a rotational symmetry in the plastic state, to which no references could be found in the paper. The writer believes that a quantitative analysis of plastic distributions of stress of this kind can give and has already given valuable information to the designers of turbine wheels, even if some of these computations have been based upon idealized conditions with regard to the flow, and despite the fact (mentioned in the paper) that duplicate tests made with bars of some of the alloy steels showed widely varying plastic behavior under stress. Whether the opinion expressed by the author "that such detailed analysis would not be fruitful of any useful information" is sufficiently justifiable or can be based on facts, must be left an open question.

Engineers are accustomed to base the design of steam- and gas-turbine disks in the elastic range of strains on the analytical methods which have been developed for such computations. It is believed that there cannot be advanced any serious reasons against attempts why these well-established methods could not be utilized with success and furnish reliable information to designers also when the plastic state has been reached in revolving disks. It may even occur that the distributions of stress in this latter state are simpler to analyze due to certain simplifications which can be introduced in the assumptions, because, for certain ductile steels (such was the case for low-carbon steel S.A.E. 1020), the tangential stresses change much less rapidly with the radial distance from the disk center, as in the elastic state. This alone probably explains several facts concerning fracture which were recorded in the author's paper in an empirical fashion.

In artillery arsenals, a related problem was investigated long ago, namely, the plastic distribution of the stresses in gun barrels which have been cold-worked and overstressed by internal hydrostatic pressure. In A. Stodola's book on steam and gas turbines, the case of an overspeeded turbine disk has been treated.[16] F. Laszlo[17] dealt with the same problem, and particularly with the stability of the equilibrium of rotating disks in the plastic state. He showed that their equilibrium may become unstable under certain conditions which depend upon the shape of the stress-strain curve of the material.

L. H. Donnell and the writer in a joint paper[18] investigated the stress distribution in rotating disks of equal thickness of ductile materials after the yield point had been reached in them. In this paper, two or three typical cases of flow were considered in detail, namely, "progressive" yielding and "complete" yielding for a material having a well-defined yield stress. In the former case, the outer portion of the disk is stressed elastically, while in the inner portion the stresses were assumed at the plastic limit. In the third case which was considered, it was assumed that the material had a stress-strain curve in which strain-hardening would become more pronounced. A case was worked out as an example in which the true stress was a linear function of the conventional permanent strains. This curve had a definite yield point and a finite slope. Such examples show that the distributions of the radial and tangential stresses can be obtained in rotating disks in the plastic state, at least in a few characteristic simple cases, in a quantitative manner. The means which are available for an analysis of the stresses in overstressed or overspeeded disks are precisely of the same or an analogous nature as those which are in use by designers in the elastic range of the strains. Stress-strain relations have been studied in the plastic range under biaxial or combined stress conditions in a satisfactory manner for moderate strains. (Such were the fairly small permanent strains which were observed in the author's overspeed tests.)

It may perhaps interest readers of the paper to note that some

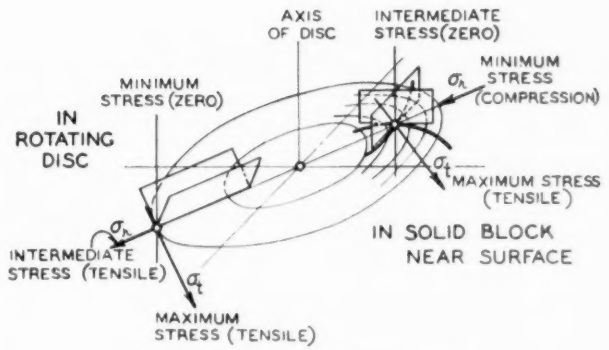

FIG. 11 ORIENTATION OF SLIP PLANES

of the author's observations, namely, those concerning the orientation of the flow figures which became visible on the flat sides of the low-carbon-steel disks, also conformed quite nicely with what was to be expected from the Mohr theory of the formation of the surfaces of slip in a ductile metal. It is characteristic that they appear usually in an orientation in which the two equivalent planes of slip in a point in a plastic metal intersect each other along the line of the intermediate principal stress. This is illustrated in Fig. 11 of this discussion, which refers to two characteristic cases of rotational symmetric plastic flow. On the right side of Fig. 11 is shown the orientation of the two slip planes in a point situated in the surface of a solid block near an impression in which high concentrated localized compression stresses are applied to the surface in the perpendicular directions to it. In this case one of the principal stresses is a high tensile stress (the peripheral stress σ_t) and the other is a compression stress (the radial stress σ_r). The direction of the intermediate stress (which in the surface is equal to zero) is therefore perpendicular to the free surface of the solid block. The two planes of slip must therefore be perpendicular to this plane and intersect the radii and concentric circles (shown in Fig. 11) under an angle of 45 deg. The flow figures should therefore consist of a series of logarithmic spirals, like the ones which are indicated in Fig. 12 of the discussion. Such flow lines are frequently observed around punched holes in heavy plates, Brinell impressions, etc., in mild steel.

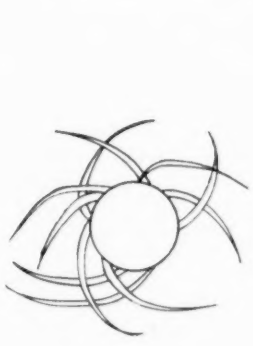

Fig. 12

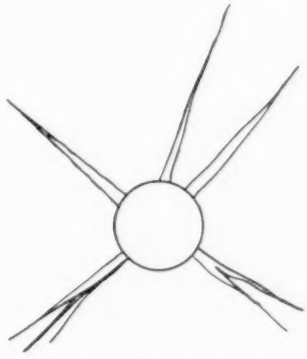

Fig. 13

FIG. 12 SURFACE OF A SOLID BLOCK NEAR AN IMPRESSION

FIG. 13 ROTATING DISK

In the case of the rotating disk, on the other hand, both principal stresses are tensile stresses. The radial (σ_r) is always smaller than the tangential (σ_t), the third one (σ_z) is again zero. The intermediate stress acts now in the radial directions. Consequently, the flow lines should appear along the radii of the revolving disks. This was the case in the Figs. 6, 7, and 8 of the paper for the overspeeded disks of low-carbon steel. The flow lines in them appeared in the directions shown in Fig. 13 of this discussion.

The tests described in the paper should throw some light on an important question, to which attention should be called also through these remarks. Suppose that a small circular hole is present in a disk which is stressed uniformly in its plane in all directions. What is the nature of the disturbance in the distribution of the stresses caused through the presence of the hole? More precisely, what is the distribution of the radial and tangential components of stress σ_r, σ_t around the hole? In an elastic material one expresses the result of such computations by stating the ratio k of the peripheral stress at the boundary of the hole to the stress in large distances of it. This is known as the factor of stress concentration. In this case it is $k = 2$. In our paper,[18] it was shown that in a rotating disk having a small hole the tangential-stress components are nearly uniformly distributed over the entire disk if the material yields under a constant stress. Since the periphery of the hole is in a state of pure tension the factor of stress concentration for a perfectly plastic disk must have been reduced to unity. From these considerations one should expect that the factor k should essentially depend upon the shape of the stress-strain curve or on the law of strain-hardening, according to which $\sigma = f(\epsilon)$, where ϵ is the plastic strain. Not much has yet become known quantitatively in this respect about values of k, the difficulty being that with the increasing stresses the dimensions of the plate near a hole must also be changing. In one case the writer has computed an exact expression for the factor of stress concentration in a plastic disk having a hole, which was uniformly stressed in its plane.[19] The strains were assumed to be small and for the material in the plastic state a stress-strain curve was assumed

$$\sigma = \sigma_0 \epsilon^m$$

or a power function (σ stress, ϵ permanent strain, σ_0, m material constants, $0 < m < 1$). Factor k for this strain-hardening law was found to equal

$$k = \left(\frac{2}{1 + 3m}\right)^{\frac{2m}{1 - 3m}}$$

which gives for

Exponent m	= 1	2/3	1/2	1/3	1/4	1/5	0
Factor of stress concentration k	= 2	1.72	1.56	1.40	1.31	1.25	1

As long as the maximum value of the peripheral stresses should occur in the boundary of the hole and not as it could in some special cases also occur, in the interior of the disk, one would expect that the material should break at the hole in pure tension. It would, however, not be permissible to base the design on the value of the tensile strength or of the true fracture stresses which were observed in ordinary tensile tests run with standard round bars, because necking in a plate around a hole or in a wide flat bar under tension must be restricted, compared to the usual mode of necking in the standard round-bar tensile test. This points to the need of studying fracture conditions in the ductile metals under special conditions which cannot be reproduced through the standard tensile test.

E. M. PHILLIPS.[20] The author's tests indicate the previously accepted theory of safety as dependent upon the maximum elas-

tic stress to be in error. The evidence presented shows rather that safety is dependent either upon the average stress or upon the ductile properties at the point of maximum elongation or reduction in area.

These tests were made upon smooth wheel disks. Disks having points of stress concentration may be expected to show less favorable performance. Table 7 of this discussion shows fracture results on nine shaped turbine-wheel disks $9^9/_{16}$ in. diam, bolted to a shaft hub through three reamed holes $^7/_{16}$ in. diam on a radius of $2^3/_4$ in. These holes are rounded by $^1/_8$ in. radius at the disk faces. In addition, there is a male rabbet $1^9/_{16}$ in. diam joined to the disk face by a radius of $^5/_{32}$ in. Breaks in these disks pass through the attaching holes and are probably influenced by the concentrations at the holes and at the rabbet. The table also includes tensile-test properties taken from broken sections of the disk. The test elongation values may have been influenced by the cold work in bursting.

It is interesting to note that the tensile strength at the center varies from 80 per cent to 100 per cent of that at the rim, the average value being 88 per cent.

In comparison, Table 8 herewith indicates a reduction due to stress concentration as high as 32 per cent when based upon center properties and 37 per cent when based upon rim properties.

ARTHUR M. G. MOODY.[21] Mr. Robinson's valuable paper supplies us with a good deal of quantitative information in a field where we have been largely limited to conjecture. It also raises some questions, one of which the writer would like to discuss.

Mr. Robinson mentions that the word "failure" is not always clearly defined. It is often taken to mean the plastic yielding of some part of a machine as a result of the presence of a stress in excess of the elastic limit. He states that this is often not detrimental to the performance of a machine, and he therefore turns our attention to the bursting speed of a disk rather than the speed at which the elastic limit is reached.

Now it is probably perfectly true that designers, in dealing with stresses, do not consciously subscribe to the view that failure refers to the elastic limit. Nonetheless, it is probably also true that the rules by which designers are guided have this philosophy implicit in them.

Most disk stress criteria consist of a comparison between a stress (maximum or average) calculated on the basis of elastic theory, and some property found from a single tensile test, such as the yield point. But Mr. Robinson has made it clear that bursting speeds have practically no connection with elastic stresses. Should we not, therefore, have other criteria?

As a matter of fact, a good deal can be said against permitting extensive yielding in a disk, so that perhaps our design criteria should, after all, be kept on a basis similar to that now in general use. One important change might, however, be made, namely, the use of an effective elastic limit making allowance for the stiffening effect of the biaxial stress condition which exists in the disk. Such an elastic limit would be based on the simple tensile test but would be corrected, perhaps empirically, according to the degree of elongation and reduction of area.

It would be most interesting if Mr. Robinson could find the opportunity to conduct further tests relating to the incidence and progress of plastic yielding.

AUTHOR'S CLOSURE

The author concurs with Mr. Dahlstrand's remarks. However, the bursting test may show the general soundness of the material, but may not reveal a weakness in the matter of fatigue resistance.

Commander Kleinschmidt inquires about the distortion preceding rupture. The wheels were run at successively higher speeds, and, after the first appearance of plastic set, records were kept of dimensional changes. These records were rather voluminous, and the author feared that the paper might get too long for publication had they been included. Suffice it to say here that the different materials behaved quite differently.

As regards his inquiry about prestressing by overspeeding before assembly, the author has always felt that just as much good or even more would be done by such overstressing as occurs in ordinary service as by deliberate overspeeding in advance of assembly. Under actual service conditions, no more prestressing than necessary is applied. Overspeeding in advance is attended by the remote possibility of aggravating some hidden flaw or weakness that would not otherwise be serious. This is only a statistical possibility. If in any particular case the material is presumed to be perfectly sound, prestressing should be beneficial. Undoubtedly, this procedure helps keep a shrunk-on wheel tight on the shaft. However, evidence is accumulating that resistance to fatigue is improved by initial compression and reduced by initial tension. Bearing this in mind, the bore of the wheel would be

[21] Chief Research Engineer, DeLaval Steam Turbine Company, Trenton, N. J. Jun. A.S.M.E.

improved in fatigue strength by the localized initial compression induced by overspeeding; whereas the outer regions of the wheel would be very slightly weakened by the small initial tension. Thus overspeeding a wheel does nothing to improve the fatigue strength of the part of a wheel which may be subject to vibration but improves the part that does not need it. On the other hand, the dovetail connections of a fully assembled turbine bucket wheel might well be improved in fatigue strength by overspeeding the finished and bucketed wheel to a speed which would result in some residual compression in the local regions of maximum stress.

Commander Kleinschmidt also inquires about holes eccentrically placed. Such holes are very likely to be located in a region where the radial and tangential stresses are not greatly different in size. Under such conditions, the behavior should be much the same. Of course, if the radial and tangential stresses differ greatly, the behavior might be expected to differ. On the other hand, the author believes that a more important consideration may be the fact that such holes are likely to be of small size and that there may be a worst size for regions of stress concentration.

Mr. Phillips has kindly contributed in Table 7 the results of bursting tests on actual shaped wheels containing small-size eccentrically located holes, such as referred to by Commander Kleinschmidt. Table 8 shows that such wheels when made of the gamma columbium material develop average bursting stresses 0.628 to 0.915 of the author's average figure. (Rim physical properties are used because all the author's comparisons are with rim tests.) In the case of the Cyclops 17W material, the actual shaped wheels containing eccentric holes were 0.745 to 0.998 as strong as the author's wheels. In both cases there is evidence of a reduction of strength due to the local stress concentration, but this reduction is not as bad as one might be led to believe on the basis of elastic theory.

Commander Kleinschmidt asks three questions covering the importance of temperature effects. These are certainly very important considerations upon which the author can only speculate as follows, at the present time:

1 High temperature is likely to be accompanied by a loss of strength and an increase of ductility while low temperature would have the opposite result. There are variations from these relationships, and certain unexpected effects connected with the nature of the ductility. Certainly the atmospheric tests must not be assumed to give conclusions valid for other temperatures.

2 There are mitigating circumstances associated with the increase of stress at the center of a wheel with a hot rim so that this condition is, perhaps, not quite so serious as it might seem to be. The colder and more highly stressed center is usually stronger than the rim by virtue of its lower temperature. Furthermore, the volume of stressed material is usually very much larger toward the center, with the result that a larger thermal strain in a rim of small cross section cannot cause a very excessive opposite strain in the very large cross section of the central web or hub.

3 Certainly the effect of rapidly varying temperatures is a very real problem. In this matter, the author can only suggest that much similar effects exist at a lower temperature level in steam turbines using lower-alloy materials. It is to be hoped that the newer alloys will behave equally well at the higher levels.

The author shares with Mr. Kroon the desire for some rationalization of the paradoxical results given in Table 6. The author believes that both influences suggested by Mr. Kroon were present. In retrospect, it is only possible to speculate on the likelihood that initial internal stresses would go a long way toward explaining what happened. As regards Mr. Kroon's question about high-temperature behavior, the author is at present unable to give any answer.

In connection with Mr. Maul's problems, it is important, of course, to consider the difference in the physical properties of the material available for a solid rotor, as compared with what may be obtained in separate shrunk-on wheels.

The author has a good deal of sympathy with Dr. McAdam's disagreement as to criteria for "failure." The crux of the question seems to be the definition of "failure," but the point of view is just as important also. If one is investigating the ultimate nature of a material, certainly, "true" breaking stresses should be determined as Dr. McAdam suggests, allowing "(if possible) for differences in total plastic deformation." In the first draft of his paper the author started to do this. However, upon reflection, it occurred to him that plastic deformations are never, and by the nature of the materials cannot with certainty, be available to a designer. Therefore having the designer's viewpoint, it seemed better to base the figures on dimensions available to the designer, as is done in the tensile test under unidirectional loading. The artificiality of the results must be admitted, but there is a corresponding directness of utility to a designer that rests for its validity only on the systematic outcome of the results. The author regrets that complete data on the progressive deformation of the wheels were omitted in the interest of brevity, as Dr. McAdam's analysis of the "true" stresses, taking account of plastic deformation, would be valuable to have.

The author agrees with Mr. McCutchan that the trapezoidal cross section should be practically identical in result with the bottle shape. In fact, the weakest point in this design was the generous fillet uniting the very modest rim with the web. This detail was not generous enough.

How to float the disks with center hole while rotating at 40,000 rpm proved to be quite a real problem by itself and various devices were tried. Suffice it to say that the most successful device was shaped like a tulip blossom and about that size, with the wheel seated just below the petal tips and the pistil of the flower serving as drive shaft. The outward centrifugal pressure of the petals at the small central radius was practically inconsequential but sufficed to transmit the small torque required for acceleration.

The author agrees as to the importance of securing similar information at high temperature in order to find out how to apply conventional creep and rupture tests.

The author is completely indebted to Messrs. McMahan and Stoeckly for carrying out all his bursting tests in their high-speed stands and looks forward to the time when these most useful testing machines may be adequately described. Their remarks in passing about the different behavior of certain aluminum alloys should be noted.

Mr. Moody recalls a totally different implication in the use of the term "failure" from that suggested by Dr. McAdam. Designers must certainly always have in mind that their machines may be put out of business by a very little permanent deformation of an amount which may not suffice to permit bursting or stresses anywhere near bursting. Doubtless this is a legitimate use of the word "failure," but the author regrets the practice of basing a "factor of safety" on the attainment of the elastic limit, because usually no safety is in jeopardy when this occurs even though the type of failure mentioned may be imminent.

The author wishes to express his appreciation of Dr. Nadai's valuable and illuminating discussion. He makes a good case in favor of attempting to predict behavior after plastic action has set in with sufficient accuracy to be useful to designers. The author would regret having the skepticism expressed in his quoted remark taken to mean that a sound and useful analysis would not be welcome. Certainly it would be desirable if a satisfactory analysis could be agreed upon which would improve upon the simple average stress suggested by the author. However, such a setup for design purposes would have to be accompanied by data on the appropriate strength values. It is plain from both

Dr. McAdam's remarks and from Dr. Nadai's also that ordinary tensile-test results could not be used. The author believes that Dr. Nadai's last paragraph expresses opinions pretty much in agreement with his own and also with those of Dr. McAdam. The more common use of high-speed test stands may, in future, make it possible to determine the bursting strength of a test coupon having the size and shape of a baker's cookie instead of a stick of candy.

In answering one of Commander Kleinschmidt's questions, the author made use of some of the data contributed by Mr. Phillips. There is another lesson to be learned from these figures. Mr. Phillips gives physical tests from both rim and center of the gamma columbium wheels, showing the center usually to have lower tensile strength anywhere from 80 to 100 per cent of the rim tensile strength. All the tensile tests cited by the author were based upon coupons taken from the rims before the wheels were made. Since all the bursts except those of the wheels of uniform stress design apparently originated near the center or at the edge of the center hole, this variation of material strength may go a long way to explain the deviation from a uniform relationship between average bursting stress and ordinary tensile strength. The author does not, of course, claim that this relationship is other than fortuitous with so artificial a property as the conventional tensile test. It may, however, be nonetheless quite a real and useful relationship.

Fluid Flow Through Two Orifices in Series—II

By MILTON C. STUART[1] AND D. ROBERT YARNALL[2]

This is the second of a series of papers on the characteristics of fluid flow through two orifices in series. The first paper (1)[3] presented a theoretical analysis of the flow of water and steam through two orifices in series over a wide range of pressures and temperatures. This paper presents the results of experimental investigations on this subject using water at an initial pressure of 100 psia and over a range of temperatures from room temperature to saturation temperature. The principal data sought were the pressures established in the intermediate chamber between the two orifices, and especially the variations of this intermediate pressure with reference to the temperature of water supplied and the type of orifice. One of the most significant facts revealed by these researches is that under certain conditions of flow the fluid assumes a metastable state which greatly influences the characteristics of the process. Finally, a device responsive to the pressure variations obtained between two orifices in series constitutes a control element, useful, among other things, to control flow in response to the state of the fluid supplied.

Nomenclature

The following nomenclature is used in the paper:

M/A = mass rate of flow, lb per sec per sq ft
U = velocity, fps
V = specific volume, cu ft per lb
H = enthalpy, Btu per lb
P = absolute pressure, psf
p = absolute pressure, psi
F = temperature,

Subscript 1 refers to entrance to first orifice
Subscript x refers to intermediate chamber
Subscript 2 refers to downstream section following second orifice
Subscript s refers to constant entropy process
"Chamber pressure," (p_x), is absolute pressure in intermediate chamber between two orifices
"Cold water" is water which has a temperature lower than saturation temperature corresponding to lowest pressure attained by water during flow
"Compressed liquid," see "subsaturated" liquid
"Critical pressure" is lowest pressure which will exist for flow of expanding fluid in converging portion of nozzle
"Discharge pressure," (P_2), is pressure of liquid after passage through second orifice
"Flashing" is process of partial evaporation of liquid caused by adiabatic reduction of pressure
"Hot water" is water which has a temperature higher than saturation temperature corresponding to lowest pressure attained by water during flow
"Initial temperature" (t_1) is temperature of fluid at entrance to first orifice
"Initial pressure" (p_1) is absolute total pressure of liquid at entrance to first orifice
"Metastable" refers to a fluid condition in which pressure of fluid is less than saturation pressure of liquid corresponding to existing temperature, or, alternately, a fluid condition in which temperature of fluid is higher than saturation temperature of liquid at existing pressure
"Orifice" is a converging or parallel-sided passage provided for flow
"Quality" is percentage of vapor present in a liquid-vapor mixture
"Saturated liquid" refers to water having a temperature equal to temperature listed in Steam Tables corresponding to existing pressure
"Saturation pressure" refers to pressure listed in Steam Tables corresponding to existing temperature of water
"Saturation temperature" refers to temperature of water as listed in Steam Tables corresponding to existing pressure
"Stable" refers to a fluid condition in which pressure of fluid is equal to or greater than saturation pressure, or alternately, a fluid condition in which temperature of fluid is equal to or less than saturation temperature
"Subpressure" is reduction of pressure of metastable water below saturation pressure
"Subsaturated liquid" (compressed liquid) is a liquid having a temperature less than saturation temperature, or alternately, a liquid having a pressure higher than saturation pressure
"Superheated liquid," same as "metastable liquid"
"Superpressure" is excess of pressure of stable water over saturation pressure
"Supertemperature" is excess of temperature of metastable water over saturation temperature
"Total pressure" is measured absolute pressure of a fluid at any point
Vapor is used in this paper to designate vapor phase of water
Water is used in this paper to designate liquid phase of water

Introduction

In a previous paper (1) the authors presented a theoretical analysis of the flow of saturated and subsaturated water through two orifices in series over a wide range of pressures and temperatures. Since the presentation of that paper an extensive experimental investigation has been conducted in the high-pressure laboratory (2) of the Yarnall-Waring Company to determine the characteristics of flow of hot water through various types of orifices in series. The most significant facts revealed by these researches are that in many types of flow the fluid is in a metastable state and that in the metastable state the characteristics of the

flow of water through orifices differ greatly from the characteristics under stable conditions. This paper presents the experimentally determined characteristics and a thermodynamic analysis of the flow of saturated and subsaturated water through orifices in series with special consideration of the existing metastable state.

FIG. 2 PRESSURE DIAGRAM FOR IDEAL STABLE FLOW OF WATER THROUGH TWO ORIFICES IN SERIES

FLOW OF HOT WATER UNDER STABLE CONDITIONS THROUGH TWO ORIFICES IN SERIES

In the paper presented by the authors in 1936 (1) on fluid flow through two orifices in series a thermodynamically stable condition of the fluid was predicated. It was assumed that when the pressure decreased to a point as low as the saturation pressure corresponding to the temperature of the liquid, vapor immediately started to form and the temperature of the resulting mixture of liquid and vapor was subsequently that corresponding to the saturation pressure. Following are some of the conclusions of the former paper which pertain to the present investigations:

(*a*) The flow of subsaturated water under stable conditions through an orifice or nozzle is characterized by a critical-pressure phenomenon just as is the flow of a gas or vapor. For subsaturated water this critical pressure is practically equal to the saturation pressure of the entering liquid.

(*b*) Because of this critical-pressure phenomenon, the rate of flow of hot water under stable condition through orifices is much lower than the rate of flow of cold water. In orifice flow, the energy available to cause flow is limited by the amount of energy rendered available by the change in state of the liquid from the initial pressure to the critical pressure.

(*c*) In flow of hot water under stable conditions through two identical sharp-edged or rounded-entrance orifices in series, critical pressure existed at the outlet of the second orifice and the intermediate pressure in the chamber between the two orifices automatically adjusted itself to be midway between the initial pressure at the entrance to the first orifice and the critical pressure. Flashing did not occur in the intermediate chamber until the saturation pressure of the liquid closely approached the initial pressure.

Pressures existing throughout the system for flow under stable conditions through two orifices in series, Fig. 1, are shown graphically in the pressure diagram, Fig. 2. In this diagram the abscissa is the initial saturation pressure of the water entering the first of two identical orifices with an initial total pressure 100 psia. The corresponding initial temperatures are also marked on the abscissa. Ordinates represent pressures existing throughout the system for flow under conditions of the various initial temperatures (and corresponding initial saturation pressures).

Line 1 represents the constant initial pressure; line 2 represents the constant pressure in the discharge region beyond the second orifice; line 3 represents the initial saturation pressure and is also the pressure which, under stable conditions, must necessarily exist at the throat of the second orifice. Line 4 represents the variation of the pressure in the intermediate chamber between the two orifices. It may be noted that for initial temperatures below 213 F the intermediate pressure is always 57.5 psi, being midway between the initial pressure, p_1, of 100 psi, line 1, and the discharge pressure, p_2, of 15 psi, line 2. For any initial temperature above 213 F the intermediate pressure increases linearly with initial saturation pressure and is midway between initial total pressure and initial saturation pressure. This feature, it was pointed out in the former paper, constitutes the factor in the utilization of two orifices in series for controlling the flow of hot water. For initial temperatures very near the saturation temperature, the critical pressure is only slightly less than the saturation pressure with a correspondingly slight effect on the intermediate pressure.

In Fig. 2 are also indicated the liquid region of the first orifice, the liquid region of the second orifice, the region of flashing which occurs after the second orifice, and the corresponding pressure drops in the first orifice, in the second orifice, and beyond the second orifice.

It should be recalled that the foregoing analysis of flow under stable conditions applies equally well to sharp-edged and rounded-entrance orifices.

DESCRIPTION OF APPARATUS AND EXPERIMENTAL METHODS

The apparatus used in this investigation, Fig. 3, consists essentially of a continuous hot-water supply leading to two identical orifices arranged in series and a means of measuring the following quantities: Pressure of water at the entrance to the first orifice; temperature of water at the entrance to the first orifice; intermediate pressure; intermediate temperature; downstream pressure beyond the second orifice; and the rate of flow.

Hot water and steam were obtained from blowoff and steam connections, respectively, of a gas-fired high-pressure boiler (2) supplied with distilled water. Initial temperature control of water entering the apparatus was obtained by maintaining the boiler pressure considerably above the desired pressure and by proportioning flow from a direct boiler connection and a parallel connection through a water-cooled coil. Valves with by-passes served further to throttle the water to the pressure maintained in

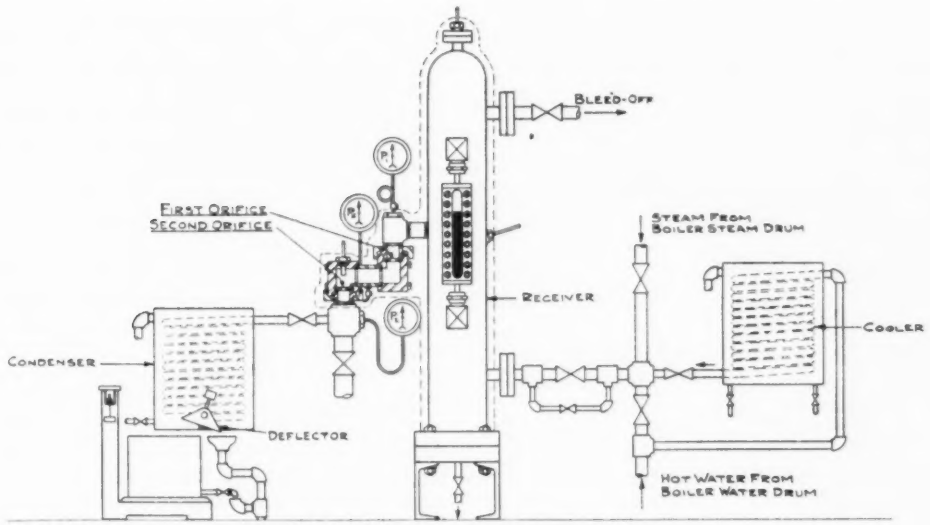

FIG. 3 ARRANGEMENT OF APPARATUS

the receiver. The column-type receiver was provided with water glass, thermometer well, upper and lower bleedoff connections, and an outlet leading to the orifices under investigation. Pressure gages served to indicate the initial, intermediate, and discharge pressures. The orifices, clamped between gaskets in union-type fittings, were purposely offset to eliminate velocity effects of the first orifice upon the second orifice and to return the enthalpy of the fluid in the intermediate chamber to its initial value.

The intermediate chamber between the orifices was provided with a thermometer well and a pressure gage. On the downstream side of the orifices a connection was provided through the gate valve to the water-cooled condenser which served to cool the discharged fluid preparatory to weighing. A deflector provided means of diverting the flow from the drain connection to the weighing tank on a platform scale, so that it was possible to measure accurately by a stop watch the rate of flow over a period of time.

The operating procedure consisted of establishing steady flow through the orifices at the desired initial temperature and pressure. The initial pressure was maintained at 100 psia for all experiments. The initial temperature was varied from 70 F to the saturation temperature of 327.8 F. Discharge pressure was maintained at approximately 15 psia.

Flow determinations were based upon time intervals ranging from 1 to 4 min. The stop watch was checked against a watch of known accuracy. The platform scale was sensitive to $^1/_2$ oz, approximately equivalent to 0.1 per cent of the average quantity of water weighed. At the beginning and end of each interval, observations were taken of initial pressure, initial temperature, intermediate-chamber pressure and temperature, and discharge pressure.

Pressure gages were of the standard Bourdon-tube type and were frequently checked by a dead-weight tester during the course of the investigation. Temperature readings were obtained by means of accurately calibrated mercury-in-glass thermometers inserted in mercury-filled thermometer wells.

THE METASTABLE CONDITION

Before presenting the results of this investigation, a word of explanation is given concerning stable and metastable conditions of water. By definition, "stable" refers to the condition in which the pressure of the liquid, or of the mixture of liquid and vapor, is not less than the saturation pressure corresponding to the existing temperature, or, conversely, that the temperature of the liquid or the mixture is never higher than the saturation temperature corresponding to the existing pressure. If a condition exists where the pressure of a liquid, or of a liquid-and-vapor mixture, is less than the saturation pressure corresponding to the existing temperature, the condition is said to be "metastable." The most important characteristic of the metastable state is the delay in an anticipated phase change. Metastable states are known to exist in many circumstances where a change of phase is about to occur (3). Examples are the cooling of liquid water below the freezing temperature and the cooling of steam below the condensation temperature; the latter condition occurs in the well-known supersaturation phenomenon which exists in steam flow through nozzles.

The metastable state of a liquid may be attained in several ways, all of which involve the phenomenon that bubbles of vapor do not form in the mass of liquid when temperatures exceed the saturation temperature corresponding to the existing pressure of the liquid, or, alternately stated, when pressures become lower than the saturation pressure corresponding to the existing temperature of the liquid. Some of the means of attaining a metastable state in a liquid are by the careful heating of water at constant pressure; by the sudden release of the pressure of a quiescent liquid; and by the flow of a liquid without turbulence through an orifice or nozzle to a discharge pressure less than the saturation pressure of the liquid. The retardation of the formation of bubbles has been attributed to the time necessary for the mass and heat transfers which are required for a bubble formation.

A more basic explanation of the metastable state depends upon the phenomenon of surface tension and the role of surface energy in delaying the initiation of very small steam bubbles in a mass of pure liquid (3). It is supposed that the formation of the initially minute bubbles is accelerated by impurities in the liquid, gases, or solids in solution, turbulence, ionization, or any other factor which will assist in creating an initially minute curved surface or nucleus about which the bubble may form.

In the flow of water through orifices it is known that the attainment of metastable states is favored by the purity of the water and by the smoothness of the passage, and also by a minimum of turbulence and friction. The existence of metastable states in the flow of water through orifices has been established by a number of investigators (4, 5, 7, 8).

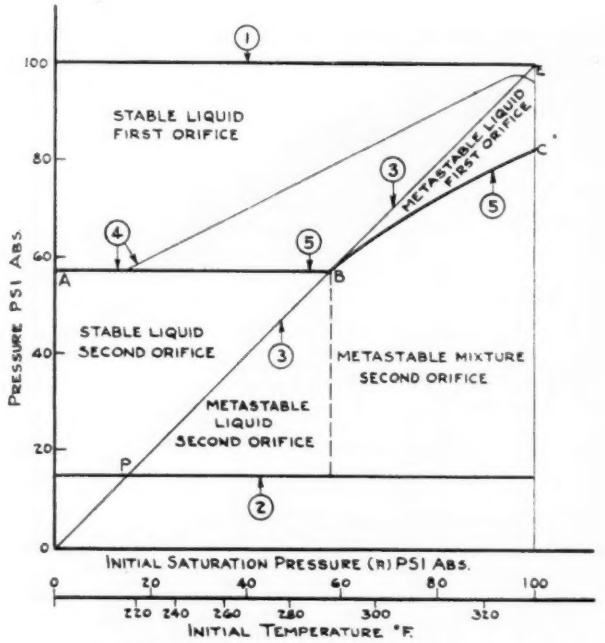

FIG. 4 PRESSURE DIAGRAM FOR FLOW THROUGH TWO SHARP-EDGED ORIFICES IN SERIES

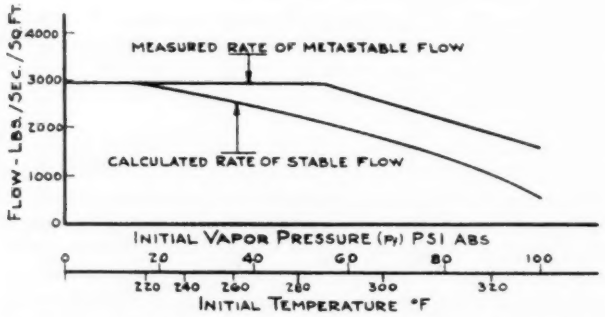

FIG. 5 RATES OF STABLE AND METASTABLE FLOW; SHARP-EDGED ORIFICES

FLOW OF HOT WATER UNDER METASTABLE CONDITIONS THROUGH TWO SHARP-EDGED ORIFICES IN SERIES

The characteristics of flow of hot water through orifices in series will vary greatly with the type of orifice used. The sharp-edged orifice was selected as a standard for determining the basic phenomena of the process. Two sharp-edged orifices $^1/_8$ in. diam, $^1/_8$ in. thick, and chamfered at 45 deg to a working edge of 0.020 in. were arranged in series in the apparatus shown in Fig. 3. The essential data yielded by a run consisted of the initial pressure, the initial temperature, the intermediate pressure, and the measured rate of flow through the orifices.

Results for runs over the entire range of initial temperatures are presented in Figs. 4 and 5. In the pressure diagram, Fig. 4, the abscissa is the initial saturation pressure. The measured temperatures of the inlet water are also marked along the abscissa. Ordinates represent pressures existing throughout the system for various inlet temperatures. As in Fig. 2, line 1 represents the constant initial pressure of 100 psi, line 2 represents the constant discharge-region pressure of 15 psi, and line 3 is the initial saturation pressure. The measured intermediate pressures are shown by line 5. Line 4, which represents intermediate pressures for flow under stable conditions, is redrawn from Fig. 2 for purposes of comparing characteristics. In Fig. 5 are plotted the rates of flow as measured and, for comparison, the rates as calculated for ideal stable fluid flow. The most significant results of this investigation, as disclosed by an examination of Figs. 4 and 5, are (*a*) that the intermediate-chamber pressure, as calculated for stable fluid flow, line 4, is much higher than the measured intermediate pressure, line 5, and (*b*) that the calculated rate of stable fluid flow is much lower than the actual measured rate of flow. These striking differences in the measured characteristics and the similar characteristics, as calculated for stable fluid flow, can be accounted for completely and uniquely by recognizing the existence of the metastable state of the fluid in certain regions during the passage of the hot water through the orifices.

In stable fluid flow, the lowest pressure which can exist at the end of the second orifice is the saturation pressure, as shown by line 3 in Fig. 4. In actual flow, under certain conditions, the water continues through an orifice as a liquid in the metastable condition, that is, at pressures lower than the saturation pressure, without flashing, and with temperatures higher than saturation temperatures. In order definitely to establish the regions in which metastable conditions exist, a thermodynamic analysis is made in the following paragraphs.

THERMODYNAMIC ANALYSIS OF METASTABLE FLOW

It may be established quite directly from the pressure diagram in Fig. 4 that the metastable condition must exist in the second orifice for initial temperatures of water at least up to the point *B* because equal pressure drops and equal flow in each orifice can be accounted for only by the maintenance of a liquid condition in the second orifice along the entire line *A-B*. If flashing occurred in the second orifice, as would be required for the stable condition, a greater pressure drop would be required in the second orifice than in the first orifice. However, in the region from *B* to *C* it is not immediately evident to what extent metastable conditions exist, since a greater pressure drop exists in the second orifice than in the first. In order to investigate the existence of the metastable state, a complete thermodynamic analysis was made of the flow of initially saturated water at 100 psi and 327.8 F by assuming in turn that the fluid was stable in both orifices, metastable in the first orifice only, and finally metastable in both orifices. By comparing the results of this analysis with the data obtained in the experiment in regard to intermediate pressure and rate of flow, it was definitely established that the metastable condition existed in the first orifice in the region bounded by *EBC* in Fig. 4. The metastable condition also existed in the second orifice in the entire region below the line *PBC*.

The results of this thermodynamic analysis of the flow of saturated water through two sharp-edged orifices in series under both stable and metastable conditions are shown graphically in Fig. 6. The intermediate pressure is the measured value of 84 psia. The calculations for stable conditions were made on the basis of constant entropy during flow. Calculations for flow through the first orifice were made for quality, specific volume, change of enthalpy, velocity, and mass rate of flow per unit area. All calculations were by usual methods, except that calculations for the change of enthalpy were made by numerical integration of $\int V dP$ (ref. 1). The state in the intermediate chamber was known because in the throttling process H_1 equals H_2.

Calculations for flow through the second orifice, assuming constant entropy and stable expansion, were made in the same manner as for the first orifice. These results, plotted in Fig. 6, disclosed the usual critical pressures and the corresponding possible maximum rates of flow through each orifice. The maximum

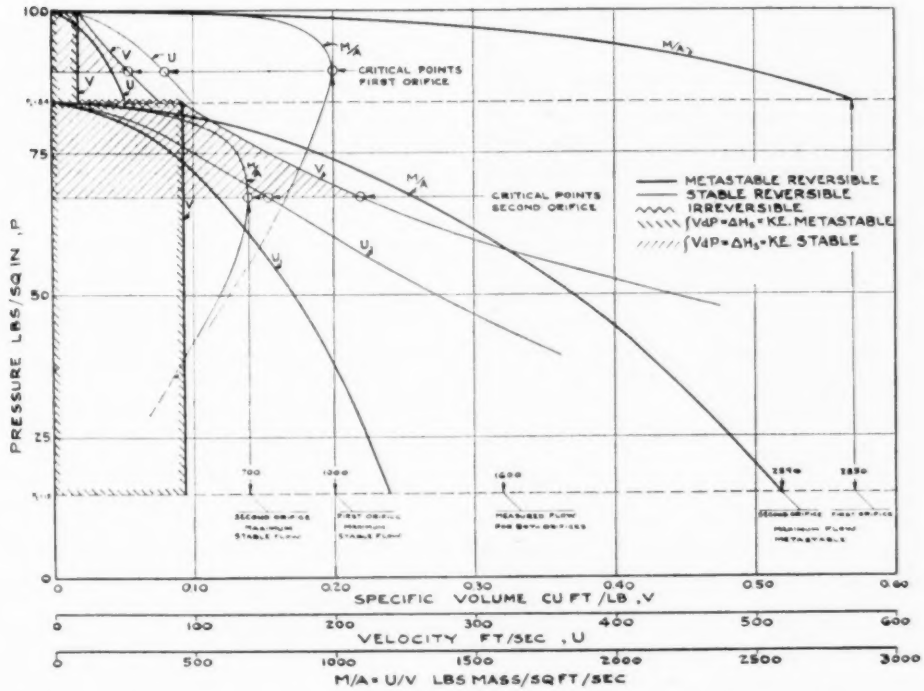

FIG. 6 THERMODYNAMIC ANALYSIS OF FLOW OF SATURATED WATER THROUGH TWO SHARP-EDGED ORIFICES IN SERIES

calculated rates of flow obtainable under stable conditions were each much lower than the actual measured rates of flow. This phenomenon of actual rates of flow in excess of ideal rates of flow is characteristic of the metastable state.

Calculations were next performed assuming the existence of metastable conditions. For these calculations it was assumed that the fluid passed through the first orifice as a liquid with no change in volume from the initial volume of the saturated liquid. Further assumptions were that in the intermediate chamber stable conditions were restored, flashing occurred, and the enthalpy, H_2, returned to the original enthalpy, H_1. For the metastable condition in the second orifice it was assumed that the fluid, consisting of liquid and vapor bubbles, passed completely through the second orifice with no change in volume, no further evaporation, and no decrease in temperature. Calculations of enthalpy change, velocity, and mass rate of flow were thus made for metastable conditions in each orifice. The calculated rates of flow for metastable conditions were 2850 lb per sec per sq ft for the first orifice, and 2590 lb per sec per sq ft for the second orifice. These calculated rates of flow exceeded the measured rate of flow for each orifice, which was 1600 lb per sec per sq ft. The flow coefficients for the first and second orifice were 0.562 and 0.618, respectively. These coefficients, although not equal, were both acceptable for fluid flow through sharp-edged orifices. This circumstance, contrasted with the similar circumstance for previously assumed stable condition, established the condition of the flow as metastable or nearly metastable, in both orifices.

Similar thermodynamic analyses showed that, as previously anticipated in Fig. 4, the metastable condition existed in the first orifice in the region bounded by *EBC* and in the second orifice in the entire region below the line *PBC* which extends completely down to the discharge pressure. Even with some vapor present at the entrance to the second orifice, further evaporation was suppressed by the persistence of the metastable state.

It is noted that in the second orifice the liquid-vapor mixture attained a supertemperature of 102.4 F, which is the excess of

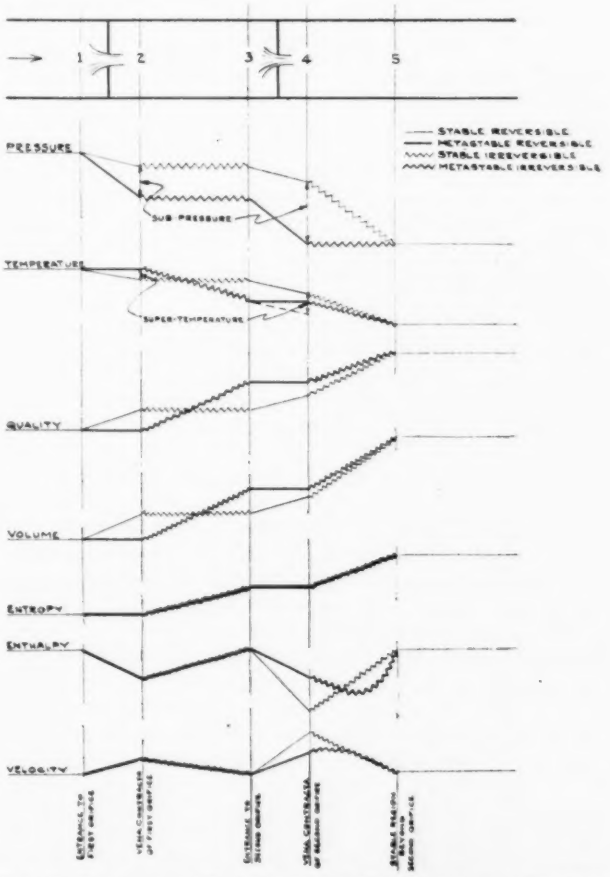

FIG. 7 CHANGES IN THERMODYNAMIC PROPERTIES FOR FLOW OF SATURATED WATER THROUGH TWO ORIFICES IN SERIES

the actual temperature of 315.4 F over the saturation temperature of 213.0 F.

Qualitative Changes in Properties of Fluid During Flow

Comparisons of progressive changes in the properties of the fluid as it passes through the two orifices in series under stable and metastable flow conditions are portrayed graphically, but not to scale, in Fig. 7. Pressure, temperature, quality, volume, entropy, enthalpy, and velocity changes of the fluid throughout the system for stable and metastable conditions of initially saturated water are indicated at five significant reference points, viz., 1, entrance to first orifice, 2, vena contracta of first orifice, 3, entrance to second orifice, 4, vena contracta of second orifice, and 5, stable discharge region beyond the second orifice. It should be noted that in the region from orifice entrance to vena contracta the metastable state persists, and that immediately beyond the vena contracta there is an irreversible turbulent return of the fluid to a stable condition.

Physical Appearance of Jet of Hot Water Discharging From Sharp-Edged Orifice Into Atmosphere

In order further to verify the existence of the metastable state during flow, photographs were taken of jets of hot water discharging vertically downward from a sharp-edged $^1/_8$-in-diam orifice into the atmosphere. The initial pressure of the water was 100 psia, and temperatures were varied from 155 F to saturation temperature of 327.8 F. The apparatus used to produce the jet is shown in Fig. 8. The views, Fig. 9, are arranged progressively with increasing initial temperatures from 155 F to 327.8 F.

With cool water supplied, the jet was clear and of constant area and shape to a distance of 10 in. or more from the orifice. This form of jet persisted with increasing temperature but vapor was emitted from the surface of the stream as the temperature approached the boiling point. Fig. 9(*a*) for a temperature of 155 F, is characteristic of the appearance of the jet at all temperatures below 212 F. At 212 F there was no indication of boiling within the observed length of jet, but vapor emission from the surface of the stream was more pronounced. This vapor emitted from the jet was hot to the touch, and at temperatures somewhat in excess of 212 F the vapor emission was of noticeable intensity although the jet remained clear, an indication that there was no boiling in the interior of the stream.

With increase in temperature to about 225 F, Fig. 9(*b*), the vapor emission increased and the jet started to stream into filaments at a point about 12 in. from the orifice. Further increase in temperature caused a greater degree of streaming and spreading of the jet closer to the orifice, as shown in Fig. 9(*c*), for a temperature of 260 F.

The spreading of the stream assumed the conical form at a temperature of 275 F, indicated in Fig. 9(*d*). As the temperature increased, a transition point was reached at about 280 F where the streaming previously referred to changed to droplet formation. In contrast to the rather smooth and uniformly increasing streaming action, droplet formation proceeded explosively from a clear jet at a point 2 or 3 in. beyond the end of the orifice. Fig. 9(*e*) shows the form of the jet at a temperature of 285 F, slightly above this transition point, in contrast to Fig. 9(*d*) taken at a temperature just below the transition point. At a temperature of 300 F, Fig. 9(*f*), the average distance from the throat section of the orifice to the point of jet expansion was about 1 in. The discharge cooled rapidly in the region beyond the point of jet expansion and was relatively cool to the touch beyond the region of full expansion. The point of jet expansion did not remain at a fixed distance from the orifice, but moved up and down the jet over a range of possibly $^3/_4$ in. with a crackling explosive sound.

Figs. 9(*g*) and 9(*h*) show the decreasing length of clear jet at temperatures of 310 F and 322 F, respectively. The transition point where marked jet expansion occurred was taken to be indicative of transition from the metastable to the stable state. If the region beyond the transition point assumed a conical form, it was presumed that the fluid consisted of a continuous liquid phase containing bubbles of vapor. If at the transition point the expansion was marked and explosive, it was presumed that the subsequent fluid consisted of a continuous vapor phase with entrained drops of liquid.

In the case of saturated water supplied to the orifice, Fig. 9(*i*), an explosive transition was definite, the change occurring quite near the orifice.

With steam flow, Fig. 9(*j*), the issuing jet assumed approximate conical form within a very short distance from the orifice. Because the jet was almost invisible for initially dry saturated steam a trace of moisture was introduced to outline the jet. The form of the jet did not appear to be visibly affected by this moisture addition.

These observations verify the existence of the metastable condition of hot water during flow through, and somewhat beyond, the sharp-edged orifice. The distance beyond the orifice marked by the existence of the metastable state appears to be an inverse function of the temperature of the water. For the jet of water at a temperature of 225 F (a supertemperature of 12 deg) the jet persists for a distance of 12 in. For the jet of water at a temperature of 322 F (a supertemperature of 107 deg) the metastable jet persists only for a fraction of an inch. Thus the time of existence of metastability is an inverse function of the supertemperature.

Flow Characteristics of Rounded-Entrance Orifices

The maintenance of the metastable condition in both sharp-edged orifices down to the vena contracta is attributed to the almost completely reversible (frictionless and nonturbulent) flow produced by the sharp-edged orifice. Anything which produces friction or turbulence will prevent the maintenance of the metastable state during flow. A rounded-entrance orifice introduces a much larger surface of contact than the sharp-edged orifice, and to this extent may produce conditions departing from the metastable. Investigations were conducted with various pairs of identical rounded-entrance orifices in series. The radius of entrance was $^1/_8$ in. and the minimum diameter about $^1/_8$ in. The lengths

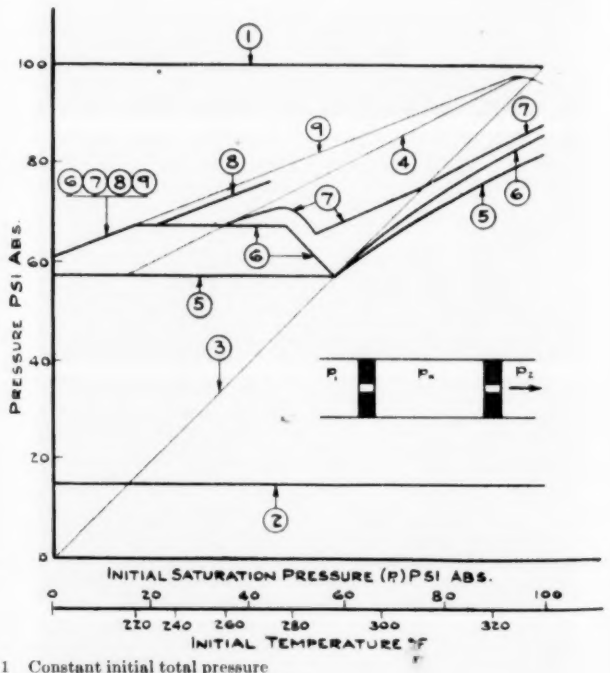
FIG. 10 PRESSURE DIAGRAM FOR FLOW OF HOT WATER THROUGH ROUNDED-ENTRANCE ORIFICES IN SERIES

including the straight parallel-sided portion and the rounded entrance were 1, 5, and 8 diam in each pair of experimental orifices. The results with these orifices, plotted as a pressure diagram in Fig. 10, show that the intermediate pressures attained with rounded-entrance orifices were between those for the ideal stable fluid flow, line 4, and the complete metastable fluid flow of the sharp-edged orifices, line 5. Line 6, for the 1-diam rounded-entrance orifice, shows an intermediate pressure similar to that for the sharp-edged orifice. It should be noted, however, that the intermediate pressure increases gradually before the saturation pressure reaches intermediate pressure. This, together with the observed reduction in flow, is indication that the point marking the start of the transformation from metastable liquid to the stable mixture had moved upstream and into the second orifice with increasing saturation pressure. This movement of the transformation point with respect to saturation pressure is illustrated in the views shown in Fig. 9. For flow through longer rounded-entrance orifices the state of the fluid approached a stable condition at the end of the orifice. This confirms the theory for stable flow as presented in the former paper by the authors (1) and agrees with the results of Benjamin and Miller in their paper on the flow of flashing mixtures of water and steam through pipes (6).

FLOW CHARACTERISTICS OF SHORT TUBES

Experiments were made with the orifices in the form of standard short tubes with sharp-edged entrance, as shown in Fig. 11. A characteristic of a short tube, well known in hydraulics, is that a vena contracta forms in the tube and upon expansion causes the water to fill the tube at the exit. This fact introduces distinctive characteristics in the flow of hot water through short tubes. As shown in Fig. 11, the intermediate pressures for short tubes are somewhat similar to those for rounded-entrance orifices but differ in the important aspect that intermediate pressures obtained were higher than for orifices with rounded entrances and even higher than for stable flow with sharp-edged orifices.



All of the data presented are based upon flow through two identical orifices in series. The combination of various types and differing sizes of orifices makes it possible to obtain desired intermediate-chamber pressure characteristics.

CONTROL OF FLOW OF HOT WATER BY MEANS OF ORIFICES IN SERIES

The characteristics of fluid flow through two orifices in series, as presented in this paper, may serve as a basis for the design of a control element. Such an element consists of an arrangement of two orifices in series, in which the state of the fluid supplied causes variations in pressure between the two orifices, these pressures being in turn communicated to a pressure-sensitive member. Fig. 12 shows the practical form of a two-orifice control element developed for automatic condensate drainage.

The piston valve, which constitutes the only moving part, fulfills the combined requirements of the series-control orifices, pressure-sensitive element, and drainage valve. The annular clearance between the disk on the piston valve and the wall of the cylinder forms the first orifice, the space in the cylinder above the disk constitutes the intermediate chamber, and a small rounded-entrance orifice at the top of the piston valve communicating with the discharge through the center of the valve constitutes the second orifice.

In order to obtain the required area relationship between the two orifices, the cylinder wall is tapered and the cylinder is made vertically adjustable to permit variation of the clearance between disk and cylinder wall.

9 Intermediate pressure for short tube 1 diam long and over, stable state

FIG. 11 PRESSURE DIAGRAM FOR FLOW OF HOT WATER THROUGH SHORT TUBES IN SERIES

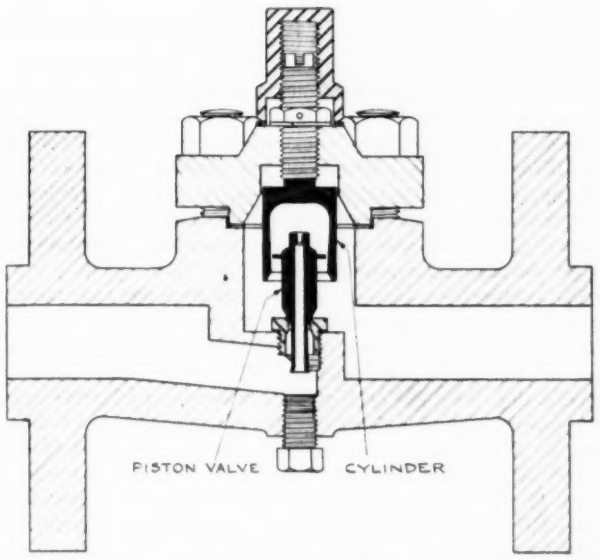

FIG. 12 PRACTICAL FORM OF CONTROL ELEMENT FOR CONDENSATE DRAINAGE

On proper adjustment, the relatively high intermediate pressure acting on the upper surface of the piston for steam and very hot condensate flow is sufficient to close the valve. With cooler condensate the correspondingly lower intermediate pressure permits the valve to lift and discharge the condensate.

The device is operative in like manner over a wide range of initial pressures without further adjustment. As suggested earlier in the paper, desired characteristics for the variation of the intermediate pressure with initial temperature may be obtained by suitable choice of types of orifices and by relative sizes of the orifices. Further, the existence of the metastable state, as disclosed in this paper, makes it possible to obtain a far wider range of control conditions than would be possible if the fluid remained in the stable state throughout the process.

ACKNOWLEDGMENTS

The authors acknowledge with appreciation the work of John F. McKee, engineer associated with the Yarnall-Waring Company, in the original development of the control element of fluid flow through two orifices in series.

The authors are indebted to W. J. Kinderman, of the Yarnall-Waring Company, for his invaluable aid in the design and construction of the apparatus, conduct of the research, and interpretation of the results. They also wish to acknowledge the assistance of J. A. Karas, of the mechanical-engineering department of Lehigh University, in the preparation of this paper.

Discussion

E. BROWN.[4] Study of the metastable state of water will probably help toward a better understanding of pitting in water turbines of the pressure type. As the water passes from the scroll case to the draft tube its pressure is lowered, and high vacuum may occur in the draft tube near the discharge tips of the blades. It is probable that in certain localized zones the vacuum is much higher than the general average vacuum across the whole section of the draft tube. In such zones the pressure may fall below the saturation pressure corresponding to the temperature of the water, because the drop of pressure is fairly rapid. The time element is probably an important factor in determining the rate at which small pockets or bubbles of water vapor, or of gases held in solution, are formed. The rapid collapse of such bubbles or voids may cause local pressures of great intensity which destroy the metal with which the water comes in contact. This was first demonstrated by the late Sir Charles Parsons in connection with the corrosion or pitting of ships' propellers. Whether this theory, or the alternative one of chemical action, be accepted, the fundamental conception is the formation of bubbles of released gases or water vapor. In water turbines such gases or vapor tend to be reabsorbed as the pressure in the water rises during its passage to the tailrace. The gradual formation of such voids, and their subsequent gradual disappearance, has been proved by photographs, and the writer has found experimental evidence of distinct differences between the gas content of water drawn from the draft tube of a small turbine from a zone where erosion was occurring, and a zone where there was no erosion. In both cases the gas content was less than that of water at the intake.

The writer has tested many models of water turbines during the past 20 years in connection with water-power developments. His experiences of corrosion or pitting have been varied, and in many cases seemingly contradictory. He has long held the view however that more intensive pitting may develop in a large turbine than in a small model even when they are operated on the same head. Under such conditions, the velocity of the water will be the same in both cases. But if the model is to, say, one-twelfth scale, the water in the large turbine will take 12 times as long as the water in the model to flow between corresponding points above and below the runner, and the harmful bubbles will probably be created at a different rate. Questions of heat transfer and surface tension are involved, and impurities in water may have some definite influence. The problem of relating the behavior of models to that of water turbines of greatly increased size is fraught with many difficulties. The work of the authors, apart from its evident value in such processes as those discussed in their paper, should contribute toward a clearer scientific understanding of some of the troubles of the engineer engaged in the development of water power.

G. A. HORNE.[5] This paper suggests some interesting points to the refrigerating engineer. In the refrigeration cycle, the liquid refrigerant is generally assumed to be in a stable condition throughout.

The writer has two-stage ammonia compression systems in

[4] Professor of Applied Mechanics and Hydraulics, McGill University, Montreal, Canada.

[5] Consulting Engineer, Merchants Refrigerating Company, New York, N. Y. Mem. A.S.M.E.

which all the liquid passes from the condenser through Venturi meters for measurement. To insure any change of state from liquid to vapor at the throat of the meter, the liquid is sufficiently reduced below saturation temperature by means of a cooling coil placed between condenser and meter.

In these two-stage compression systems all of the liquid is passed through an expansion valve into an intermediate cooler at the intermediate pressure between the two stages of the compressor. In this operation, it is generally assumed that the refrigerant remains in a stable condition so that the amount of vapor formed is the anticipated quantity in accordance with the pressure drop. However, the liquid which accumulates in the intermediate cooler is in a quiescent state and is maintained at a certain level while the vapor mixes with the balance of the vapor from the low-pressure cylinder, thence to the high-pressure cylinder.

The liquid from the bottom of the intermediate receiver passes through an expansion valve into the low-temperature evaporator or brine cooler. A certain residual amount remains in the receiver to serve as a trap.

The question which is prompted by the authors' work on fluid flow is therefore: Under the operation just described, would a metastable condition of the liquid refrigerant be apt to exist in the intermediate receiver?

Obviously, if this were the case, the efficiency of the system would be lowered and would result in an increase in the horsepower to drive the compressors.

The authors refer to certain means of attaining a metastable state in a liquid. A few years ago the writer was interested to observe an example of this phenomenon in determining the freezing point of grapefruit juice. It had generally been assumed in the fruit trade that oranges and grapefruit should be carried in cold storage at temperatures varying from 34 to 38 F. It had been found that lower temperatures, as low as 30 F were of considerable advantage in lengthening the storage period and improving the quality of the products. Although certain authorities showed the freezing point of the juice to be around 29 F, we decided to check it.

A 1-in. test tube was filled with juice, inserted through a cork into a bottle, and the bottle immersed in a large vessel containing brine at —5 F. Through a cork in the test tube an accurate thermometer was placed. It was expected that crystals would appear when the temperature of the juice reached 28 or 29 F. However, nothing happened while the temperature gradually dropped to 19 F. At that point the writer stirred the juice a little and immediately the entire contents became a mass of grapefruit ice, the temperature rose to 28.6 F and stayed there for some time.

It seems probable that the greater subcooling of water and water solutions, as compared to other liquids, is partly due to the fact that the maximum density of water is several degrees above the freezing point. As the authors point out, the metastable state depends upon surface tension. The ice crystals must form at the surface instead of at the bottom.

J. H. KEENAN.[6] This paper is an important contribution to our knowledge of the flow of liquids in the neighborhood of the saturation state. The literature on this subject, as indicated by the Bibliography included in the paper, is indeed limited.

As pointed out by the authors, the expansion of a liquid across its saturation line, like the flow of a vapor across its saturation line, results in metastable states. Various investigators from Wilson to Yellott[7] have attempted with a degree of success to determine the extent to which the expansion of a vapor may be extended beyond the saturation line before the first evidence of condensation appears.

This paper sheds some light on the analogous problem in the liquid phase, namely, to determine the extent to which the expansion of the liquid may be extended beyond the saturation line before the first evidence of vaporization appears. The photographs of Fig. 9 suggest that expansion to atmospheric pressure may occur at a temperature as high as 285 F without vaporization. This corresponds to an expansion of about 40 psi below the saturation pressure.

These illustrations, however, are not conclusive in this regard, because they are of such small scale that it would be impossible to detect the presence of small bubbles of vapor where the stream first attains atmospheric pressure. Somewhat better evidence appears in curve 6 of Fig. 10, which indicates that for rounded-entrance nozzles no evidence of vaporization appears for expansion to atmospheric pressure until the temperature exceeds 280 F. In a rounded-entrance nozzle, the pressure in the exit plane of the nozzle approximates the pressure in the exhaust space for a radius of rounding equal, as in this case, to the diameter of the nozzle. It appears, therefore, that expansion to approximately atmospheric pressure occurred in the downstream rounded-entrance nozzle without vaporization.

The rough agreement between the indications of the views in Fig. 9 and curve 6 in Fig. 10 does not support the statement of the authors that "a rounded-entrance orifice introduces a much larger surface of contact than the sharp-edged orifice, and to this extent may produce conditions departing from the metastable." The statement may be true, nevertheless.

In this connection, it should be noted that curve 5 in Fig. 10, which represents the performance of sharp-edged orifices, offers no such conclusive evidence as curve 6. In flow through a sharp-edged orifice the pressure in the plane of the orifice does not even approximate the pressure in the exhaust space but exceeds it by a large fraction of the total pressure drop. It would be entirely possible, therefore, to have considerable vaporization in the stream at pressures in excess of the exhaust pressure without any effect on the flow through the orifice. Thus the calculated curve 4 is relevant to the rounded-entrance orifice but not to the sharp-edged orifice.

The curves in Fig. 11, for flow through short tubes, show many curious characteristics. Perhaps the authors could suggest some explanation of the reversal in the effect of rising temperature on the intermediate pressure which appears in curves 6 and 7.

If the heavy lines in Figs. 4, 10, and 11 represent experimental values, as they appear to, that fact is somewhat obscured by the label "metastable flow." Labeling of curves should be factual rather than interpretive.

It is a temptation not to be resisted to point out that the so-called metastable expansion assumed in Fig. 6 for the second orifice is an adiabatic process of decreasing entropy.

In the absence of experimental points, some indication should be given of the reproducibility and the precision of the data.

L. K. SPINK.[8] Referring to the diagrammatic arrangement of the apparatus, some of the pressure gages are shown connected with loops or syphons. The gage registering Px is connected with a self-draining connection. Bourdon-tube gages not only zero differently but also calibrate slightly differently when the tube is filled with a material of different density. The magnitude of the discrepancy is not sufficient to affect the reliability of this work, but is mentioned as a point of general interest.

The dimensions of the conduit between the two orifices are not

[6] Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Mem. A.S.M.E.

[7] For references see "Thermodynamics," Bibliography (3) of the paper.

[8] The Foxboro Company, Foxboro, Mass.

given but appear sufficient to reduce the velocity of approach to a negligible value. Only in that case would the location of the taps and the shape of the tap openings be of no importance. This low velocity of approach would also minimize the effect of the disturbed flow condition set up by the two right-angle turns in the conduit.

Although it is natural to expect a variation in the discharge coefficients of nearly identical orifices as small as $^1/_8$ in., the value 0.562 appears abnormally low. The orifice thickness is slightly in excess of that generally accepted for thin-plate orifices for flow measurement; but this, and the small diameter, would tend to increase the coefficient. If both values were true discharge coefficients, an intermediate pressure midway between the initial pressure and the discharge pressure, as shown by line *A-B* in Fig. 4, would be difficult to explain. The exact significance of the coefficient of the second orifice is obscured by the assumption that the vapor bubbles undergo a change in pressure without any change in volume.

Presumably the authors have a reason for assuming that the vapor does not expand in passing through the second orifice, and have additional data or a theory to explain the apparent inconsistency of the coefficients. Further elaboration on these points would be appreciated.

P. W. Swain.[9] This paper, like its predecessor, published in 1936, interests the writer chiefly because of the directness of its application to commercial power equipment.

In recent years American engineers have advanced notably in their ability and will to analyze phenomena in terms of the abstractions of mechanics and thermodynamics. Of this trend, this paper is a good example. However, it would seem that too many of the engineer researchers and analysts have been happy to stop with a published report and analysis. This the writer could never understand, for it would seem that the whole life of the true engineer is so wrapped up in the building and operation of machines that abstractions, even experiment and experimental data, could never satisfy him, except as a means to some practical end.

[9] Editor, *Power*, New York, N. Y. Mem. A.S.M.E.

The condensate drainer, pictured in Fig. 12, gives everyday meaning to the research and analysis of the authors. The writer sincerely hopes that it evidences an increasing interest of scientifically minded engineers in practical applications. It is possible that this interest in application largely explains the immense productivity of American engineering as compared, for example, with that of prewar France, a country gifted with many fine and highly trained technical minds, yet singularly sterile in engineering results.

Authors' Closure

The discussions pertain chiefly to metastable phenomena rather than directly to the characteristics of flow through series orifices. Most significant are the remarks of Professor Brown in regard to the influence of the metastable state in promoting cavitation in water turbines, and the instances cited by Mr. Horne where the possibility of metastable phenomena are encountered in refrigeration.

The authors accept the criticisms of both Professor Keenan and Mr. Spink that the assumption of a truly constant volume process in the second orifice is undoubtedly too dogmatic. An assumption more nearly in agreement with the facts is that the vapor bubbles in the mixture increase in volume adiabatically, with perhaps a slight increment due to evaporation from the metastable liquid portion of the mixture.

The reversal in the effect of the rising temperature on the intermediate pressure for flow through short tubes, referred to by Professor Keenan, is attributed to the limitation of the minimum pressures which may exist in the vena contracta as within the short tubes. When a short tube is flowing full at the exit, the pressure at the vena contracta within the tube does not become less than the saturation pressure.

Mr. Swain correctly surmises that it was the embodiment of a scientific principle in a practical commercial device which prompted the authors to undertake these experiments, intended both to explain the operation of the device and to reveal further basic information on the principles involved.

The Combustion of Barley Anthracite

By ALLEN J. JOHNSON,[1] PHILADELPHIA, PA.

Because of its availability, excellent combustion qualities, and low cost, "barley" or No. 3 buckwheat anthracite is one of the most economical of all industrial fuels. After giving the analyses and physical properties of this fuel, the author discusses the effect of utilizing barley upon boiler performance. Details of the equipment available for burning this fuel, either by hand or stoker firing, are outlined, as well as practical suggestions for actual operation of the various types.

Preparation, Quality, and Characteristics

THE 1942 production of "barley" or No. 3 buckwheat amounted to 5,800,000 tons which represented 10 per cent of the total production of anthracite. Interest in its industrial use centers around the combined facts that it is an excellent fuel for both hand and stoker firing, and that it is one of the most economical of all industrial fuels. At the present time, barley is one of the few fuels, if not actually the only one, of which there is a substantial surplus at the mines with adequate transportation facilities.

Adequate Supply Available. Because of the greatly increased demand for the larger or domestic sizes of coal without a corresponding industrial absorption, the production of barley now exceeds consumption by several thousand tons a week, thus creating substantial stock piles, available without fear of interruption to all plants having suitable utilization equipment. Sizing specifications, analyses, and physical properties of barley anthracite are given in Tables 1 and 2, respectively.

Quality of Barley. Like many other valuable commodities, barley originates as a by-product prepared from the breakage of the larger sizes of anthracite. With this accidental beginning, all resemblance to a by-product ceases, as the modern concentrator tables and other equipment upon which barley is cleaned are capable of preparing it to a high quality with any reasonable specifications of size and ash content. In fact, the fineness of the coal particles actually facilitates the removal of impurities. However, because of its small size and the consequent limitation of use to plants having specific combustion equipment, the price of barley is low, as shown in Table 3.

Effect of Coal Size and Quality Upon Boiler Performance

Several characteristics of coal affect the efficiency and capacity of boilers. However, in comparing the properties of coals, the terms efficiency, capacity, and economy are likely to be confused. Increased efficiency from a quality fuel may not overbalance its increased cost in one plant; while in another, increased capacity may be of sufficient importance to justify a sacrifice of efficiency and even of economy. The following factors should thus be carefully considered.

When to Use Barley. Barley anthracite is the smallest and cheapest size commonly used in all but the largest (traveling-grate) plants. Many plants now using rice (No. 2 buckwheat), or even No. 1 buckwheat would effect substantial savings by changing to this size, with the important advantage of assurance of supply.

Even where excessive loads in existing equipment preclude the continuous use of barley, substantial economies may be effected by burning it during off-peak seasons, as for example during mild weather in heating plants.

In general the following are requisite to the use of barley:

(*a*) Adequate forced draft or natural draft from unusually high stacks (preferably 300 ft or more as in large hotels or office buildings).

TABLE 1 STANDARD SIZING SPECIFICATIONS OF BARLEY ANTHRACITE AT BREAKER[a]

Through round-mesh screen, in.	3/16
Over round-mesh screen, in.	3/32

[1] Mechanical Engineer, Anthracite Industries, Inc. Mem. A.S.M.E.

Contributed by the Fuels Division and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

(*b*) Stationary or dumping grates having a mesh of not over $^{3}/_{16}$ in.

(*c*) Semi- or hand stokers, with grates as described in (*b*).

(*d*) Traveling-grate stokers.

(*e*) Proper arch and furnace design when stokers or semi-stokers are used.

(*f*) Properly proportioned grate areas.

The use of straight barley anthracite upon underfeed stokers is not often recommended, unless the load is considerably below boiler and stoker rating, because of reduced effective grate areas available. However, mixtures of barley and bituminous are in use very successfully upon underfeed stokers.

Effect of Btu Value. The heat value or Btu content of coal is of course a direct measure of its value. In addition, since freight rates are on a per-ton basis, it costs more, per pound of useful combustible, to transport low Btu fuel. In considering this point, it is noteworthy that the further the plant is located from the mines the more significant coal quality becomes, because of the greater effect of freight rate.

Boiler ratings are also in direct proportion to Btu because, for any given number of pounds of coal per hour, fewer pounds of combustible will be consumed, as the percentage of inert material or ash increases. In plant design, however, this point can be overcome to permit the use of coal with practically any Btu content by adding grate surface. In this connection, the additional cost of the grates is usually insignificant, as compared with fuel savings over the life of the equipment.

Boiler efficiency is not always proportionately affected by heat value especially if the plant has been designed with the particular coal in mind. It is entirely possible to obtain "relatively" high efficiencies with low-grade coals even though the design problems are materially increased.

Effect of Ash. In anthracite, heat value is inversely proportional to ash content, Fig. 1. The effects of high ash upon economy, ratings, and efficiency are therefore as described for low heat content.

With respect to efficiency, Fig. 2 shows that, in a representative test over the entire range of ash contents, there was a drop of only 2 per cent in over-all boiler efficiency. Thus if the plant has been designed with sufficient grate surface to compensate for the lower outputs of high-ash coal it should operate satisfactorily, although never at the ratings obtainable with better fuel.

In all cases, the cost of handling and removing ash should be added to the price of coal plus the freight rate, in making cost comparisons. The best system consists of placing all fireroom labor, fuel and ash costs, and handling charges on a basis of cost per million Btu. Direct comparisons may then be made, which will place costs on a basis of the heat actually received rather than the relatively meaningless price of Btu at the mines.

Effect of Undersize. Fig. 3, based upon tests by L. A. Stenger (1),[2] shows the rate of air flow through coals having different percentages of dust content. The shape of this curve illustrates the well-known fact that uniformity of sizing is one of the most important points in connection with the combustion of barley. With more than 20 per cent undersize, the resistance of the fuel bed to the flow of air rises so rapidly as to change completely all combustion characteristics. It is thus significant that the Anthracite Institute Committee on Standards of Sizing selected 20 per cent as the maximum allowable undersize for barley. Conversely, however, 10 per cent was set as a minimum limit of undersize as it was not considered practical to prepare coal to finer standards.

With anthracite, the effect of dust is severalfold. It is difficult to maintain a uniform fuel bed because of a segregation of fines and the consequent blowing of holes; and the fines impede the flow of air to increase any tendency toward clinker and reduce combustion rates. In addition, fly ash and siftings are usually in proportion to the dust content.

In analyzing undersize content, one additional point is of particular importance, i.e., the character of the fines is as important as the percentage. Thus if a given percentage of undersize is almost all dust, serious difficulties may ensue; if, however, a large percentage of the fines is just slightly under the minimum screen size, considerably better results may be expected. It is thus suggested that sizing tests be reported on the following basis:

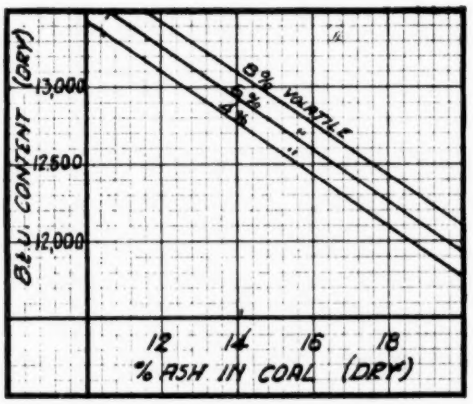

Fig. 1 Btu Versus Ash Content for Anthracite

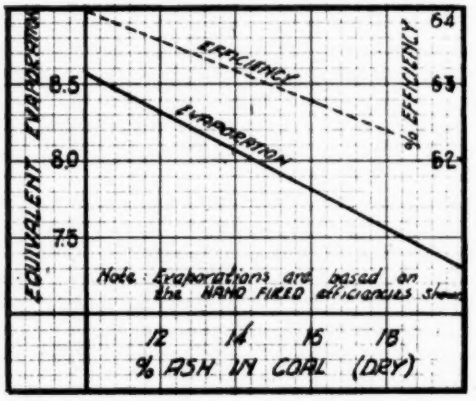

Fig. 2 Effect of Ash on Performance

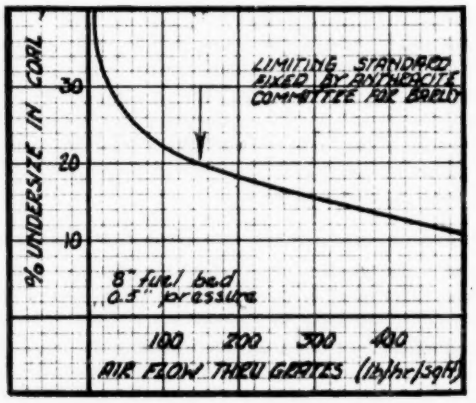

Fig. 3 Reduction of Air Flow to Undersize

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

(*a*) Per cent larger than No. 3 buckwheat (over $^3/_{16}$ in. screen)
(*b*) Per cent of No. 3 buckwheat through ($^3/_{16}$ in. over $^7/_{32}$ in.)
(*c*) Per cent of No. 4 buckwheat through ($^3/_{32}$ in. over $^3/_{64}$ in.)
(*d*) Per cent smaller than No. 4 buckwheat (through $^3/_{64}$ in.)

This method of analysis will show whether the undersize is really dust, or whether it is merely a mixture of No. 3 and No. 4 buckwheats, a much more desirable condition.

Effect of Moisture. As will be seen in Fig. 4, the boiler efficiency, calculated mathematically, is in direct relation to the moisture content of coal in that each 1 per cent of increase in moisture content will result in 0.4 per cent decrease in boiler efficiency. In actual practice, however, there is a reason to doubt the infallibility of this rule. A certain percentage of moisture (probably as high as 4 per cent) is credited by many engineers with being useful in tempering the fire to produce better combustion conditions. In many plants jets of steam are introduced into the ashpit to supply this moisture artificially. Properly controlled, they are believed helpful in reducing clinker formation. In addition Stenger (1), in reporting the effect of dust, remarked, "wetting dust-bearing coal practically doubles the air flow." It is thus probable that if Fig. 4 could be based upon actual tests instead of upon calculations it would be a flat curve, or even rise to show a maximum efficiency at about 4 per cent moisture. However, beyond 12 to 14 per cent moisture, much difficulty may be expected in obtaining either capacity, efficiency, or even ignition.

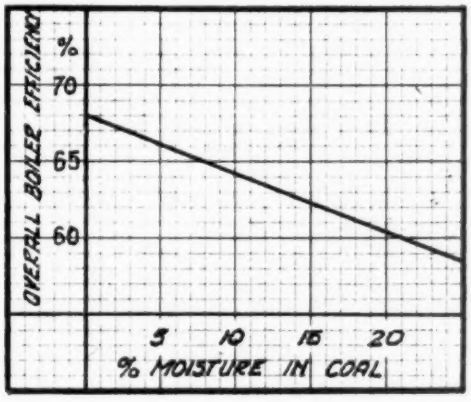

FIG. 4 EFFECT OF MOISTURE ON EFFICIENCY

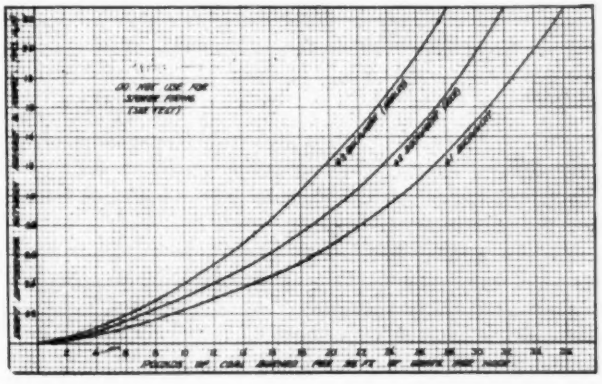

FIG. 5 DRAFT REQUIRED AT DIFFERENT COMBUSTION RATES WHEN BURNING COMMERCIAL SIZES OF ANTHRACITE

In a car or in a rectangular pile 8 ft deep, 1 in. of rain could produce only 1 per cent of moisture even if none drained off or evaporated. Furthermore, with anthracite, moisture is merely a surface condition which may be readily drained and dried. It is thus unlikely to become a significant factor especially if the storage pile is properly drained.

Effect of Volatile. Generally speaking, high fixed-carbon coals, such as anthracite, are the most efficient because the problem of a proper supply of secondary air is simplified. Within the anthracite industry, the entire range between the lowest- and highest-volatile coals mined is so small that this is a negligible factor, except when comparing anthracite with other fuels.

Furnace Volume. One other practical advantage of the relatively low volatile content of anthracite is the greatly increased permissible heat release per cubic foot of furnace volume. This results from the fact that, with anthracite, combustion is much more nearly complete at the surface of the fuel bed than with bituminous coal. However, it is the concensus of leading engineers that proper mixing of gases, turbulence, secondary combustion, and slag or fly-ash formation are directly and materially affected by furnace and arch design.

Air Requirements. The theoretical weight of air for the complete combustion of any fuel is practically a constant at an average of 7.65 lb of air per 10,000 Btu. With 12,900-Btu (dry) barley, 9.85 lb of air are thus required per lb of coal. With entering-air temperatures of 90 F, 13.85 cu ft equals 1 lb. Thus 137 cu ft of air will be required theoretically for the combustion of each pound at maximum CO_2 of 20.1 per cent (no excess air). Table 4 shows similar air requirements for other CO_2 values.

TABLE 4 AIR REQUIREMENTS FOR BARLEY ANTHRACITE

CO_2 in furnace, per cent	Excess air, per cent	Air required, lb[a]	Air at 90 deg F, cu ft[a]
6	225	32.0	445
8	150	24.6	342
10	100	19.7	274
12	65	16.2	226
14	43	14.1	196
16	25	12.3	172

[a] Total cubic feet per pound of coal burned.

Air and Draft Pressure. With barley as with other sizes, the combustion rate per square foot of grate varies in accordance with the differential pressure between the ashpit and the furnace. These rates, as shown in Fig. 5, will apply irrespective of the source of air supply (i.e., on either forced, induced, or natural draft, or any combination). Thus natural draft may be used for barley where it is adequate to produce the necessary combustion rate. However, where natural draft is used, it will produce such a high suction above the fire that extreme care should be exercised to keep all brickwork and openings extremely tight. For this reason many operators prefer a "balancing" forced-draft fan even though sufficient natural draft is available.

With both hand-firing and semistokers, it is necessary (on forced draft) to provide sufficient maximum air pressure in the ashpit to burn the coal properly when the fuel bed is at maximum thickness just before cleaning. A static pressure of $2^1/_2$ in. of water is suitable for fans when delivering the rated quantity of air for barley anthracite.

Air pressures, as shown in Fig. 5, will not apply with traveling-grate equipment because the continuous discharge of ash permits materially thinner fuel beds with correspondingly lower air requirements. The zoning of air on traveling grates also permits the admission of air in steps proportional to the actual rate of combustion. On traveling grates, maximum air pressures do not usually exceed $1^1/_2$ to 2 in. of water.

(As the exact air pressure required depends entirely upon such factors as fuel-bed thickness and rating, these rules refer to the maximum pressure that should be available to the operator rather than the pressures to be actually used.)

Furnace Draft. Where forced draft is available, it is customary to balance it against the pull of the stack or induced draft. However, in such cases, the furnace draft should not be below 0.05 in. of water since lower pressures will result in excessive gas and heat penetration into the brickwork with greatly increased maintenance costs. Conversely, drafts in excess of about 0.10 in. of water can be considered to carry an unnecessary amount of heat to the stack.

Furnace drafts of about 0.05 in. of water should be maintained under the nose of the rear arch of traveling- or chain-grate-stoker installations for best results.

Mechanical draft regulators, designed to hold furnace drafts between these limits, are very desirable. In their absence visual furnace draft gages are a "must" in every plant.

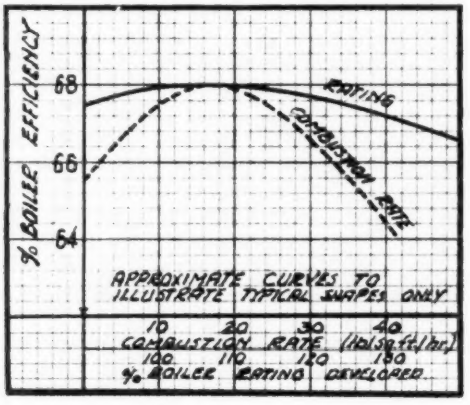

FIG. 6 BOILER EFFICIENCY VERSUS RATE AND OUTPUT

Proper Boiler Ratings. In many plants it is common practice to attempt to carry as much of the load as possible on a relatively few boilers, even though idle boilers are available. This is particularly noticeable in plants that have just recently converted from oil. From Fig. 6, it will be seen that this does not always result in the most efficient or economical operation. While boiler installations differ materially, they all have characteristics similar to those shown in the curves.

Peak test efficiencies usually occur somewhere between 100 and 150 per cent of rating on boilers without heat-recovery equipment, however, in actual daily operation, the best operating efficiency will be at a somewhat higher rating because of greater stability in the furnace and fuel bed. The addition of heat-recovery equipment may make the most economical point at some higher rating, and the efficiency will not fall off as rapidly with increased rating. The problem of whether or not to operate a sufficient number of boilers so that each will be as nearly as possible at its peak operating efficiency is a rather complex one requiring careful study for each individual case. This involves the shape of the daily load curve, maintenance and operating labor costs because of having extra equipment in service, etc. For example, in a plant with a flat load curve or a long-sustained peak, it may be advisable to operate a sufficient number of boilers to hold each boiler close to its maximum efficiency, whereas in a plant where the load is of shorter duration, the banking loss during light-load periods may offset any possible increase in efficiency. In some cases, operation of additional boilers requires additional operating labor, which nullifies the fuel savings possible.

On the other hand, attempts to operate barley fires at excessive rates of combustion frequently necessitate cleaning the fires before they are completely burned out with resultant high ashpit losses. The additional skill required for high ratings, and the strain on labor due to too frequent attention and cleaning periods are further factors.

In brief, the question of the number of boilers to be used is one of sufficient importance to warrant careful study, as based upon individual plant conditions.

EQUIPMENT AVAILABLE FOR BURNING BARLEY

In general three types of equipment are employed for burning barley:

1 Pinhole grates or grates with narrow slots (such as herringbone).
2 Semistokers with inclined grates.
3 Traveling-grate stokers.

A selection between these is usually made on a basis of size of installation and degree of automatic operation desired, as balanced against relative equipment costs. Approximate costs are shown in Table 5.

TABLE 5 APPROXIMATE COST OF BARLEY EQUIPMENT[a]

Pinhole grates (dumping), per sq ft	$10 to $12
Semistokers, per developed hp[b]	$12.50 to $13
Traveling-grate stokers per developed hp	$20 to $26

[a] All prices f.o.b. factories, not including installation.
[b] Includes forced-draft equipment.

HAND-FIRED BARLEY GRATES

Description and Design Data. Hand-fired grates for barley should be of the "pinhole" or slotted type. The latter are commonly known as herringbone grates when the adjacent rows of slots are set at an angle. A choice between the two types seems largely to be a matter of manufacturer and plant preference. The minimum practical limitation of size is about 10 sq ft; the maximum is a fuel-bed length of about 10 to 12 ft. Dumping-grate weights will usually be between 60 and 80 lb per sq ft.

Both dumping and stationary grates are available, but a substantial percentage of all grates now being sold is of the dumping type. Grates that dump to the center have the advantage of keeping hot ash away from the front of the ashpit and the rear ash closer to the point of removal.

The size of the pinholes ranges from $^3/_{16}$ to $^5/_{64}$ in., depending upon the manufacturer. They are flared or tapered underneath to make them self-cleaning and to secure a modified Venturi effect. The distance between individual pinholes is usually about $^3/_4$ in.; and the over-all metal thickness of the grates is also usually about the same.

Important points of design are the percentage of free air space and the uniformity of air delivery. If the free air space through the grates is less than 4 per cent, they are likely to restrict the flow of air unduly, and thus necessitate excessive velocities; if on the other hand the free air space exceeds 8 to 10 per cent of the grate area, the velocity will be so low for the required air delivery that much of the desired "jet" or blast effect will be lost.

Uniformity of air delivery is unusually important because of the "jet" type of operation. Either dead or unusually active areas of only a few inches will invariably produce unequal air distribution, resulting in ridges or patches of less or more active combustion with corresponding difficulty due to spotty fires.

Method of Hand-Firing. The primary rule in firing any size of anthracite is "let it alone." This applies with full force to barley. In addition, it should be fired lightly and often. It is also good practice to clean only one half of a boiler at a time, skipping every other door, going back to them only after the row has been completed. By this method, the output will be more nearly continuous, the CO_2 higher, and the gases more completely consumed.

In the case of all barley equipment, the drafts should be ad-

justed so that the surface of the fuel bed just begins to float without either being dormant or "boiling" too violently.

While the frequency of cleaning the fires is necessarily a function of design, boiler load, and quality of fuel, cleaning not oftener than once per 8-hr shift is recommended as being easier both on labor and equipment.

Spreading Method of Firing. In the spreading method, sometimes called "the alternate" method, a small amount of coal is fired at one time and spread evenly over the fuel bed from the front to the rear. The firing is done alternately through the fire doors, so that the entire fire is not blanketed with green coal. Hand-firing practice leans more and more to spread-firing.

The Bureau of Mines recommends burning coal rapidly and at high temperatures in order to secure the best available economy. Fire small quantities of coal at short intervals, so that thin places do not burn through and admit large excess of air. The quantity depends upon the grate area and draft. Firing and cleaning should be so co-ordinated as to produce a total fuel-bed depth of not over 6 to 8 in. just prior to cleaning.

Cleaning Hand Fires. Cleaning of the fire is necessitated by the fact that clinker and coarse ash will not pass through the grates. The intervals between cleanings depend upon the proportion of ash in the coal, the character of ash, and the type of the grate. If the coal contains much ash, or ash that is fusible, the fires have to be cleaned often; if light fires are carried, less clinker forms, and under such conditions the fire can often be run through a day shift without cleaning. The cleaning of the fires should be done thoroughly. All the clinker and ash should be removed, so that they cannot fuse to the side wall. They should be removed in such a way as to waste very little combustible. There are two methods of cleaning hand-fired furnaces.

In the side method one side of the fire is cleaned at a time. The good coal is scraped and pushed from one side to the other. The clinkers may have to be removed from the grates by the slice bar. When they have been loosened and broken up, they are dumped into the ashpit, or on stationary grates, and scraped out of the furnace with the hoe. The fireman should gather the clinker on the front part of the grate before pulling it out into the wheelbarrow, as this saves him from exposure to the heat. After the one side is cleaned, the burning coal from the other is moved and scraped to the clean side.

At this point, it is advisable first to spread a thin layer of coal on the grates so that the full heat of the live fire will not rest directly on the grates. A few shovelfuls of fresh coal are then added, in order to have enough burning coal to cover the entire grate when the cleaning is done. This adding of coal is important, especially when the cleaning must be done with the load on the boiler. The clinkers are then removed from the second half of the grate. In cases where the load is heavy, a time interval is recommended between cleaning the two halves of the grate, in order to allow the new fire to build up to its load-carrying capacity.

When cleaning is started, there should be so much burning coal in the furnace that enough will be left to start a hot fire quickly, when the cleaning is completed. If a light fire is carried, it may be necessary when starting to clean to put some fresh coal on the side to be cleaned last. During cleaning the damper should be partly closed. A fireman, after becoming familiar with the side method, should be able to clean a 200-hp boiler furnace in 10 to 12 min.

In the front-to-rear method of cleaning, the burning coal is pushed with the hoe against the bridge wall. It is usually preferable to clean one half of the grate at a time. The clinker is loosened and pulled out of the furnace and the burning coal is spread evenly over the bare grates. If the front-to-rear method must be used while the load is on the boiler, the side method should be employed after the day's run is over, so as to prevent

the large accumulation of thick and hard clinker at the bridge wall.

Some firemen have the habit of pulling the clinkers out of the furnace without scraping and pushing the burning coal against the bridge wall or to one side. This really is not a method of cleaning the fire. They run a slice bar under the clinker to lift it to the surface of the fuel. Then they take a hoe and pull the large pieces out. The small pieces are not easily detected and are left in the fire. These fuse in a few minutes, due to the high temperature near the surface of the fuel bed, and to the air deficiency under the clinker. Thus more masses of clinker are formed which are usually worse than those previously removed. This habit should be discouraged.

The cleaning of a banked fire should be done about 2 hr before steam is needed. It is advisable to bank the fire at the front of the grate near one of the doors. This exposes the clinkers which can be pulled out.
